The 10 per cent that require operative treatment are those with a compound fracture, those who have survived the first ten hours but in whom intracranial pressure is increasing, and, lastly, those who have a torn middle meningeal artery. The first group require careful débridement. The scalp should be shaved widely and the wound carefully cleansed with quarts of physiological saline solution. All foreign bodies are removed and the scalp is closed. The local use of sulfonamides is not recommended because of the foreign body reaction which may ensue. This is particularly true if the dura is exposed or has been torn. The second group require a subtemporal decompression to relieve pressure. Depressed fractures do not necessarily require operative interference. If the skull has been fragmented or spiculated with injury to the dura or when depression of the skull is over functioning cortical areas, producing symptoms, then the depressed fragments should be elevated. All defects of 3 to 5 cm. or more of the skull require some interference. They may be repaired by osteoperiosteal transplants from the outer table in small defects in young people. Large defects may be filled in with tantalum or methyl methacrylate. Exenteration of the mucous membrane of the frontal sinus and occlusion of the osteum of the vasofrontal duct is necessary to avoid potential sources of infection. The third group require a trephine opening to tie off the bleeding vessel. A line drawn 1½ inches behind and ½ inch above the external angular process will locate the site of this vessel. If it is torn, the patient will have a more or less definite set of symptoms. When a patient is first injured, he has a *concussion* or "shaking up" of the brain, producing mild, transitory symptoms. He "sees stars," loses consciousness, but soon recovers. If the middle meningeal artery is torn, he soon loses consciousness again, due to hemorrhage and an increase in intracranial pressure. A *period of consciousness between two periods of unconsciousness means a torn artery.* If it is a large tear, bleeding will be profuse and consciousness will be short. If it is a very small tear, the patient may remain conscious for three or four hours, or even longer. There will be a dilatation of the pupil on the same side due to pressure on the oculomotor nerve inactivating it. This is not always present. A *subdural* hematoma is usually venous and is more apt to produce dilatation of the pupil and paralyses with irritability (like a frontal lobe tumor). Subarachnoid hemorrhage is more apt to produce irritative and general symptoms.

Penetrating and perforating wounds require x-ray examination to determine the presence of foreign bodies. These wounds may be closed after careful débridement except in cranio-orbital and frontal sinus wounds where later repair is preferable because of infection. Metallic bodies should be removed if possible because they may lead to secondary abscess and convulsions (epilepsy). The defect in the dura should be

closed promptly and completely in clean wounds by primary suture or if too large a defect, by periosteal or fascial grafts.

A good rule to follow is: All head injuries must be carefully observed, preferably in the hospital, for at least forty-eight hours.

In fractures of the base of the skull, there may be bleeding from the nose, or ecchymosis under the eyes (anterior fossa), or bleeding from the ears (middle fossa), or ecchymosis behind the ear (posterior fossa). This bleeding should not be controlled, for to do so may mean the introduction of infection in the brain covering (meningitis), and it stops nature's way of doing a decompression.

Complications of skull fractures may be divided into early and late. Early complications include (1) extradural hematoma, (2) subdural hematoma, (present in about 12 per cent), (3) ruptured eardrum, (4) foreign bodies (bone, metallic fragments), (5) infections inside the skull (meningitis, brain abscess), (6) infections outside the dura (osteomyelitis, cellulitis of the scalp).

Late complications and sequelae are (1) extradural hematoma, (2) convulsions (jacksonian); (3) headache, dizziness, pain in the temporal and occipital regions, (4) mild disturbances in mentality, nervousness, (5) aphasia, (6) hemipareses, (7) involvement of the first, second, third, fourth, sixth, and eighth cranial nerves. Many of these sequelae are due to arachnoidal adhesions or subdural hematoma or depressed fragment of bone. Diagnosis is made with difficulty and must be separate—the true case from the malingerer and the functional from the organic. X-ray studies, encephalograms, and symptoms and signs may lead to a focal area which may be explored. Sometimes an old clot beneath the dura is the cause. Its removal may result in complete cure. More often arachnoidal adhesions are found and separated—the results may be good but often are discouraging.

Epilepsy.—The term epilepsy is loosely used to mean any convulsion state, tonic, or clonic. Really epilepsy is not a disease entity but a symptom of vaguely understood brain dysfunction. There may be slight convulsions (petit mal) or prolonged convulsions (grand mal), with frothing mouth and tongue biting. The laity speaks of it as "fits." There is no specific treatment; however, phenobarbital, sodium diphenylhydantoin, insulin shock, acidosis, and even surgical intervention have been tried.

Jacksonian convulsions (jacksonian epilepsy) refers to focal motor convulsive seizures which most often affect the upper extremity. Although cicatrices and space-consuming lesions may produce the symptom complex, often no abnormality is demonstrable. The treatment may be by drugs (Dilantin sodium) or by surgery. The latter consists of electrical exploration to find the focal area involved (usually lower portion of anterior lip of central sulcus), then resection with the electrosurgical cutting current of the pia and superficial gray matter, and then by blunt dissection resection of the cortex to the depth of the central sulcus. Removal of tissue is usually confined to the precentral convolution.

Cerebral Complications Following Surgical Operations not Performed on the Brain.—These may be due to: (1) cerebral hemorrhage in older group; may be coincidental; (2) embolism in younger group especially; may occur in all age groups and is especially to be feared after chest operations, particularly lung abscess and empyema; (3) peculiar idiosyncrasy to anesthetic(?); (4) coma, tremors, and convulsions and psychic disturbances due to "toxic" psychosis, especially after thyroid operations; (5) "readjustment psychosis" thought to be due to sudden change from more to less sick state; (6) *cerebral anoxia* which produces most psychoses, comas, convulsions, and paralyses after surgical operations. This results from alteration in blood pressure, cardiac inadequacy, and anoxic anoxemia due directly to the anestheic or its administration. The cerebral changes are parenchymatous edema and congestion and perivascular fibrosis.

Brain Abscess and Sinus Thrombosis.—Brain abscess and sinus thrombosis occur usually from middle ear disease and mastoid infections. The abscess is usually in the temporal lobe; it evokes no fever because there is no absorption (absence of lymphatics and looseness of tissue). Drainage is done by needle aspiration after complete localization. However, better results follow surgical drainage. The mortality, including complications, is about 40 per cent. Sinus thrombosis is simply a phlebitis of the lateral sinus. The treatment is conservative as in phlebitis elsewhere but includes the use of penicillin and sulfadiazine.

New Growths.—New growths such as *gliomas, hypophyseal adenomas, meningiomas,* and *neuromas occur.* They may be encapsulated and therefore easily removable or infiltrative (gliomas) which defy extirpation, although some of these have been successfully removed. More than half of all brain tumors may be successfully removed if seen early. Most tumors in adults occur above the tentorium, except the cerebellopontine angle tumor or perineural fibroblastoma of the eighth (auditory and vestibular) nerve. Most brain tumors in children are of the cerebellum or below the tentorium, except epithelial cysts near the pituitary (Rathke's pouch cysts, craniopharyngioma). *Gliomas* make up 50 per cent of all intracranial neoplasms and include all types of glial cells in their various stages of embryonic growth and development. *Astrocytomas* make up about one-fourth of gliomas. There are three subtypes: (1) fibrous (piloid or pilocytic) astrocytomas which are composed of cells rich in fibers; this type carries best prognosis; (2) protoplasmic (diffuse) astrocytomas seen in cerebrum with infiltrating cells; tumor limits poorly defined; responds to x-ray; (3) Gemistocytic astrocytoma which is composed chiefly of Nissl's plump cells; most rapidly growing and is the most unfavorable. *Glioblastoma multiforme* (spongioblastoma multiforme) originates in the white matter but is very invasive and usually grows rapidly; unless it is removed very early, it cannot be entirely removed. *Medulloblastoma* is the commonest type of glioma in childhood. It arises in the cerebellum

and early involves the fourth ventricle and other areas because of its friability and early cellular desquamation. It is radiosensitive. *Cerebellar sarcoma* resembles medulloblastoma and involves the cerebellum in older persons. *Ependymomas* occur in the brain and spinal cord and have connections with the ventricular system. They grow slowly, are firm, as a rule, and may be removed if in a favorable position. They are radioresistant. *Polar spongioblastoma* (spongioblastoma polare) is another type of glioma seen in the pons, optic chiasm, and corpus collosum. The tumor is invasive and usually defies extirpation and is not radiosensitive. *Oligodendroglioma* is a form of glioma which grows slowly and is firm. It occurs in the cerebrum and is difficult to remove and is radioresistant.

Meningiomas make up about 16 per cent of brain tumors. They are seen usually above the tentorium and therefore affect the cerebrum more frequently than the cerebellum and brain stem. They usually arise in the arachnoid but may invade the skull and are often attached to the dura. They are usually not invasive, pushing the brain aside, although they are vascular and do invade the cerebral sinuses. The prognosis is good because complete extirpation is possible, although this may require several stages. *Cerebellopontine* angle tumor (eighth nerve tumor, perineural fibroblastoma of the eighth nerve; acoustic neuroma) arises from the perineurium of the eighth nerve just at the porus acusticus. It is usually encapsulated and may be completely removed, producing a cure. *Pituitary tumors* (see Chapter 22.) *Chromophobe* adenomas cause local signs (bitemporal hemianopsia) and endocrine disturbances such as progressive reduction of sexual function. *Eosinophilic* adenomas cause acromegaly. *Basophilic* adenomas are not usually of surgical importance. Adenomas are sometimes cystic. Early excision is feasible.

Tumors of the hypophysial duct (Rathke's pouch cyst, craniopharyngioma, pituitary admantinoma) are slowly growing, usually cystic. They produce delayed sexual development and after puberty they alter this function. If they press on structures in the region of the third ventricle, metabolic changes, obesity, and dwarfism may be produced. They occur early in life, are often calcified, and although not easily removed, the cysts may be emptied, giving relief or symptoms.

Epidermoid and *dermoid cysts* (cholesteatoma, pearly tumor) are found in the third ventricle, posterior fossa, and in the skull itself (lateral margin of orbit). They occur early in life and give evidence of their presence by pressure symptoms. If they cannot be removed, they may be drained, relieving symptoms. *Vascular tumors:* (1) *Angiomas* are congenital malformations (see Chapter 17) and in the brain are classified as telangiectases or venous and arteriovenous angiomas. Sometimes they produce convulsions by causing a scarring or by hemorrhage. They may become calcified and thus may be seen by x-ray. The arteriovenous fistulas often produce a discernible bruit and the "swish" may be heard by the patient. They should be removed if possible. Sometimes ligation of

principal vessels produces relief. (2) *Hemangioblastoma* is a tumor of proliferating blood vessels and endothelial cells. It is usually found in the posterior fossa and may be cystic. Rarely there is an associated angioma of the retina and cystic degeneration of the liver, kidneys, and spleen (Lindau's disease). X-ray therapy may help if removal is not feasible. *Metastatic tumors* may come from the thorax, retroperitoneal region, and breast and malignant melanoma from anywhere. Cancers of neck and throat may invade by direct extension. A single lesion may be removed to give relief, just as a single metastasis to the lung may warrant a lobectomy.

Even *tuberculomas* or *gummas* may give the classical symptoms and signs of brain tumor. Whether removal is necessary or not, the surgeon will perform a *decompression* (subtemporal, usually) to reduce the intracranial pressure and thereby relieve the headache and save the sight until the growth is reduced by radium or (when caused by tuberculosis or syphilis) by medication (streptomycin in tuberculosis and penicillin in syphilis). Schistosomiasis japonica may also invade the brain (see Chapter 7).

Cerebral hemorrhage in the newborn results when the veins of the tentorium are torn. Often it is due to a hemorrhagic diathesis in the child (Rh factor, erythroblastosis). Transfusion is the best treatment in addition to vitamin K.

THE SPINAL CORD

The spinal cord lies within the vertebral column and extends from the brain, or rather medulla oblongata, to the second lumbar vertebra although the dura and arachnoid extend down to the third sacral vertebra. A lumbar puncture is done at the level of the iliac crests; that is, between the third and fourth lumbar vertebrae, thus avoiding injury to the cord. Some prefer the interspace between the last lumbar and the first sacral, especially for the inexperienced. The reason is to avoid injury to the posterior part of the annulus fibrosus, thereby predisposing to herniated nucleus pulposus. The cord ends in a group of nerve fibers called the cauda equina. The peripheral portion of the cord is white and is made up of ascending (sensory) neurons and descending (motor) neurons. The central portion is gray and is composed of nerve cells. The various tracts are indicated in the diagram.

The *medulla oblongata* lies just above the foramen magnum, through which the cord emerges. Here lie the important respiratory, cardiac, and vasomotor centers. A sudden jamming of the medulla into the foramen magnum may produce death. Therefore, lumbar punctures are done with the patient lying on his side. In a patient with increased intracranial pressure, a lumbar puncture should be done with extreme caution, if at all.

The simplest cord function is the spinal reflex, which is mediated by an afferent or ingoing neuron, entering the cord by the dorsal root; a connector neuron within the cord; and an efferent or outgoing neuron, leaving the cord by the anterior root. Some tracts cross high in the cord (the pyramidal tracts), some at various levels (the sensory fibers for pain and temperature). The cord is roughly distributed to different zones of the body. The first costal interspace marks the boundary between the fourth cervical and the second thoracic zones (most nerves from this region go to the arm); the region of the nipple line is innervated by the fourth thoracic nerves; the umbilical region, by the tenth thoracic nerves; the pubic, by the twelfth thoracic nerves; and the anal

region by the third, fourth, and fifth sacral nerves; the lower legs are innervated by the lower lumbar and first two sacral nerves (Homans).

Since the spinal column "grows away" from the cord in its development, the segments of the cord are not at the level of the corresponding vertebrae. There are eight cervical pairs of spinal nerve roots, twelve thoracic, five lumbar, and five sacral. Since the cord ends at the second lumbar vertebra, the five sacral nerves and the three lower lumbar lie above this point. The lower thoracic and upper lumbar segments will be found three vertebrae higher; the upper thoracic and lower cervical, two vertebrae higher; and the upper cervical, one vertebra higher. In other words, pain originating in the pelvis (level of third lumbar vertebra) is referred to the twelfth thoracic segment by way of the iliolingual nerve (T 12 and L 1).

Each spinal segment supplying a peripheral zone makes possible sensation, movement, reflex movement, and autonomic control. Therefore, in cord lesions of any kind, a disturbance of any or all of the above functions may be expected. Sensory changes may manifest themselves as *paresthesia* (numbness), *hypesthesia* (decreased sensation), *hyperesthesia* (pain from touch), or actual *pain*. Crossed paralyses of *Brown-Séquard* are seen in patients with tumors which press on one side of the cord only. Pressure on the lateral pyramidal (decussates in medulla) will cause muscle weakness on the same

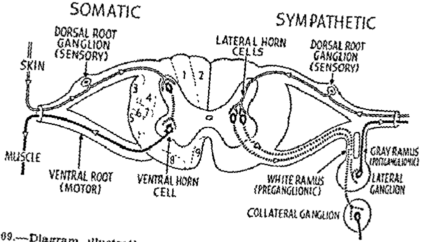

Fig. 209.—Diagram illustrating cross section of spinal cord. On the left are the somatic, and on the right, the sympathetic nerves. The neurons (efferent, connecting, and afferent) necessary to complete a simple reflex are shown. *1* and *2*. Fasciculus gracilis (Goll) and fasiculus cuneatus (Burdach). These are the sensory spinobulbar tracts (tactile and kinesthetic impulses). *3*. Cerebellar tract (direct coordination). 4. Corticospinal crossed-pyramidal, or motor tract (voluntary motion). *5*. Spinothalamic tract of the lateral column (pain and temperature). Fibers arise in the posterior ganglion of the opposite side and cross in the anterior commissure. *6*. Cerebellar tract (indirect coordination). 7. Rubrospinal tract or crossed-motor tract aids the pyramidals. 8. Spinothalamic tract of the anterior column (tactile sensation). Fibers arise in the posterior ganglion of the opposite side. 9. Corticospinal, or direct pyramidal tract (voluntary motion). The preganglionic fibers of the sympathetics are shown by the dotted line; the postganglionic fibers, by the black line (See Fig. 202.)

side, whereas pressure on the posterior columns (also decussates in the medulla) will cause diminution of common sensibility and sense position (kinesthesia) on the same side, producing a tabetic form of ataxia, or if above the level of the brachial plexus, astereognosis as well. However, when pressure exists on the anterolateral columns there will be a disappearance of pain and temperature sense on the opposite side because these tracts cross over at the anterior commissure after they enter from the posterior root ganglion. In syringomyelia or hemorrhagic or other lesions of the central part of the cord, pain and temperature sensations are absent, tactile sense remains. Cordotomy to relieve pain is done here. Motor changes may be flaccid paralysis (from injury to anterior horn cells or to the lower motor segment, as in *anterior poliomyelitis*), or spastic paralysis, or hyperflexia (from injury to the upper motor segment), when the long tracts are irritated as in hemorrhage, injury, etc.

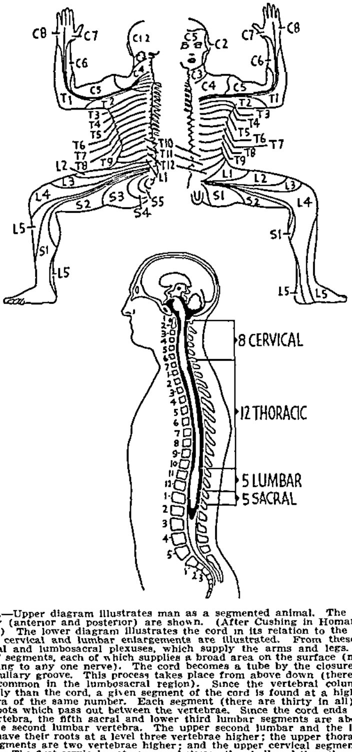

Fig. 210.—Upper diagram illustrates man as a segmented animal. The sensory zones of the body (anterior and posterior) are shown. (After Cushing in Homans: Textbook of Surgery.) The lower diagram illustrates the cord in its relation to the vertebral column. The cervical and lumbar enlargements are illustrated. From these areas come the brachial and lumbosacral plexuses, which supply the arms and legs. The cord is made up of segments, each of which supplies a broad area on the surface (not necessarily corresponding to any one nerve). The cord becomes a tube by the closure of the edges of the medullary groove. This process takes place from above down (therefore anomalies are most common in the lumbosacral region). Since the vertebral column grows far more rapidly than the cord, a given segment of the cord is found at a higher level than the vertebra of the same number. Each segment (there are thirty in all) has its pair of nerve roots which pass out between the vertebrae. Since the cord ends at the second lumbar vertebra, the fifth sacral and lower third lumbar segments are above the upper level of the second lumbar vertebra. The upper second lumbar and the lower thoracic segments have their roots at a level three vertebrae higher; the upper thoracic and lower cervical segments are two vertebrae higher; and the upper cervical segments, one vertebra higher. The first cervical roots emerge between the skull and the atlas. By carefully studying the sensory, motor, and visceral changes, the segment which is involved in disease or injury may be identified. In addition to symptoms and signs referable to the segment involved, changes due to the interruption of the long tracts aid in the proper diagnosis of the level of the lesion.

region by the third, fourth, and fifth sacral nerves; the lower legs are innervated by the lower lumbar and first two sacral nerves (Homans).

Since the spinal column "grows away" from the cord in its development, the segments of the cord are not at the level of the corresponding vertebrae. side, whereas pressure on the posterior columns (also decussates in the medulla) will cause diminution of common sensibility and sense position (kinesthesia) on the same side, producing a tabetic form of ataxia, or if above the level of the brachial plexus, astereognosis as well. However, when pressure exists on the anterolateral columns there will be a disappearance of pain and temperature sense on the opposite side because these tracts cross over at the anterior commissure after they enter from the posterior root ganglion. In syringomyelia or hemorrhagic or other lesions of the central part of the cord, pain and temperature sensations are absent, tactile sense remains. Cordotomy to relieve pain is done here. Motor changes may be flaccid paralysis (from injury to anterior horn cells or to the lower motor segment, as in *anterior poliomyelitis*), or spastic paralysis, or hyperflexia (from injury to the upper motor segment), when the long tracts are irritated as in hemorrhage, injury, etc.

anoxia (from anesthetic reaching too high a level and causing paralyses of diaphragm, or intercostal muscles; the drop in blood pressure plus loss of blood during operation; mechanical difficulties due to pressure on the diaphragm, etc.), and lastly, thrombosis and embolism due to hypotension and stasis from leg inactivity. Spinal anesthesia has a definite and useful place in surgery because of the good relaxation that is obtained.

Injuries to the cord may be produced by fractures, dislocations, and fracture dislocations of the vertebra (see Chapter 21), penetrating and perforating wounds, severe jarring with resultant hemorrhage. Rarely hemorrhage occurs without injury as in hypertension and arteriosclerosis.

As in injury to the head, it is impossible to tell the degree of cord damage by the extent of vertebra trauma. The spinal cord is subject to the same degrees of injuries as the brain; namely, (1) concussion, (2) edema, (3) contusion or bruising, (4) laceration (incomplete or complete), (5) hemorrhage, hematomyelia (bleeding within the cord), and hematorachis (bleeding outside the cord with pressure on it). Also as in brain injuries these changes are rarely encountered singly and therefore in most instances there is some edema and hemorrhage with lacerations or penetrations, etc.

Nerve cells and nerve fibers (no neurilemma) in the cord are incapable of regeneration if destroyed. *Concussion* produces a complete functional block due to cell alterations principally in interneurons consisting of chromatolysis. Long ascending and descending fiber tracts are involved. The effects are transient.

Edema and some degree of hemorrhage may accompany any injury to the cord and may produce temporary functional impairment by compression. Therefore in examining a patient who has been injured any remnant of function gives hope that nerve cells and fibers have not been destroyed by laceration or severe contusion. Compression by localized accumulation of blood clot or by fracture dislocation may produce symptoms requiring surgical intervention.

Clinical Manifestations of Cord Injury

The history of the accident and points of injury often give a clue as to the level and degree of injury. If in transit there is some motion of the upper extremities and none of the lower, the level may be suspected. Cervical injuries may interfere with respiration. If, in addition, the legs are moved ever so little, there is hope of a functional impairment rather than complete destruction. Examination must be painstaking and thorough, remembering always that associated injuries of the skull, thorax, abdomen, and extremities may be present. Penetrating and perforating injuries may be definitely located, but the extent of internal damage is determined by symptoms and signs.

The motor function, sensory function (light touch, pain sense, heat, and cold), reflexes, and visceral functions are carefully observed. Bedside x-ray examinations are also made to help in the diagnosis.

Complete transection of the cord may produce three stages; namely, (1) spinal shock with complete loss of visceral and somatic sensations and flaccid paralysis; may last two to three weeks; (2) stage of reflex activity with paraplegia in flexion; may be entirely absent; (3) failure of all reflex activity (Bastian's rule).

Autonomic changes are chiefly visceral but may produce pallor or redness (angiomotor), with or without sweating (sudomotor). Sphincteric control of the bladder and rectum may be interfered with. By carefully testing zones of the body for these changes, and by tracing the zones back to the spinal segments, the lesion may be located. Manometric readings may be helpful. A lumbar puncture is made and a water manometer (Becton-Dickinson, # 5027) attached. The initial pressure is recorded (normal, 60 to 180 mm.). With each pulsation there is a 2 to 5 mm. variation and with respiration, 4 to 10 mm. If there is no obstruction in the subarachnoid space (tumor adhesive arachnoiditis, compression from outside dura), pressure will rise on straining or coughing. If a block exists, no change occurs. *Queckenstedt's* test consists of compressing the neck veins for ten seconds. This results in a rise in pressure 150 to 300 mm. and ten seconds after release there is a fall to normal. If a block is present, the rise is delayed or incomplete. Partial blocks cannot be detected by this method unless there is combined lobar and cisternal puncture. In addition, opaque media are sometimes injected into the cisterna magna or lumbar puncture and traced with the x-ray, although intrathecal injection of iodized oil is followed in over 50 per cent of the cases by fever, headache and aggravation of previous symptoms. The oil is very poorly absorbed and some patients have definite, permanent clinical ill effects due to arachnoiditis or encysted accumulations.

Diseases and Injuries of the Spinal Cord

Congenital anomalies of the spinal column and cord are discussed in Chapter 21.

Functional alterations in the cord or its nerve trunks may be purposefully produced by the injection of anesthetic agents. The following methods are employed: (1) Local field block—injection of anesthetic agent into the skin or mucous membrane; (2) nerve block—intraneural or paraneural injections of nerve trunks; (3) paravertebral block—injection of spinal nerves at their points of exit from the spine; (4) plexus block—injection of anesthetic into the cervical, brachial, or lumbosacral nerve trunks; (5) splanchnic block—injection of anesthetic agent into the prevertebral tissues reaching the splanchnics and celiac plexus; (6) caudal block or epidural block—use of anesthetic agents in the sacral canal to anesthetize the terminal trunks of the cauda equina; (7) spinal anesthesia—the introduction of anesthetic agents into the subdural space with quick absorption by the nerve roots blocking the passage of sensory motor and sympathetic impulses.

Spinal anesthesia produces a fall in blood pressure as a result of vasodilation. To limit this effect, some advocate the Trendelenburg position so that blood can reach the brain and vital centers and heart. At the same time this position favors the upward flow of the agent (if its specific gravity is heavier than the spinal fluid), causing more widespread vasodilation. Ephedrine or Adrenalin must be available to relieve this effect. Usually the Fowler position is used to hold the anesthetic agent at a low level. *Complications* of this type of anesthesia include paresthesias, bladder difficulties, convulsions, meningitis, coma due to

anoxia (from anesthetic reaching too high a level and causing paralyses of diaphragm, or intercostal muscles; the drop in blood pressure plus loss of blood during operation; mechanical difficulties due to pressure on the diaphragm, etc.), and lastly, thrombosis and embolism due to hypotension and stasis from leg inactivity. Spinal anesthesia has a definite and useful place in surgery because of the good relaxation that is obtained.

Injuries to the cord may be produced by fractures, dislocations, and fracture dislocations of the vertebra (see Chapter 21), penetrating and perforating wounds, severe jarring with resultant hemorrhage. Rarely hemorrhage occurs without injury as in hypertension and arteriosclerosis.

As in injury to the head, it is impossible to tell the degree of cord damage by the extent of vertebra trauma. The spinal cord is subject to the same degrees of injuries as the brain; namely, (1) concussion, (2) edema, (3) contusion or bruising, (4) laceration (incomplete or complete), (5) hemorrhage, hematomyelia (bleeding within the cord), and hematorachis (bleeding outside the cord with pressure on it). Also as in brain injuries these changes are rarely encountered singly and therefore in most instances there is some edema and hemorrhage with lacerations or penetrations, etc.

Nerve cells and nerve fibers (no neurilemma) in the cord are incapable of regeneration if destroyed. *Concussion* produces a complete functional block due to cell alterations principally in interneurons consisting of chromatolysis. Long ascending and descending fiber tracts are involved. The effects are transient.

Edema and some degree of hemorrhage may accompany any injury to the cord and may produce temporary functional impairment by compression. Therefore in examining a patient who has been injured any remnant of function gives hope that nerve cells and fibers have not been destroyed by laceration or severe contusion. Compression by localized accumulation of blood clot or by fracture dislocation may produce symptoms requiring surgical intervention.

Clinical Manifestations of Cord Injury

The history of the accident and points of injury often give a clue as to the level and degree of injury. If in transit there is some motion of the upper extremities and none of the lower, the level may be suspected. Cervical injuries may interfere with respiration. If, in addition, the legs are moved ever so little, there is hope of a functional impairment rather than complete destruction. Examination must be painstaking and thorough, remembering always that associated injuries of the skull, thorax, abdomen, and extremities may be present. Penetrating and perforating injuries may be definitely located, but the extent of internal damage is determined by symptoms and signs.

The motor function, sensory function (light touch, pain sense, heat, and cold), reflexes, and visceral functions are carefully observed. Bedside x-ray examinations are also made to help in the diagnosis.

Complications and sequelae of cord injuries include the paraplegic state, disordered urinary bladder function, the occurrence of root pains or visceral or diffuse burning pains, dysfunctions of the autonomic nervous system, decubitus ulcers, urinary calculi, bowel dysfunction, and psychological and emotional disturbances.

The bladder dysfunction is a major problem, since it occurs with lesions anywhere in the cord—the more complete, the closer the injury, so that destruction of the sacral cord completely denervates the bladder. Although the bladder becomes atonic at first, later it may become autonomous, actually undergoing hypertrophy if residual is kept down by catheter drainage and infection forestalled by this drainage plus chemotherapy and antibiotics. Automatic micturition finally develops—earlier and with greater efficiency in lesions between the seventh cervical and fifth thoracic. It does not appear in the presence of incomplete cord lesions. It is less apt to occur early in lesions below the tenth thoracic. Of course if there are bladder neck obstructions, bladder sepsis, multiple calculi, or severe debilitation, the bladder will not become automatic, and cystotomy may be necessary.

Paraplegia is the inevitable result of severe cord injury, rendering the patient helpless, and if not properly supervised and treated, many complications may occur; namely, malnutrition, decubitus ulcers, injuries to the paralyzed extremities with poor healing (due chiefly to inactivity, venous stasis, and hypoproteinemia), urinary infection, and mental depression. In addition, there may be severe pain which may be of three types, alone or in combination: (1) Somatic pain which is sharp and intermittent and conforms to dermatome patterns, especially those in which no sensation is present. It is seen frequently in injuries of the cauda equina and corresponds to the "phantom pain" previously discussed. Hyperalgesia of the segments directly over the site of injury may amount to pain. (2) Sympathetic pain is constant, dull, aching, or burning and is referred to the back of the leg. This includes so-called visceral pain. (3) Psychic pain which has no definite pattern.

Treatment depends upon causative factors but in all types and particularly those due to vertebral fracture or fracture dislocation the patient must be handled with extensive care and the spine carefully supported. After the patient enters the hospital, a careful examination is made, including bedside x-ray. The examiner looks for associated injuries, evaluates blood loss and anoxemia, and institutes treatment along all lines, but the relief of anoxia and arrest of hemorrhage take precedence over all other problems. Then gastrointestinal or other visceral disruptions must be closed.

Pressure on the cord, like cerebral compression, is usually treated conservatively. If the cord has been hopelessly lacerated, surgery does no good and, if not, laminectomy may jeopardize the life of the patient and at the same time may actually add to the cord injury. If edema or

hemorrhage is the cause, cautious observation is best because the former will be absorbed and the latter may be. Therefore immobilization of the spine in a plaster jacket is indicated. In cervical fractures head traction is indicated and is obtained by calipers or tongs or by a special metal bar included in the head cast. The patient is placed in a special bed with an incorporated Bradford frame arrangement to permit turning and use of the bedpan.

Surgery (laminectomy) is instituted to relieve persistent subarachnoid block due to hemorrhage or foreign bodies. This may be determined by symptoms and signs and lumbar puncture. Penetrating wounds of the spine were treated by prompt exploration during World War II.

The *bladder* requires meticulous care until automatic emptying occurs. At first there will be constant dribbling due to distention and overflow and this predisposes to bladder infection as well as decubitus ulcers. An indwelling catheter is anchored and irrigated with weak potassium permanganate. Antibiotics may be necessary. Manometric readings show the progress of response of the bladder to sensory stimuli, from the bladder itself, the region of the external genitals by way of the sacral cord segments below the injured area, or by other pathways previously discussed. (See Chapter 23.)

The bowel also requires much care and usually does not become automatic as readily as the bladder. Enemas are used after the morning or evening meal to encourage regular bowel emptying.

Good nursing care is required to prevent decubitus ulcer and injury to the insensitive areas. Early ambulation is desired and may be helped by reconstructive orthopedic procedures to provide stabilization of joints and return to motion. Rehabilitation includes corrective exercises, special training in the use of braces, crutches, traction, and special sliding and walking devices to enable the patient to handle himself and to earn a living. Pain may be relieved by sympathetic nerve block, procaine hydrochloride injection in "trigger zones," caudal or spinal anesthesia as a trial for surgical procedures: sympathectomy, decompressive laminectomy having dura open, dorsal rhizotomy (section of posterior roots at certain levels), and chordotomy (section of anterolateral spinothalamic tracts).

Hematomyelia or diffuse hemorrhage into the cord not due to injury is treated by bed rest and prevention of decubitus ulcers. Early ambulation is desirable. Spinal apoplexy belongs in this group.

Inflammations may occur outside the dura in the epidural space, in the meninges, or in the cord itself. The *epidural* space is dorsal to the spinal roots; there is no space anteriorly where the dura is firmly adherent to the vertebrae. There is a potential space in the cervical region and a variable one from the seventh thoracic to the second sacral where the space ends. It is widest at the ninth to eleventh thoracic and third and fourth lumbar. It is filled with fat, blood vessels, and loose areolar tissue. An abscess may form in this space from a pyemia (furuncles,

middle ear disease), from vertebral osteomyelitis, or from injury and direct infection. The disease is rare and is recognized by the history of boils or injury, fever, root pains, and weakness in the legs. Treatment consists of prompt relief of pressure by laminectomy well above and below the involved area and drainage. The dura is not opened. Penicillin should be used.

As a result of delayed softening of a vertebra following a compression fracture (Kümmell's disease) or tuberculous infection with necrosis (Pott's disease), the cord is compressed due to angulation of the vertebral column, passive congestion, and thickening of the dura. Treatment is directed to stabilization of the vertebral column by cast or fusion.

The Meninges

The dura may be irritated by contiguous infection (pachymeningitis) originating in the vertebral bodies or by an open wound or rarely following laminectomy. Tuberculosis and syphilis may also cause inflammation of the dura alone. In all such cases the clinical manifestations may suggest meningitis. However, the spinal cord is free of cells and globulin though under increased pressure.

Leptomeningitis may be caused by the meningococcus, the tubercle bacillus, and the spirocheta pallida. The infection may reach the meninges by the blood or lymph stream, by trauma, or by extension from neighboring structures. The diagnosis is made by the symptoms and signs: headache, malaise, irritability, restlessness, delirium, coma. Vomiting is often present. Convulsions, root pains, and paralysis are common. Stiffness of the neck (Kernig's sign) is characteristic but is not always present and the reflexes may be normal. The spinal fluid is turbid, filled with polymorphonuclears (acute type). A pellicle may form in the tuberculous type. The treatment for the acute variety consists of large doses of penicillin and sulfadiazine. The tuberculous type is helped by streptomycin and the syphilitic variety by penicillin and antisyphilitic therapy. The spinal medulla may be inflamed (myelitis). The causes are (1) infection, which may be primary (poliomyelitis) or secondary (postvaccinal meningitis, by lymphatic extension from kidney, bladder, or pelvic viscera, direct extension from empyema; embolism in septicemia and endocarditis); (2) toxins, carbon monoxide, chloroform, spinal anesthetics, alcohol injections, cachetic and anemic states, pregnancy; (3) trauma, direct or indirect injury (electric shock), penetrating and perforating wounds. The symptoms and signs include motor, sensory, reflex, visceral, and trophic disturbances. The diagnosis is made by the history, symptoms, and signs and study of the spinal fluid. There is a chronic type of myelitis which evolves slowing, causing weakness, heaviness, and stiffness of the extremities and paresthesias. Treatment depends upon the cause, and except for the compression types associated with injury or disease of the vertebrae, surgery is not indicated. The

diagnosis is difficult to make because of the similarity of the symptoms in cord tumors, vertebral disease, combined sclerosis, *multiple sclerosis*, myelomalacia and pachymeningitis.

Neoplasms of Spinal Cord

Neoplasms of the spinal cord produce alterations in sensation and motor function in the extremities, pain which is usually worse at night and is a constant radicular pain, impairment of bladder function which is progressive as well as sexual impotence in the male. The diagnosis is made by careful general and neurological examination, x-ray of the spine, lumbar puncture with study of spinal fluid, Queckenstedt test, and myelography with radiopaque substances. Fifty per cent of the tumors affecting the spinal cord are amenable to surgery. The earlier the diagnosis the less chance for irreparable cord damage.

Types of Tumors

Extramedullary tumors produce sensory changes in the distal parts of the extremities and saddle area and radicular pain which is severe and persistent; they usually do not involve the sphincters. Sometimes these growths contain calcium or alter the size of the interpedicular space, giving rise to x-ray evidence of their location. They consist of: *Meningioma*, which is encapsulated, grows from the dentate ligament, and may project on either or both sides of the vertebrae. It can be completely removed, although the nerve root may be injured in the process. *Perineural fibroblastoma* which requires the sacrifice of the nerve root for its removal. It may be associated with multiple cord tumors (von Recklinghausen's disease) and occasionally gliomas. In multiple neurofibromas only those causing symptoms are removed.

Gliomas may be primary or secondary to brain gliomas. They include: *Medulloblastoma* (usually secondary). *Ependymoma*, the most common primary spinal glioma. It arises in conjunction with the filum terminale and the central canal and may be cystic. Removal is difficult, especially when the cauda is extensively involved. Decompression relieves pain, and x-ray therapy may influence the rate of growth favorably. *Astrocytomas* and *glioblastomas multiforme* are usually not removable. *Angioma* is usually of the cavernous type and occurs at any age. It is usually diagnosed by its position (cervical and thoracic region) and x-ray studies with myelography.

Epidermoid cysts are seen in the caudal region with increasing pressure on the cauda equina. The same is true of neurenteric cysts. They are often completely removable.

Tumors of the vertebra which may exert pressure on the cord or invade it include Hodgkin's disease, lymphosarcoma, metastatic neoplasms (carcinoma of prostate, breast, and hypernephroma, etc.), neurofibromas and perineural fibromas of the posterior mediastinum (hour

glass tumors, Chapter 19) and elsewhere along the cord, tuberculoma, and protruding intervertebral disc (lumbar usually, sometimes cervical). Treatment depends on the cause. Neurofibromas and degenerated nucleus pulposus may be completely removed. Lymphoblastomas respond to x-ray therapy as a rule.

Chapter 19

The Respiratory System

EMBRYOLOGY AND HISTOLOGY

In the early embryo, when the head and tail folds develop, blind entodermal tubes are formed, both cranially and caudally from the vitelline sac. These are known as the foregut and hindgut, respectively. The foregut later forms part of the oral cavity and is further differentiated into the pharynx and its derivations into the esophagus, respiratory organs, stomach, and duodenum. In 2½ mm. embryos, the respiratory organs appear as a groove in the floor of the entodermal tube caudal to the pharyngeal pouches. On the outside of the tube this groove produces a ridge which becomes larger and rounded at its caudal end. This laryngeal tracheal groove and the ridge develop into the larynx and trachea. The rounded end is the forerunner of the lung.

Externally, two lateral longitudinal grooves mark off the posterior esophagus from the anterior respiratory anlage. The lung bud increases in size and becomes bilobed in 4 to 5 mm. embryos. The lateral furrows become deeper and separate the lung anlages and the tracheal tube from the esophagus. Sometimes the upper part of the esophagus ends blindly and the lower portion opens into the posterior portion of the trachea just above the bifurcation, forming a tracheoesophageal fistula at birth. These anomalies are discussed in Chapter 20. Soon the lung bud extends caudally and divides into two branches, forming the two main bronchi, which divide repeatedly and become separated by a mass of dense entodermal or mesenchymal tissue. It is not definitely known which type prevails. This tissue has a glandlike structure and later unites with the alveolar ducts. It is thought by some that a failure of this union is responsible for congenital cystic disease of the lung.

The primitive bronchi are lined with cuboidal epithelium. They branch dichotomously and are completed by end buds lined with cylindrical epithelium. In the 3- to 4 month stage, many blood vessels appear within this tissue and there is an increase in connective tisue. Also, large lymphatics, which seem to divide the pulmonary tissue into lobules, make their appearance. At 6 to 7 months, the bronchi are lined in part with ciliated epithelium which flattens toward the peripheral ends of the bronchi. These bronchi branch and end in the terminal ducts capped with end knobs. The latter finally become the alveoli. The cuboidal entodermal cells lining the alveoli become interrupted by blood vessels penetrating them and their exact fate is unknown (Bloom). The lung does not increase in size by distention of existing ducts and alveoli, for it has been shown by actual count that there are many more alveoli in the adult than in the newborn.

The trachea divides into two main stem bronchi and these divide into ten smaller bronchi on each side, although their distribution varies. These give rise to still smaller bronchi, from which fifty to eighty bronchioles originate in each lobule. Terminal bronchioles continue into one or more respiratory bronchioles. These divide into two to eleven alveolar ducts from which arise the alveolar sacs or alveoli. Accompanying the bronchi are the pulmonary veins and arteries, forming a surgical unit but not strictly a bronchovascular unit because of intersegmental distribution.

The trachea is lined with ciliated pseudostratified columnar epithelium. It is often referred to as respiratory epithelium. Many elastic fibers, glands, and an incomplete ring of hyaline cartilage (posteriorly there is none) surround the trachea and make up its wall. The bronchi are lined with the same type of epithelium. They have much elastic tissue and smooth muscle. The latter is more plentiful in the

bronchioles and continues into the alveolar ducts. This myoelastic layer is important in connection with the physiology of respiration as it provides the elastic recoil of the lung. The cartilage gradually disappears in bronchioles of 1 mm. The respiratory bronchioles are lined with ciliated columnar epithelium in their proximal parts, and in their distal extremities this becomes low cuboidal without cilia. Some alveoli bud off here opposite the side along which the pulmonary artery runs. These are the first alveoli and, therefore, these tubes have been called respiratory bronchioles.

The alveolar ducts contain strands of elastic and collagenous fibers and smooth cells. Their lining is probably made up of flattened epithelium. The space between the alveolar ducts and sacs is called the atrium. This space is surrounded by collagenous fibers. The alveoli are polyhedral formations, one side of which is always lacking, so that air may get in. There are many capillaries in the alveolar walls and they anastomose freely. Reticular and elastic fibers form the supporting framework for the air vesicles and the capillaries. The elastic and collagenous fibers around the alveoli and ducts are connected with the collagenous fibers in the walls of the arteries, veins, and bronchioles.

There is much dispute concerning a lining of the alveoli. The cells which are present are thought to be endothelial cells making up the walls of the capillaries. The cells outside the capillaries may be connective tissue or epithelial, but they have the appearance and functions of macrophages. These are called septal cells. It would seem that many alveoli are composed merely of capillary loops without any lining at all, or at best a discontinuous membrane with capillaries uncovered and surrounded by a small amount of fluid (lymph).

Histologists have long maintained that alveolar apertures exist permitting collateral ventilation to occur when differences in pressure arise between contiguous lobuli during respiration. Thus the component parts of a pulmonary lobe have communications between them as described by van Allen and co-workers and more recently by Baarsma and Dirkin and van Allen and Lindskog. The existence of anastomoses between the finer ramifications of bronchi has not been proved.

Clinical observations have confirmed the morphological studies which show the existence of interalveolar communications. Upon obstruction of a bronchus, atelectasis occurs only when access of air to an entire lobe has been prevented. If the obstruction affects only part of a lobe, no atelectasis occurs. Thus air must get in around the obstruction. However, inflammation in the obstructed parts prevents the collateral ingress of air and causes atelectasis.

Experimental studies by van Allen and Jung confirmed the morphological studies and clinical observations of collateral ventilation. They introduced a catheter which obstructed the lower lobe bronchus *just past the first bifurcation*. The free end of the catheter was kept under water. At every inspiration water was sucked up into the catheter about 5 cm., and with every expiration air bubbled out as long as the experiment lasted. If now the catheter was introduced so that the obstruction in the bronchus was placed before the first bifurcation and so that the entire lobe could only ventilate through the catheter, air escaped from the immersed end only once. This proved that a collateral access of air outside the obstructed bronchus is possible provided there is free communication of a part of the lobe with the air outside. Moreover, the recent work of Baarsma and Dirkin shows that such communications are not the result of ruptured alveoli.

The collateral air drifts fill in the alveoli distal to obliterated bronchi, thereby avoiding dead space. The ''leafless limb'' is, in reality, an obliterated bronchus with alveoli filled with air from adjacent lung. Bronchiectasis may start as an obliterative bronchiolitis with fibrosis, and the element of inflammation prevents collateral air drifts from functioning so that areas of atelectasis are present.

Frequently the alveoli in the fetus are epithelialized but this epithelialization disappears before birth. Rarely this epithelialization is seen at birth. Such children do

not usually survive. Their lung alveoli show definite epithelial layers and capillary loops between the epithelialized septa.

The reasons for discussing the various types of cells which make up the lining of the lung tubes and sacs are, first, to be able to better understand the physiology of respiration and, second, to understand the various types of lung neoplasm which may be as variable as the cells found in this system.

Anatomy

The pulmonary artery, pulmonary veins, and bronchi are subject to great variations. The same must necessarily be true of the lung segments which constitute the "lung units." Angiocardiographic studies help to define the normal and recent cadaver dissections have added to the knowledge of aberrancies or variations.

The pulmonary artery arises from the conus arteriosus at the pulmonary semilunar valves to the left of the ascending aorta and then ascends to a point below the aortic arch where it gives off the left and right main branches. The *right branch* lies posterior to the ascending aorta and the superior vena cava and anterior to the bifurcation of the trachea, the esophagus, and thoracic duct. In the lung it divides into superior and inferior branches. The *left branch* lies in front of the left main bronchus and descending aorta and below the descending aortic arch of the aorta, to which it is connected by the ligamentum arteriosum, and above the pulmonary veins. The right main branch as seen by angiocardiography averages about 23 mm.; the pulmonary trunk, 26 mm.; and the conus 19 mm. Aneurysms of the pulmonary artery have been described.

The terminal pulmonary veins, two on each side, open into the left atrium of the heart. Then tributaries arise in capillary plexuses in the walls of pulmonary alveoli.* Smaller veins unite to form larger ones, which run along the anterior aspects of the bronchial tubes. The bronchi, arteries, and veins form *segments* within the lobes. Between the segments there exist communications between veins known as "intersegmental veins." They constitute a landmark for the dissection of segments during surgery which should be briefly described. First the segmental artery and bronchus are identified as described by Overholt and Langer and divided. Any subpleural veins and the segmental veins are divided. The lung is then inflated and the distal end of the divided branches grasped. Close inspection reveals one or more veins not following the branches which border the segment being retracted. By carefully following this distally, dividing the small veins which go from the diseased to the healthy segment, the surgeon will find the areolar tissue between segments. The terminal pulmonary veins are in relation with the following structures at the hilus: the upper pulmonary veins on each side lie below and in front of the pulmonary artery. The lower veins are in the lowest part of the root, in a plane slightly posterior to the upper. On the right side the upper vein passes behind the superior vena cava and the lower behind the right atrium close to the interatrial septum. On the left side both upper and lower pulmonary veins cross anterior to the descending aorta and they terminate in the upper and posterior part of the left atrium near its left border. All four pulmonary veins perforate the fibrous layer of the pericardium and receive partial coverings of the serous layer before they enter the atrium.

THE CHEST WALL

The thoracic wall forms a bony cartilaginous and muscular cage, anchored in front to the sternum and behind to the vertebrae. The muscles attached to the first rib, the clavicle, and the scapula on each side form what might be called the roof, and the diaphragm, the floor. The intercostal muscles fill in the spaces between the ribs; and the latissimus dorsi, the serratus anterior, the shoulder muscles, and the erector spinae group cover the posterior and the lateral surface of the chest, the pectoral muscles cover the upper anterior surface, while the rectus abdominis is attached to the lower anterior

surface. The opening of the thorax at the top is small. It lies between the manubrium sterni, in front, and the vertebral column, behind. Through it pass the great vessels (the carotid arteries and the subclavian and internal jugular veins), the vagus nerves, the trachea, and the esophagus. Small openings in the diaphragm permit the esophagus to join the stomach and allow the abdominal aorta to emerge and the inferior vena cava to enter. The blood supply of the thoracic wall is chiefly through the intercostal arteries, which come from the thoracic aorta and (together with the intercostal nerves) run along a groove on the inferior margin of each rib. In addition, the important internal mammary arteries run along the lateral aspect of the sternum to join the superior epigastric artery, whereas behind, the vertebral arteries follow the course of the spine. The nerves which control the movements of the thorax are the intercostal nerves, the long thoracic nerve to the serratus anterior, the thoracodorsal nerve to the latissimus dorsi, and the phrenic nerve which runs inside the chest to the diaphragm. These nerves supply the impulses necessary for breathing. Since the ribs slant downward, their elevation increases the anteroposterior diameter of the chest. During the act of inspiration the ribs are elevated and the diaphragm descends; the negative pressure thus created together with the elasticity of the lung permits inhalation to occur. This is the active phase. Then the ribs fall downward, the diaphragm ascends to its normal position, and the lung, due to its elastic recoil, contracts, thus allowing expiration to take place. Within the chest wall are the pleura, the lungs, and the mediastinum, with its vital contents; namely, the heart and the great vessels.

THE PLEURA

The pleura is a thin sheet of mesothelium made up of a single layer of cells. It is folded upon itself, forming two layers: a parietal layer, which lines the inside of the thorax, and a visceral layer, which is firmly attached to the outside of the lung. The folding occurs at the root of the lung, but the pleura is everywhere continuous, forming an airtight cavity. Since the pleural cavity is larger than the lung, a pleural space exists, which is important in respiration. The pressure in the pleural cavity is normally always negative; that is, lower than atmospheric pressure. It is more negative with inspiration and less negative with expiration, and this change, as we have seen, is due to changes in the position of the chest wall and diaphragm. Normally we breathe both with our thorax (thoracic breathing) and with our diaphragm (diaphragmatic breathing); however, we can breathe with one or the other, if necessary. It is easily seen that when the pleural space is increased, a greater degree of negative pressure results, creating a partial vacuum and thereby pulling the elastic lung out. This is an active process and differs from expiration, which is passive and consists of a decrease in the size of the pleural space, permitting the elastic lung to recoil. If, however, the intrathoracic pressure is positive, as a result of air entering through a rupture or wound of the pleura or lungs, then the lung immediately collapses. If this occurs on one side, a dangerous mediastinal shift may occur, but life is usually preserved; if on both sides, death from asphyxia may result. This process is slightly different in children and will be discussed later under empyema.

The blood pressure in veins is much lower than in arteries (see Chapter 17), being highest in peripheral veins and lowest in the vena cavae as they enter the right auricle. At this point the pressure is negative, thereby permitting the blood to find its way back to the heart through the valveless veins of the abdomen and thorax. *But the blood pressure in the large veins, though low, is higher than the pressure in the thoracic cavity, else the flow of blood would be interrupted. Thus, any lesion which increases the intrathoracic pressure will cause passive congestion in the veins, causing the large veins of the neck to stand out. Also,* there will be a dangerous dilatation of the right side of the heart because of its effort to pump the blood through collapsed ... the left ventricle will beat rapidly, though weakly, in an attempt to keep the

arterial system supplied. Should this continue, less and less blood, poor in oxygen, will reach the left ventricle. There will be extreme cyanosis due to an increased amount of reduced hemoglobin. The blood pressure will fall rapidly due to cardiac failure. Except in accidents, or erosions of a vessel from disease, pathological changes develop slowly, permitting adjustments to take place.

PHYSIOLOGY OF RESPIRATION

Breathing consists of moving blood (perfusion) and moving air (ventilation) through the lungs. The respiratory center is normally under the control of:

1. Chemical influences. Carbon dioxide is probably the controlling factor; however, lack of oxygen may excite the center also. In Chapter 12 we have seen that the pH of the blood may influence the center. Carbon dioxide excess increases chiefly the depth of breathing.

2. Nervous stimuli.

a. These are carried chiefly by the vagi, which act to offset any changes in respiration. When the lungs are distended with air, afferent vagal impulses inhibit the automatic action of the center and arrest inspiration, thereby bringing on expiration: when the lungs are empty of air, these impulses stop, thereby arresting expiration and permitting inspiration to occur. (Hering-Breuer reflex). Therefore, the vagi influence both the *rate* and *depth* of breathing.

b. Sensory stimuli for any portion of the body carried over sensory nerves may have a *pressor* effect, causing quicker and stronger inspiration, or a *depressor* effect, causing respirations to become slower, or more feeble, or even to cease entirely.

c. Voluntary control may be exerted over respiratory movements.

d. The carotid sinus is influenced by pressure changes (see Chapter 14). The carotid body is stimulated by a low oxygen content of arterial blood or by carbon dioxide content to some extent. As blood pressure rises, the depth of respiration decreases and if this continues, apnea occurs. It is the lack of oxygen and the hydrogen ion concentration which affects the carotid sinus.

The passage of gases is but a process of simple diffusion. The total epithelial surface of the lungs is 70 square meters. Of this, 55 square meters is respiratory; that is, over 25 times the surface area of the skin. The capillaries in the respiratory portions of the lungs have a surface of 140 square meters. The lungs eliminate about 800 c.c. of water per day and may eliminate other substances from the blood, such as alcohol. The body at rest uses only about one-twentieth of areating surface. The alveoli change little during inspiration and the flow of blood is faster then. The alveolar ducts become distended and also the small bronchi and bronchioles providing the area into which air is inspired.

The fetus probably makes some furtive respiratory movements in utero, sucking small amounts of liquor amnii into the lungs. Air gets into the body through the trachea and to some degree by swallowing or sucking, with resultant absorption of oxygen from the gastrointestinal tract. Tissue pressures are everywhere equal to atmospheric pressure except in the thorax and abdominal cavities. At birth, the intrapleural and intrapulmonic pressures are probably equal. This condition would not permit respiration to occur. However, very soon after birth, the pressure within the pleural cavity becomes negative to atmospheric pressure. This is possible because of two conditions: (1) the walls of the pleural cavities are mechanically resistant enough to allow pressure differences to occur. (2) the withdrawal of water and crystalloids from the pleural space permits the lungs to expand by creating the negative pressure. Since the osmotic pressure in the capillaries of the pleura is normally about 360 to 400 mm. of water and since the hydrostatic pressure is not more than a few centimeters of water, therefore water is drawn out of the pleural cavity into the blood, and the lungs are thereby expanded (Krogh). The changes necessary to expand the lungs fully will determine the final pressure reached.

surface. The opening of the thorax at the top is small. It lies between the manubrium sterni, in front, and the vertebral column, behind. Through it pass the great vessels (the carotid arteries and the subclavian and internal jugular veins), the vagus nerves, the trachea, and the esophagus. Small openings in the diaphragm permit the esophagus to join the stomach and allow the abdominal aorta to emerge and the inferior vena cava to enter. The blood supply of the thoracic wall is chiefly through the intercostal arteries, which come from the thoracic aorta and (together with the intercostal nerves) run along a groove on the inferior margin of each rib. In addition, the important internal mammary arteries run along the lateral aspect of the sternum to join the superior epigastric artery, whereas behind, the vertebral arteries follow the course of the spine. The nerves which control the movements of the thorax are the intercostal nerves, the long thoracic nerve to the serratus anterior, the thoracodorsal nerve to the latissimus dorsi, and the phrenic nerve which runs inside the chest to the diaphragm. These nerves supply the impulses necessary for breathing. Since the ribs slant downward, their elevation increases the anteroposterior diameter of the chest. During the act of inspiration the ribs are elevated and the diaphragm descends; the negative pressure thus created together with the elasticity of the lung permits inhalation to occur. *This is the active phase. Then the ribs fall downward, the diaphragm* ascends to its normal position, and the lung, due to its elastic recoil, contracts, thus allowing expiration to take place. Within the chest wall are the pleura, the lungs, and the mediastinum, with its vital contents; namely, the heart and the great vessels.

THE PLEURA

The pleura is a thin sheet of mesothelium made up of a single layer of cells. It is folded upon itself, *forming two layers:* a parietal layer, which lines the inside of the thorax, and a visceral layer, which is firmly attached to the outside of the lung. The folding occurs at the root of the lung, but the pleura is everywhere continuous, forming an airtight cavity. Since the pleural cavity *is larger than the lung,* a pleural space exists, which is important in respiration. The pressure in the pleural cavity is normally always negative; that is, lower than atmospheric pressure. It is more negative with inspiration and less negative with expiration, and this change, as we have *seen,* is due to changes in the position of the chest wall and diaphragm. Normally we breathe both with our thorax (thoracic breathing) and with our diaphragm (diaphragmatic breathing); however, we can breathe with one or the other, if necessary. *It is* easily seen that when the pleural space is increased, a greater degree of negative pressure *results, creating a partial vacuum and thereby* pulling the elastic lung out. This is an active process and differs from expiration, which is passive and consists of a decrease in the size of the pleural space, permitting the elastic lung to recoil. If, however, the intrathoracic pressure is positive, *as a result of* air entering through a rupture or wound of the pleura or lungs, then the lung immediately collapses. If this occurs on one side, a dangerous mediastinal shift may occur, but life is usually preserved; if on both sides, death from asphyxia may result. This *process* is slightly different in children and will be discussed later under empyema.

The blood pressure in veins is much lower than in arteries (see Chapter 17), being highest in peripheral veins and lowest in the vena cavae as they enter the right auricle. At this point the pressure is negative, thereby permitting the blood to find its way back to the heart *through the valveless veins of the* abdomen and thorax. *But the blood pressure in the large veins, though low, is higher than the pressure in the thoracic cavity, else the flow of blood would be interrupted. Thus, any lesion which increases the intrathoracic pressure will cause passive congestion in the veins, causing the large veins of the neck to stand out. Also,* there will be a dangerous dilatation of the right side of the heart because of its effort to pump the blood through collapsed lungs, and the left ventricle will beat rapidly, though weakly, in an *attempt* to keep the

The child is therefore born with a negative intrapleural pressure; that is, negative to atmospheric pressure. At birth, therefore, even though the lungs almost fill the pleural cavities, there is a disproportion between the thoracic cage and the lungs which are therefore filled with air due to its inrush to fill the enlarged space. If nothing further occurred, the lungs would remain expanded unless, of course, the pleura should be punctured. However, with a descent of the diaphragm and enlargement of the anteroposterior diameter of the chest which occurs with the first breath, the thoracic cage becomes too large for the lungs to fill by a simple unfolding of the walls of the air spaces. The elastic tissue of the bronchiole tree, blood vessels, and air sacs is put under stress and is constantly pulling against the stretching force. This pull or recoil is about 4 to 5 mm. of mercury.

Intrapulmonic pressure varies from about -2 mm. of mercury or 758 during the inspiratory phase to a 3 or 4 mm. of mercury or 764 during the expiratory phase of ordinary quiet respiration. With the lungs at rest, the pressure is atmospheric or 760 mm. of mercury.

The intrapleural pressure varies from -6 mm. of mercury during quiet inspiration in the adult to -2½ mm. of mercury during expiration. Therefore, at expiration, the intrapulmonic pressure may be 763 mm. of mercury and the intrapleural 757½ mm. of mercury because the entire process began with an elastic recoil of the lungs at birth of -2 to 3, and in the adult it reaches -4 due to the enlargement of the thoracic cavity. Even after forced expiration, the lung is not totally collapsed and the elastic recoil is still there. However, if great enough, this recoil is lost because the chest is made so small that the intrapleural pressure may be 50 or more (that is, 810 mm. of mercury).

Whether the pleural sac is normally real or apparent is inconsequential because the two layers are continuous throughout, although in diseased states they may not be. Therefore, pressures affecting one layer will affect the other unless adhesions or other abnormalities exist.

Blood goes from the right to the left side of the heart through the pulmonary circuit, and the quantity passing per minute must equal the quantity flowing at the same time through the rest of the body; namely, about 5 liters under basal conditions. The mean arterial pressure in the pulmonary circuit is about one-sixth that of the aorta, or about 18-20 mm. of mercury. In the dog there is a systolic pressure of about

---

laries. Although this is slight, nevertheless, it does occur in small amounts, and it is quickly picked up by the lymphatics and carried back to the blood stream. Also, the lymph capillaries pick up particulate matter and since they behave as semipermeable membranes, they are entirely dependent upon the positive pressures within the chest. The capillaries in the thorax have a hydrostatic pressure of about 20 mm. of mercury. The osmotic pressure within the capillaries is approximately the same as elsewhere; namely, 25 to 30 mm. of mercury. As we have seen, the negative pressure within the pleural cavity during an ordinary respiratory cycle varies from a -5 to -10 mm. of mercury in an adult. The pressures within the alveolus will vary between a -2 during inspiration to a +4 during expiration. The sum of the outward pressures, if we may use that term, would be the hydrostatic pressure in the capillary, which is 20, plus the negative pressure in the pleura, which is 10, plus the negative pressure in the alveolus during inspiration, which is 2, a total of 32 mm. of mercury. The sum of the pressures tending to keep fluid within the capillaries would be the osmotic pressure, which is about 30, plus the positive pressure in the alveolus during expiration, which is about 4, a total of 34 mm. of mercury. The effective pressure, therefore, tending to keep fluid from leaving the capillaries is about 2 mm. of mercury. In addition, the lymphatics help to keep the lungs dry. It will be noted that during expiration the negative pressure within the pleural cavity is reduced to -5 and, therefore, the total outward pressure, if we may use the term, is 20 plus 5, making 25, whereas the pressure tending to keep the fluid within the capillaries is 30 plus 4, or 34; in other words, an effective pressure keeping fluids within the capillaries of 9 mm. of mercury. We may look upon the pressure within the alveolus as roughly corresponding to that of the interstitial spaces in other tissues of the body. When there is the slightest leakage of fluid within the alveolus, a cough reflex is initiated which increases the intra-alveolar pressure, thereby greatly reducing the effective pressure outward and increasing the effective osmotic pressure or pull inward. So long as the increased alveolar pressure is delegated to segments of the lung and does not include the entire lung space, this method is very effective in preventing the loss of fluid within the alveolus. However, when the entire lungs are simultaneously laboring under increased intra-alveolar pressure, an acute type of emphysema would be present and this, of course, would give rise to labored breathing and anoxia. This actually occurs sometimes in bronchial asthma. The diagram on the lower right is based upon studies by Drinker and Warren: The Genesis and Resolution of Pulmonary Transudates and Exudates: J. A. M. A. 122: 269, 1943.

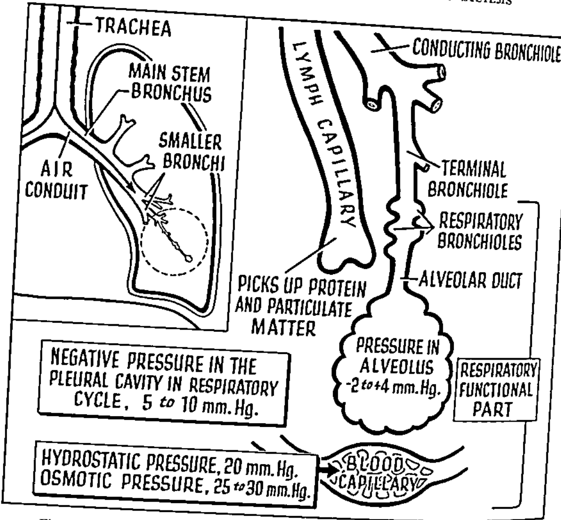

Fig. 211.—Diagram illustrating the physiology of the respiratory functional unit and its relationship to fluid balance. The bronchial tree is divided roughly into two parts. The first part serves merely as an air conduit and apparently has no respiratory function. It consists of the trachea and the bronchi. These divide into ten smaller bronchi on each side, although their distribution varies, as we shall see in subsequent diagrams. These, in turn, give rise to still smaller bronchi from which fifty to eighty bronchioles originate in each lobula. The beginning of the functional unit is probably in the respiratory bronchioles, although the terminal bronchioles may have some respiratory function. The respiratory bronchioles branch into the alveolar ducts and these, in turn, into the atria which communicate with the alveoli.

The pressure within the pleural cavity ranges roughly from -5 to -10 mm. of mercury. They are never positive or the lungs would collapse. During inspiration they will reach a −10, and during expiration a −5 or thereabouts. At the same time, the intrapulmonary pressure will vary from about a -2 mm. of mercury during the inspiratory phase to a +3 or 4 mm. of mercury during the expiratory phase of ordinary quiet respiration. These figures vary greatly. For example· the maximal negative pressure capable of being developed within the lungs by forced inspiration is probably −40 to 50 mm. of mercury; on the other hand, when an expiratory effort is made with the glottis closed, as during coughing or strong muscular effort, the intrapulmonary pressure becomes raised to +10 up 40 mm. of mercury. In the pleural cavity the pressures will also vary greatly, although the normal is between a −2 to −6 mm. of mercury during ordinary respiration. With a strong inspiratory effort with the glottis closed, it may amount to −40 mm. of mercury, and in forced expiration under the same circumstances the entire negative pressure may be abolished and instead a positive pressure up to 50 mm. of mercury may be substituted. With these extremes in mind it will be seen that during inspiration the average negative pressure within the pleural space is about a −6 and during expiration it is about a −2.

The arrangement within the lungs is such that it roughly corresponds to the arrangement in the rest of the tissues of the body insofar as the interchange of fluids is concerned. As in other parts of the body, we have learned in Chapter 11 that the fluid portions of the blood are under two forces as described by Starling. In the lungs the same conditions prevail. The lungs are admirably suited for dryness because it must be obvious that should the alveoli contain fluid, oxygenation would be interfered with. Consequently, in ordinary respiration the lungs remain dry. This is possible because of a prodigious lymph supply which takes care of the protein that might leak from the capil-

(Continued on opposite page)

lieves it is the dyspnea with increased negative pressure of the thorax plus the anoxia which tends to draw fluid out of the capillaries.

The capillaries of the lungs are in a unique position. They get their oxygen from the air and not secondarily from the blood. Therefore, if oxygen is administered therapeutically, it must be given early and under positive pressure.

Lymph capillaries in the lung are constantly picking up protein, and the movement of lymph is greater in moving lungs than in the more quiescent. This is important postoperatively where patients should be urged to take deep breaths.

It is thought by Krogh and Landsberg that protein in pleuritic exudates is gradually broken down by enzymes produced in adjoining cells. The cleavage products are able to diffuse into the blood, and a direct reabsorption of the exudate is made possible.

Due to the negative pressure in the pleura, the lymphatics are usually unable to take up much protein fluid. The positive pressure in the abdomen moves fluid up the lymphatics through the diaphragm into the mediastinum, and, to some extent, into the pleural, lymphatics, and then into the right lymphatic and thoracic ducts.

Exchange of Gases

Atmospheric pressure is 760 mm. of mercury or 14.7 pounds to the square inch. Oxygen pressure in the lungs is 100 mm. of mercury. Ten millimeters of mercury pressure is lost in the capillaries, leaving 90 mm. of mercury in the arteries and a decline to about 30 mm. of mercury in the veins. Only about one-third of the oxygen is given up normally. Sixteen to 24 volumes per cent is the normal capacity in the arteries, a level rarely attained; 0.5 volumes per cent is normal for plasma; and 19 (females) to 20.5 (males) volumes per cent in the hemoglobin. In the veins it is 10 to 14 volumes per cent. The average adult uses about 200 to 250 c.c. of oxygen per minute while at rest.

Anoxic Anoxemia or Oxygen Want Due to High Altitudes

Gases expand in the atmosphere in inverse relation to the pressure. One liter of gas at 18,000 feet expands to 2 liters; at 33,700 feet, to 4 liters; and at 42,000 feet, to 6 liters. Since the volume of the chest remains the same, the expanded air contains small amounts of air constituents, and at 42,000 feet there is about one-sixth as much oxygen available as at sea level. Breathing 100 per cent oxygen would do no good because the oxygen molecules will be so diluted that a normal pressure of 100 mm. mercury cannot be maintained. The number of oxygen molecules in a given space become progressively less as the pressure is lowered. Water vapor pressure is constant, but carbon dioxide is lowered by increased breathing as altitude increases. The sum of the carbon dioxide pressure and water vapor pressure must be subtracted from the total to get the oxygen pressure. At a high altitude with a man breathing 100 per cent oxygen, the water vapor pressure may be about 47 and the carbon dioxide about 35 mm. of mercury, a total of 82 mm. of mercury. If the barometric pressure is 138 mm. of mercury, the pressure of oxygen in the lungs would be 56 mm. of mercury at 50,000 feet; alveolar partial pressure is zero.

Altitudes of 3,000 feet or less have no effect on respiration because barometric pressure remains at 760 mm. of mercury up to 5,000 feet, as will be noted from Table XVI.

According to Boyle's law, the volume of gas varies inversely with the pressure, provided the absolute temperature remains constant. This fact is important in entrapped air within the body at high altitudes; also in the anoxic anoxia resulting from low partial pressure within the lungs, as shown above, as well as in the lowered carbon dioxide content due to hyperpnea. The effects of centrifugal force in aviation have been discussed in Chapter 14—Shock, but should be mentioned here as a cause of stagnant anoxemia, "air bends" or "aeroembolism." Air is in the fluids of the body under

40 mm. of mercury and a diastolic pressure of about 10 mm. of mercury and a pulse pressure of 30 mm. of mercury which is higher than the mean pressure. This is the reverse of the systemic pressures. Pressure in the pulmonary veins varies from -3 mm. water in inspiration to +4 mm. of water during expiration. The tone of pulmonary arterioles is low so that a rise on the venous side is transmitted to the arterial side.

Blood pressure in the lungs remains constant even though peripheral pressure rises. However, a rise in aortic pressure is attended by a rise in pulmonary arterial pressure due to a greater amount of blood returned to the right ventricle through the coronary system and not due to back pressure from an inadequate emptying of the left ventricle. The lung has great adaptability and, according to Drinker, a young adult can increase his pulmonary ventilation from a resting volume of 6 liters to 125 liters during exercise. With this change, the cardiac output may rise from 5 liters per minute to 20 liters per minute. With each cardiac systole the lungs receive from the right ventricle as much blood as the left ventricle pumps to the whole body. The lungs possess a blood capacity in terms of instant cardiac output equal to that of the entire body.

The pulmonary circulation is probably not under vasomotor control. The lungs must receive and oxygenate all the blood brought to them. This is accomplished by adjusting the breathing and letting the increased blood flow passively through a capillary bed great enough to carry all the blood that can be sent to it even under the most extreme conditions of cardiac output.

Fluid escaping from the blood capillaries must first be interstitial and, therefore, would result in a thickening of the alveolar partitions which normally, in cross section, contain the blood capillaries and nothing else. If the alveolar wall is deficient, as Josslyn believes, then fluid would go directly into the alveoli. Even the lymphatics do not extend into the alveolar wall past the very beginning of the respiratory portion; that is, the atrium. Any foreign material in the alveolar wall is a barrier to the exchange of gas.

The arrangement in the lungs makes for dryness because the hydrostatic pressure in the capillaries is low, about 20 mm. of mercury. The osmotic is higher, about 25 to 30 mm. of mercury. The pressure in the alveoli is -2 to +3 or 4 and in the pleura -5 to -10 mm. of mercury, an effective outward pressure of about 20 mm. of mercury. The result is an effective osmotic pressure of 5 to 10 mm. of mercury. In addition, the lungs are profusely supplied with lymphatics and lymphoid tissues, both lymphocytes and nodes. By consulting the diagram, it will be apparent that although the hydrostatic pressure of the capillaries plus the negative pressure in the pleural cavity tend to force fluid out, yet the osmotic pressure is so great that the flow is always toward the capillaries.

It is difficult for lymphatics to pick up much in quiet respiration for they behave as a semipermeable membrane and are sensitive to the hydrostatic pressure surrounding them. Their osmotic pressure is very low and therefore perhaps most absorption takes place in expiration when the negative pressure within the pleura is decreased and the positive pressure within the lungs is increased. The same is true during coughing. The right lymphatic duct contains lymph from the heart and lungs on the right side—perhaps some from the lower portion of the left. This duct enters the subclavian vein above the lymph node. The greater part of the left lung supplies lymph to the thoracic duct. Severe respiratory movements, which increase negative pressure in the chest, will produce pleural and pulmonary transudates even if the oxygen is sufficient. If, in addition, there is an anoxia, capillaries will become leaky and edema will easily follow. The lymphatics of the lungs are large and ample and they return the transudates to the blood stream.

In total cardiac decompensation, fluid in the pleural sacs is due to increased pressure in the pulmonary vessels. Drinker believes that the right heart is capable of great dilatation, especially when this occurs gradually, and that leakage due to an increased hydrostatic pressure in the capillaries does not occur for a long time. He be-

lieves it is the dyspnea with increased negative pressure of the thorax plus the anoxia which tends to draw fluid out of the capillaries.

The capillaries of the lungs are in a unique position. They get their oxygen from the air and not secondarily from the blood. Therefore, if oxygen is administered therapeutically, it must be given early and under positive pressure.

Lymph capillaries in the lung are constantly picking up protein, and the movement of lymph is greater in moving lungs than in the more quiescent. This is important postoperatively where patients should be urged to take deep breaths.

It is thought by Krogh and Landsberg that protein in pleuritic exudates is gradually broken down by enzymes produced in adjoining cells. The cleavage products are able to diffuse into the blood, and a direct reabsorption of the exudate is made possible.

Due to the negative pressure in the pleura, the lymphatics are usually unable to take up much protein fluid. The positive pressure in the abdomen moves fluid up the lymphatics through the diaphragm into the mediastinum, and, to some extent, into the pleural, lymphatics, and then into the right lymphatic and thoracic ducts.

Exchange of Gases

Atmospheric pressure is 760 mm. of mercury or 14.7 pounds to the square inch. Oxygen pressure in the lungs is 100 mm. of mercury. Ten millimeters of mercury pressure is lost in the capillaries, leaving 90 mm. of mercury in the arteries and a decline to about 30 mm. of mercury in the veins. Only about one-third of the oxygen is given up normally. Sixteen to 24 volumes per cent is the normal capacity in the arteries, a level rarely attained; 0.5 volumes per cent is normal for plasma; and 19 (females) to 20.5 (males) volumes per cent in the hemoglobin. In the veins it is 10 to 14 volumes per cent. The average adult uses about 200 to 250 c.c. of oxygen per minute while at rest.

Anoxic Anoxemia or Oxygen Want Due to High Altitudes

Gases expand in the atmosphere in inverse relation to the pressure. One liter of gas at 18,000 feet expands to 2 liters; at 33,700 feet, to 4 liters; and at 42,000 feet, to 6 liters. Since the volume of the chest remains the same, the expanded air contains small amounts of air constituents, and at 42,000 feet there is about one-sixth as much oxygen available as at sea level. Breathing 100 per cent oxygen would do no good because the oxygen molecules will be so diluted that a normal pressure of 100 mm. mercury cannot be maintained. The number of oxygen molecules in a given space become progressively less as the pressure is lowered. Water vapor pressure is constant, but carbon dioxide is lowered by increased breathing as altitude increases. The sum of the carbon dioxide pressure and water vapor pressure must be subtracted from the total to get the oxygen pressure. At a high altitude with a man breathing 100 per cent oxygen, the water vapor pressure may be about 47 and the carbon dioxide about 35 mm. of mercury, a total of 82 mm. of mercury. If the barometric pressure is 138 mm. of mercury, the pressure of oxygen in the lungs would be 56 mm. of mercury at 50,000 feet; alveolar partial pressure is zero.

Altitudes of 3,000 feet or less have no effect on respiration because barometric pressure remains at 760 mm. of mercury up to 5,000 feet, as will be noted from Table XVI.

According to Boyle's law, the volume of gas varies inversely with the pressure, provided the absolute temperature remains constant. This fact is important in entrapped air within the body at high altitudes; also in the anoxic anoxia resulting from low partial pressure within the lungs, as shown above, as well as in the lowered carbon dioxide content due to hyperpnea. The effects of centrifugal force in aviation have been discussed in Chapter 14—Shock, but should be mentioned here as a cause of stagnant anoxemia, "air bends" or "aeroembolism." Air is in the fluids of the body under

40 mm. of mercury and a diastolic pressure of about 10 mm. of mercury and a pulse pressure of 30 mm. of mercury which is higher than the mean pressure. This is the reverse of the systemic pressures. Pressure in the pulmonary veins varies from -3 mm. water in inspiration to +4 mm. of water during expiration. The tone of pulmonary arterioles is low so that a rise on the venous side is transmitted to the arterial side.

Blood pressure in the lungs remains constant even though peripheral pressure rises. However, a rise in aortic pressure is attended by a rise in pulmonary arterial pressure due to a greater amount of blood returned to the right ventricle through the coronary system and not due to back pressure from an inadequate emptying of the left ventricle. The lung has great adaptability and, according to Drinker, a young adult can increase his pulmonary ventilation from a resting volume of 8 liters to 125 liters during exercise. With this change, the cardiac output may rise from 5 liters per minute to 20 liters per minute. With each cardiac systole the lungs receive from the right ventricle as much blood as the left ventricle pumps to the whole body. The lungs possess a blood capacity in terms of instant cardiac output equal to that of the entire body.

The pulmonary circulation is probably not under vasomotor control. The lungs must receive and oxygenate all the blood brought to them. This is accomplished by adjusting the breathing and letting the increased blood flow passively through a capillary bed great enough to carry all the blood that can be sent to it even under the most extreme conditions of cardiac output.

Fluid escaping from the blood capillaries must first be interstitial and, therefore, would result in a thickening of the alveolar partitions which normally, in cross section, contain the blood capillaries and nothing else. If the alveolar wall is deficient, as Josslyn believes, then fluid would go directly into the alveoli. Even the lymphatics do not extend into the alveolar wall past the very beginning of the respiratory portion; that is, the atrium. Any foreign material in the alveolar wall is a barrier to the exchange of gas.

The arrangement in the lungs makes for dryness because the hydrostatic pressure in the capillaries is low, about 20 mm. of mercury. The osmotic is higher, about 25 to 30 mm. of mercury. The pressure in the alveoli is -2 to +3 or 4 and in the pleura -5 to -10 mm. of mercury, an effective outward pressure of about 20 mm. of mercury. The result is an effective osmotic pressure of 5 to 10 mm. of mercury. In addition, the lungs are profusely supplied with lymphatics and lymphoid tissues, both lymphocytes and nodes. By consulting the diagram, it will be apparent that although the hydrostatic pressure of the capillaries plus the negative pressure in the pleural cavity tend to force fluid out, yet the osmotic pressure is so great that the flow is always toward the capillaries.

It is difficult for lymphatics to pick up much in quiet respiration for they behave as a semipermeable membrane and are sensitive to the hydrostatic pressure surrounding them. Their osmotic pressure is very low and therefore perhaps most absorption takes place in expiration when the negative pressure within the pleura is decreased and the positive pressure within the lungs is increased. The same is true during coughing. The right lymphatic duct contains lymph from the heart and lungs on the right side—perhaps some from the lower portion of the left. This duct enters the subclavian vein above the lymph node. The greater part of the left lung supplies lymph to the thoracic duct. Severe respiratory movements, which increase negative pressure in the chest, will produce pleural and pulmonary transudates even if the oxygen is sufficient. If, in addition, there is an anoxia, capillaries will become leaky and edema will easily follow. The lymphatics of the lungs are large and ample and they return the transudates to the blood stream.

In total cardiac decompensation, fluid in the pleural sacs is due to increased pressure in the pulmonary vessels. Drinker believes that the right heart is capable of great dilatation, especially when this occurs gradually, and that leakage due to an increased hydrostatic pressure in the capillaries does not occur for a long time. He be-

lieves it is the dyspnea with increased negative pressure of the thorax plus the anoxia which tends to draw fluid out of the capillaries.

The capillaries of the lungs are in a unique position. They get their oxygen from the air and not secondarily from the blood. Therefore, if oxygen is administered therapeutically, it must be given early and under positive pressure.

Lymph capillaries in the lung are constantly picking up protein, and the movement of lymph is greater in moving lungs than in the more quiescent. This is important postoperatively where patients should be urged to take deep breaths.

It is thought by Krogh and Landsberg that protein in pleuritic exudates is gradually broken down by enzymes produced in adjoining cells. The cleavage products are able to diffuse into the blood, and a direct reabsorption of the exudate is made possible.

Due to the negative pressure in the pleura, the lymphatics are usually unable to take up much protein fluid. The positive pressure in the abdomen moves fluid up the lymphatics through the diaphragm into the mediastinum, and, to some extent, into the pleural, lymphatics, and then into the right lymphatic and thoracic ducts.

Exchange of Gases

Atmospheric pressure is 760 mm. of mercury or 14.7 pounds to the square inch. Oxygen pressure in the lungs is 100 mm. of mercury. Ten millimeters of mercury pressure is lost in the capillaries, leaving 90 mm. of mercury in the arteries and a decline to about 30 mm. of mercury in the veins. Only about one-third of the oxygen is given up normally. Sixteen to 24 volumes per cent is the normal capacity in the arteries, a level rarely attained; 0.5 volumes per cent is normal for plasma; and 19 (females) to 20.5 (males) volumes per cent in the hemoglobin. In the veins it is 10 to 14 volumes per cent. The average adult uses about 200 to 250 c.c. of oxygen per minute while at rest.

Anoxic Anoxemia or Oxygen Want Due to High Altitudes

Gases expand in the atmosphere in inverse relation to the pressure. One liter of gas at 18,000 feet expands to 2 liters; at 33,700 feet, to 4 liters; and at 42,000 feet, to 6 liters. Since the volume of the chest remains the same, the expanded air contains small amounts of air constituents, and at 42,000 feet there is about one-sixth as much oxygen available as at sea level. Breathing 100 per cent oxygen would do no good because the oxygen molecules will be so diluted that a normal pressure of 100 mm. mercury cannot be maintained. The number of oxygen molecules in a given space become progressively less as the pressure is lowered. Water vapor pressure is constant, but carbon dioxide is lowered by increased breathing as altitude increases. The sum of the carbon dioxide pressure and water vapor pressure must be subtracted from the total to get the oxygen pressure. At a high altitude with a man breathing 100 per cent oxygen, the water vapor pressure may be about 47 and the carbon dioxide about 35 mm. of mercury, a total of 82 mm. of mercury. If the barometric pressure is 138 mm. of mercury, the pressure of oxygen in the lungs would be 56 mm. of mercury at 50,000 feet; alveolar partial pressure is zero.

Altitudes of 3,000 feet or less have no effect on respiration because barometric pressure remains at 760 mm. of mercury up to 5,000 feet, as will be noted from Table XVI.

According to Boyle's law, the volume of gas varies inversely with the pressure, provided the absolute temperature remains constant. This fact is important in entrapped air within the body at high altitudes; also in the anoxic anoxia resulting from low partial pressure within the lungs, as shown above, as well as in the lowered carbon dioxide content due to hyperpnea. The effects of centrifugal force in aviation have been discussed in Chapter 14—Shock, but should be mentioned here as a cause of stagnant anoxemia, "air bends" or "aeroembolism." Air is in the fluids of the body under

TABLE XVI

VOLUME OF GAS	ALTITUDE IN FEET	BAROMETRIC PRESSURE (MM. OF MERCURY)
1.0	0	760
1.2	5,000	630
1.5	10,000	520
1.9	15,000	430
2.4	20,000	350
3.0	25,000	280
4.0	30,000	230
5.4	35,000	180
7.6	40,000	140
8.8	42,000	130

atmospheric pressure. When atmospheric pressure is suddenly reduced, air will escape from body fluids like carbon dioxide from a carbonated beverage when the cap is removed. This has been termed *decompression emphysema* or "air embolism" and is a counterpart of the disease which is well known as caisson disease seen in men who work down in pressures greater than atmospheric and then suddenly rise to the surface. In either event there is a release of nitrogen from the blood to various tissues, producing pain (the bends), vertigo (the staggers), air hunger (the chokes), and cutaneous manifestations (the itch); in addition, there may be neurological manifestations and paralysis of the bladder and bowels. In each instance the predominating symptom is due to the presence of air emboli which may vary in their location from time to time. Prevention is directed toward gradual ascent, and in aviation breathing oxygen for 2 hours prior to ascent. This results in gradual elimination of nitrogen and the oxygen is used by the tissues and is not released as air bubbles, whereas the nitrogen is present in the tissues at a pressure of about 515 mm. of mercury. Treatment is based on the use of 100 per cent oxygen and recompression in special chambers for caisson disease.

Acapnia or reduced carbon dioxide pressure in lungs occurs because of hyperpnea. This may give rise to tetany as described in Chapter 22. The expanded carbon dioxide also prevents oxygen from getting in. Carbon dioxide is the respiratory stimulant. Lack or decreased oxygen makes the respiratory center sensitive. We may need oxygen and not know it unless carbon dioxide accumulates. Hyperventilation produces apnea as a rule, allowing carbon dioxide to reaccumulate. Should low carbon dioxide pressures persist, tetany may ensue. Aviators speak of being "frozen to the stick," and swimmers have muscle cramps and tetany from low carbon dioxide.

Effect of acceleration. The effects of a sudden change in motion may, if fast enough, produce a centrifugal force which may be harmful. In aviation medicine, acceleration acting from head to seat is called positive acceleration, causing a fall in carotid pressure with stagnant anoxemia, whereas seat to head is known as negative acceleration, causing increased intracranial pressure with respiratory failure.

The transfer of oxygen and carbon dioxide is accomplished by *diffusion;* that is, gas molecules will pass from a place at which the pressure (tension) is higher to one at which it is lower. The volume of each of the respiratory gases carried in chemical combination in the blood varies directly with the tension of the same gas in the plasma and inversely with the tension of the other gas. The oxygen tension of venous blood is 40 mm. and the CO_2 tension is 46 mm. In the lungs this blood is exposed to an oxygen tension of 100 mm. (due to the enormous exposed surface of the alveoli) and a CO_2 tension of 40 mm. Oxygen will diffuse into the plasma and CO_2 out. The oxygen is taken up by the hemoglobin, which is changed from the reduced to the oxygenated form (oxyhemoglobin). In the tissues the tension of oxygen is low (about 35 mm.), whereas that of CO_2 is high (about 46 mm.). Therefore, oxygen leaves the plasma and enters the tissues, while CO_2 diffuses from the tissues into the plasma.

The manner in which oxygen and carbon dioxide is exchanged is sho in Fig. 101.

From this discussion it is apparent that the use of oxygen for thera must be given under pressure since it is the 0.5 volume per cent in t must be increased if it is to reach the cell.

Since the respiration is by diffusion of gases, it would seem that of the absence of a definite alveolar wall makes the explanation of tl more understandable. If, in addition, we may accept the idea that respiratory bronchioles distend with each inspiration, then it is easy how the tuft of capillaries in the alveoli are all the more able to abs fluid. If the alveoli distend, these capillaries are stretched, their lu and the number of erythrocytes going through decreased. Also, the of capillary is reduced. If, however, the capillary loops remain in th and are exposed to a greater volume of air with each inspiration, abso enhanced.

The average total air capacity of the adult male is about 5 to 6 about 1,500 c.c. is *residual* air and cannot be displaced even in ext leaving a *vital capacity* of 4 to 4½ liters. About 500 c.c. is *tidal* ai breathed in during ordinary quiet respiration. If, now at the end inspiration, extra effort to inspire air is exerted, an additional 2 to 2 taken in—this is *complemental air;* and if at the end of quiet expiratio forces more air out, an added 2 to 2½ liters may be exhaled—this *mental air.* Total lung or air capacity is vital capacity plus residual total volume of air which the lung can hold after maximal insp liters. Minute volume is the total volume of air breathed per minute; of tidal multiplied by the number of respirations per minute. Functi is the supplemental plus the residual air—3½ to 4 liters.

Tests of pulmonary function are designed to reveal the amount taken in with each respiration or a given period of time, and what important, the absorption of oxygen and release of carbon dioxide. W *vital capacity* is the amount of air which can be displaced by the lu inspiration and forced expiration; that is, the sum of complemental, t air—about 4 to 4½ liters. This can be measured by the *spirometer.* the sum of both lungs, it may be advantageous to know how much the diseased lung contribute to the vital capacity. This may be determi tube inserted under fluoroscopic guidance into the left main bronc *spirometer. Exercise response and maximum breathing capacity* a The former shows dyspnea which may be extreme on exercise in spite capacity (emphysema). The latter depends on a series of respirati time. Some studies made with the bronchospirometer indicate the ranges:

Oxygen intake/min. (c.c.)	200-400 (Right lung, 5
Minute volume respirations	5-8 liters
Ventilation equivalent for oxygen	2.5 to 3.5 liters
Tidal air	300 to 700 c.c.
Maximum breathing capacity	100 to 150 liters per m
$\frac{\textit{Maximum breathing capacity}}{\text{Minute volume}}$	12-20

Asphyxia and Anoxemia

Asphyxia (from the Greek, *without pulse,* which is a cause the rapid weak pulse is one of the earliest signs of as that the lungs are prevented from oxygenating the blood.

Treatment is based on the use of 100 per cent oxygen and recompression in special chambers for caisson disease.

Acapnia or reduced carbon dioxide pressure in lungs occurs because of hyperpnea. This may give rise to tetany as described in Chapter 22. The expanded carbon dioxide also prevents oxygen from getting in. Carbon dioxide is the respiratory stimulant. Lack or decreased oxygen makes the respiratory center sensitive. We may need oxygen and not know it unless carbon dioxide accumulates. Hyperventilation produces apnea as a rule, allowing carbon dioxide to reaccumulate. Should low carbon dioxide pressures persist, tetany may ensue. Aviators speak of being "frozen to the stick," and swimmers have muscle cramps and tetany from low carbon dioxide.

Effect of acceleration. The effects of a sudden change in motion may, if fast enough, produce a centrifugal force which may be harmful. In aviation medicine, acceleration acting from head to seat is called *positive acceleration*, causing a fall in carotid pressure with stagnant anoxemia, whereas seat to head is known as *negative acceleration*, causing increased intracranial pressure with respiratory failure.

The transfer of oxygen and carbon dioxide is accomplished by *diffusion*; that is, gas molecules will pass from a place at which the pressure (tension) is higher to one at which it is lower. The volume of each of the respiratory gases carried in chemical combination in the blood varies directly with the tension of the same gas in the plasma and inversely with the tension of the other gas. The oxygen tension of venous blood is 40 mm. and the CO_2 tension is 46 mm. In the lungs this blood is exposed to an oxygen tension of 100 mm. (due to the enormous exposed surface of the alveoli) and a CO_2 tension of 40 mm. Oxygen will diffuse into the plasma and CO_2 out. The oxygen is taken up by the hemoglobin, which is changed from the reduced to the oxygenated form (oxyhemoglobin). In the tissues the tension of oxygen is low (about 35 mm.), whereas that of CO_2 is high (about 46 mm.). Therefore, oxygen leaves the plasma and enters the tissues, while CO_2 diffuses from the tissues into the plasma.

The manner in which oxygen and carbon dioxide is exchanged is shown graphically in Fig. 101.

From this discussion it is apparent that the use of oxygen for therapeutic purposes must be given under pressure since it is the 0.5 volume per cent in the plasma that must be increased if it is to reach the cell.

Since the respiration is by diffusion of gases, it would seem that Josselyn's idea of the absence of a definite alveolar wall makes the explanation of this phenomenon more understandable. If, in addition, we may accept the idea that the atria and respiratory bronchioles distend with each inspiration, then it is easy to understand how the tuft of capillaries in the alveoli are all the more able to absorb oxygen and fluid. If the alveoli distend, these capillaries are stretched, their lumens narrowed, and the number of erythrocytes going through decreased. Also, the exposed surface of capillary is reduced. If, however, the capillary loops remain in their normal state and are exposed to a greater volume of air with each inspiration, absorption is greatly enhanced.

The average total air capacity of the adult male is about 5 to 6 liters. Of this, about 1,500 c.c. is *residual* air and cannot be displaced even in extreme expiration, leaving a *vital capacity* of 4 to 4½ liters. About 500 c.c. is *tidal air* or the amount breathed in during ordinary quiet respiration. If, now at the end of an ordinary inspiration, extra effort to inspire air is exerted, an additional 2 to 2½ liters may be taken in—this is *complemental air;* and if at the end of quiet expiration the individual forces more air out, an added 2 to 2½ liters may be exhaled—this is called *supplemental air.* Total lung or air capacity is vital capacity plus residual air; that is, the total volume of air which the lung can hold after maximal inspiration—5 to 6 liters. Minute volume is the total volume of air breathed per minute; that is, volume of tidal multiplied by the number of respirations per minute. Functional residual air is the supplemental plus the residual air—3½ to 4 liters.

Tests of pulmonary function are designed to reveal the amount of air actually taken in with each respiration or a given period of time, and what is perhaps more important, the absorption of oxygen and release of carbon dioxide. We have seen that *vital capacity* is the amount of air which can be displaced by the lungs during deep inspiration and forced expiration; that is, the sum of complemental, tidal, and reserve air—about 4 to 4½ liters. This can be measured by the *spirometer.* Since this gives the sum of both lungs, it may be advantageous to know how much the normal and the diseased lung contribute to the vital capacity. This may be determined by a special tube inserted under fluoroscopic guidance into the left main bronchus—a *bronchospirometer. Exercise response and maximum breathing capacity* are helpful tests. The former shows dyspnea which may be extreme on exercise in spite of a good vital capacity (emphysema). The latter depends on a series of respirations per unit of time. Some studies made with the bronchospirometer indicate the following normal ranges:

Oxygen intake/min. (c.c.)	200-400 (Right lung, 54%; left, 46%)
Minute volume respirations	5-8 liters
Ventilation equivalent for oxygen	2.5 to 3.5 liters
Tidal air	300 to 700 c.c.
Maximum breathing capacity	100 to 150 liters per minute
Maximum breathing capacity / Minute volume	12-20

Asphyxia and Anoxemia

Asphyxia (from the Greek, *without pulse,* which is appropriate because the rapid weak pulse is one of the earliest signs of asphyxia) means that the lungs are prevented from oxygenating the blood. Smothering,

TABLE XVI

Treatment is based on the use of 100 per cent oxygen and recompression in special chambers for caisson disease.

Acapnia or reduced carbon dioxide pressure in lungs occurs because of hyperpnea. This may give rise to tetany as described in Chapter 22. The expanded carbon dioxide also prevents oxygen from getting in. Carbon dioxide is the respiratory stimulant. Lack or decreased oxygen makes the respiratory center sensitive. We may need oxygen and not know it unless carbon dioxide accumulates. Hyperventilation produces apnea as a rule, allowing carbon dioxide to reaccumulate. Should low carbon dioxide pressures persist, tetany may ensue. Aviators speak of being "frozen to the stick," and swimmers have muscle cramps and tetany from low carbon dioxide.

Effect of acceleration. The effects of a sudden change in motion may, if fast enough, produce a centrifugal force which may be harmful. In aviation medicine, acceleration acting from head to seat is called positive acceleration, causing a fall in carotid pressure with stagnant anoxemia, whereas seat to head is known as negative acceleration, causing increased intracranial pressure with respiratory failure.

The transfer of oxygen and carbon dioxide is accomplished by *diffusion;* that is, gas molecules will pass from a place at which the pressure (tension) is higher to one at which it is lower. The volume of each of the respiratory gases carried in chemical combination in the blood varies directly with the tension of the same gas in the plasma and inversely with the tension of the other gas. The oxygen tension of venous blood is 40 mm. and the CO_2 tension is 46 mm. In the lungs this blood is exposed to an oxygen tension of 100 mm. (due to the enormous exposed surface of the alveoli) and a CO_2 tension of 40 mm. Oxygen will diffuse into the plasma and CO_2 out. The oxygen is taken up by the hemoglobin, which is changed from the reduced to the oxygenated form (oxyhemoglobin). In the tissues the tension of oxygen is low (about 35 mm.), whereas that of CO_2 is high (about 46 mm.). Therefore, oxygen leaves the plasma and enters the tissues, while CO_2 diffuses from the tissues into the plasma.

cells. Acute cardiac decompensation leads to an anoxic anoxemia due to pulmonary edema and stagnant anoxemia from pooling of much of the blood volume in the veins.

Special Types.—

1. *Aviation or high altitude anoxic anoxemia* is due to the low barometric pressure. This has been discussed previously in this chapter.

2. *Anesthetic anoxemias.* Modern anesthesia begins with sedatives or narcotics administered in the room. These are all respiratory depressants, acting on the center and decreasing the minute volume exchange.

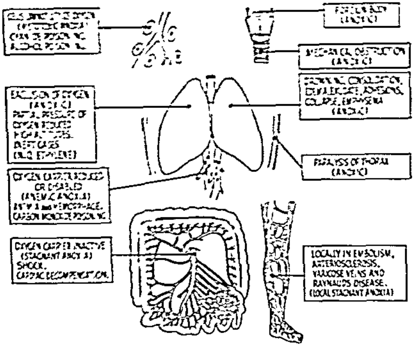

Fig. 212.—Diagram indicating some of the causes of anoxia. The splanchnic area is chosen as an example of stagnant anoxia because of its enormous capillary bed and the frequency of blood pooling in this region.

The great danger of anesthesia in surgery is anoxia. The advantage of one or another type of anesthetic depends a great deal on the ability of the individual anesthetist. Deaths from anesthetics are practically always due to anoxemia. Anoxia must be avoided and is particularly dangerous when it occurs in a patient in the Trendelenburg position (where there is stasis of blood plus a decrease in vital and total capacity of the lungs, thereby leading to stagnant and anoxic anoxemia), or in a patient with paralysis of muscles of respiration or the respiratory center from intracranial lesions or sedatives. There must be no obstruction to breathing. Common causes are: foreign bodies, gum, false teeth, meat, candy, sponges, mucus, vomitus, blood, pus; relaxation of the jaw muscles, permitting the tongue to fall back against the posterior wall of the pharynx; laryngospasm due to local irritation or reflex stimulation; tumors or edema pressing on the respiratory passages; external pressures on

stifling, and *suffocation* mean practically the same thing. *Apnea* means cessation of breathing. *Hyperpnea* is panting or rapid breathing. We use the term *asphyxia* as synonymous with *anoxia* (lack of oxygen) or a deficient supply of oxygen to the tissue cells and *anoxemia* (lack of oxygen in the blood); strictly speaking, the term is a misnomer because a complete lack of oxygen would mean death. A better term would be *hypoxemia* or deficient oxygen in the blood. *Any condition which prevents the tissues from receiving oxygen equal to their needs is spoken of as oxygen want,* oxygen lack, hypoxia, or asphyxia. The body must have oxygen to *live.* If this is absent, or deficient in amount, for even a relatively short time, irreparable damage may occur, due to degenerative changes in the brain, heart, blood vessels, lungs, and intestines.

Causes of Anoxia.—Peters and Van Slyke classify the causes of anoxia as follows:

1. *Anoxic anoxia* (anoxemia) is the reduction in tension of oxygen in the arterial blood and may be caused by:

a. An interference with the passage of oxygen from the air into the blood in the lungs, due to mechanical obstruction, a foreign body in the larynx, drowning, weak respiratory movements, edema, exudates, consolidation, adhesions, collapse, or emphysema.

b. Reduction of partial pressure of oxygen in the inspired air due to inhalation of inert gases, such as nitrogen, hydrogen, nitrous oxide, ethylene, etc.; inhalation of air under reduced (barometric) pressure, as at high altitudes.

c. Inability to use the thorax, as in poliomyelitis.

2. *Anemic anoxia* is the reduction of the oxygen that can be furnished the tissues by the blood. This results when the amount of hemoglobin is decreased, as in anemia or hemorrhage, or when the ability of the hemoglobin to yield oxygen is decreased, as in carbon monoxide poisoning.

3. *Stagnant anoxia* is due to interference with the circulation. The amount of oxygen in the blood is sufficient, but it does not circulate fast enough to supply the tissues, as in shock, hemorrhage, cardiac weakness, or abnormally high venous pressure, as in cardiac decompensation. It may be local, due to a circulatory disturbance, as in spasm of arteries, Raynaud's disease, embolism, arteriosclerosis, varicose veins, etc.

4. *Histotoxic anoxia* is caused by the inability of the cells to utilize the oxygen, even if present. This is seen in cyanide poisoning, alcohol poisoning, and after narcotics.

This classification is basic and inclusive. However, in surgical practice we encounter many *combined* types of anoxemia and some special types whose causes should be considered.

Combined Types.—By this is meant forms of anoxemia due to more than one cause, acting simultaneously. For example, in peritonitis, anoxemia may be classified as stagnant due to pooling of blood in the splanchnic bed, anoxic due to distention and therefore interference with breathing, and anemic due to the effects of the infection on the red blood

anoxemia. This has been known to physiologists for years. The principal effect of asphyxia is on the cell wall which becomes more permeable, disturbing osmotic equilibrium and the interchange of colloids and crystalloids. Different cells are more or less resistant, but the ultimate effect, whether it is in the nerve or endothelial or heart muscle cell, is an effect on the cell wall. Therefore, the similar effects of burn shock, histamine shock, epinephrine, poisoning by nicotine, digitalis, glucosides, parathyroid, carbon disulfide, carbon monoxide, cyanide, nitrites, mercury, lead, and pitressin, to mention only a few, must be interpreted as due to anoxemia—because the same effects, degeneration, necrosis and fibrosis of the myocardium, necrosis and cyst formation in the media of the ascending aorta, as well as changes in the brain, testes, and bone marrow have been observed in all of the above cases.

Recently experiments on aortic anastomosis have reaffirmed the sensitivity of nerve cells to anoxemia (Chapter 17). Reflexes may be abolished in a few seconds and coma may occur in six to eight seconds. Actual permanent damage follows within eight to ten minutes or less. Brain centers survive from twenty to thirty minutes and spinal centers forty to sixty minutes, although we have observed hind leg paralysis in dogs after 18 minutes. These effects are due to an increase in intercellular and intracellular fluid or both. A rise in carbon dioxide tension causes engorgement of the cerebral vascular tree. Blood vessels dilate when carbon dioxide is increased or oxygen reduced. Some observers believe that the so-called "second" wind of the runner is due to a more rapid flow of blood through the respiratory center, relieving the acid condition of the nerve cells. The brain actually increases in size in anoxemia.

The heart is next most sensitive to oxygen lack. At first there is a slowing of the heart rate. However, an increase in pulse rate is one of the earliest signs. This is due to the fact that heart muscle needs about five times as much oxygen as skeletal muscle, which may be deprived for an hour and a half and survive. *Chronic pulmonary disease* is the principal cause of *cor pulmonale*. It is seen in chronic obstructive emphysema, chronic pulmonary fibrosis, silicosis, bronchiectasis, tuberculosis, bronchial asthma, kyphoscoliosis, or primary sclerosis of the pulmonary artery (Ayerza's disease).

Blood vessels are also very sensitive to anoxemia. Capillaries dilate and become permeable. Capillary stasis resulting from oxygen deficiency is irreversible after about fifteen minutes (Krogh).

The lungs show the effects of anoxemia by an increased rate and amplitude of respiration. This hyperpnea reduces alveolar and arterial carbon dioxide tension and results in an increased affinity for oxygen. At the same time there is a rise in blood pressure and pulse rate. Soon there is apnea with cyanosis and if anoxemia continues, death ensues.

Nausea, vomiting, diarrhea, and distention result from the anoxic effects on the gastrointestinal tract. The liver is very resistant to anox-

the neck or chest, especially in infants. Such simple measures as holding the chin up, introducing rubber airway tubes, endotracheal anesthesia, removing bronchial mucus plugs by aspiration or bronchoscopy, limiting excessive bronchial secretions by the use of atropine, slow induction, with ample oxygen, are all designed to avoid states of anoxia. *Perhaps the best anesthetic, especially for the novice, is ether.* If there are any signs or symptoms of anoxemia, the anesthetic should be stopped long enough to determine the cause (therefore the desirability of inhalation anesthetics), and, if necessary, the operation should be interrupted as quickly as possible. Usually acarbia is the cause and this is controlled by the administration of carbon dioxide and oxygen. However, in long thoracic operations the removal of carbon dioxide from the lung is perhaps as important as the administration of oxygen.

Because of the effects of anoxia, "gas" anesthetics are under careful scrutiny at present. Nitrous oxide produces anesthesia really by a continual series of anoxic anoxias alternated with resuscitations by oxygen, although it is said to have some anesthetic properties; therefore, brain complications may occur, especially in the aged and debilitated, where it was formerly thought to be indicated. If anoxemia is present, nitrous oxide would increase it by further reducing the oxygen in the hemoglobin. If there has been a severe hemorrhage, the gas is a poor anesthetic because there is an insufficient amount of red blood cells to transport the gas. More important, if the hemoglobin is below 5 Gm., anoxemia may be present without cyanosis. Ethylene and cyclopropane are also under close observation on the same ground and also because of the liver damage which has been observed to follow cyclopropane. These agents may be given with 90 and 75 per cent oxygen, respectively, a necessary adjunct because gas anesthetics are absorbed so fast from the lungs that there would be no room in the red blood corpuscles to carry oxygen. Cyclopropane with curare is a good combination, permitting relaxation otherwise not obtainable with these agents.

Spinal anesthesia is condemned by many because of its effect on the blood pressure, the capillaries, and the nerve cells. Ephedrine is an excellent drug for the shock that may occur (see Chapter 14). Anoxemia may occur from shock or paralysis of the intercostal muscles if the anesthetic gets up to the fourth, fifth, or sixth cervical segment.

3. *Postoperative.* Anoxemia following operations is usually due to combinations of causes. In general surgery it may be anoxic due to obstruction of air passages, tight binders, anemic due to internal hemorrhage, stagnant due to loss of plasma or dehydration, or combinations. Following chest surgery, it is usually anoxic due to tension pneumothorax, exudate, or transudates but also to obstructions in the tracheobronchial tree.

Effects of Anoxemia.—Man cannot exist without oxygen. In Chapter 13 we define the loss of blood and deprivations of oxygen as the two real emergencies. Not all tissues in the body are equally vulnerable to

pressure begins to fall and the pulse rate increases with variations in the volume of individual beats (Brace syndrome), due to failure of the heart as a result of anoxemia.

The failing heart cannot force blood through the inactive lungs, and there results venous stasis, with prominence of the veins in the neck and nosebleed. There is usually deep cyanosis. Cyanosis is a bluish discoloration of the skin due to the presence of excessive amounts of reduced hemoglobin in the blood of the superficial capillaries (the subpapillary venous plexus). Since oxygen is constantly lost as the blood passes through the capillaries, the oxygen level of the blood will be lowest in the veins. The normal 15 Gm. of hemoglobin per 100 c.c. of blood can take up 20 volumes per cent of oxygen. When hemoglobin gives off oxygen it becomes *reduced hemoglobin* (blue pigment), and since 5 Gm. of hemoglobin absorbs 6.7 c.c. of oxygen, we may say that 5 Gm. of reduced hemoglobin are formed when 100 c.c. of blood give up 6.7 c.c. of oxygen. After 5 Gm. of reduced hemoglobin are formed, cyanosis appears. Therefore, cyanosis is evident when the blood in the capillaries has lost 6.7 volumes per cent of oxygen, that is, when the hemoglobin is 6.7 per cent unsaturated.

Abnormal toxic compounds of hemoglobin may produce cyanosis (methemoglobin and sulfhemoglobin, also the sulfonamides).

Cyanosis may result from anoxia (of the anoxic or stagnant type). It cannot occur in severe anemia with an extremely low hemoglobin concentration (5 Gm. or less).

Blood pressure fails due to cardiac inadequacy and pooling of the blood in the great capillaries and veins, causing shock. In milder types of anoxia there may be great muscular weakness and various mental symptoms, also headache, nausea and lassitude. Later there are vomiting, diarrhea, and mental confusion resembling alcoholic intoxication. If the anoxia is long continued, there will be convulsions and death.

Treatment of Anoxia.—*First of all, the cause of the anoxia must be relieved; then the patient must be forced to breathe by artificial respiration with an ample supply of oxygen.*

Anoxic Anoxia.—Foreign bodies must be removed from the air passages. Sometimes this can be done with the fingers. In a child, one can often dislodge a foreign body by turning the patient upside down. Artificial respiration is useless unless the foreign body is first removed, and if simple measures fail, special apparatus (such as the laryngoscope or bronchoscope) should be employed. However, these may not be available. In this case, tracheotomy should be done. An opening is made in the trachea below the site of obstruction. Artificial respiration may then be instituted. It must be started at once; four to five minutes' delay may be too late. This course of treatment will undoubtedly save lives. If the patient is in an airtight or gas-filled room, he must be moved to the open air. If in water, his lungs must be emptied. Drowning is a common cause of asphyxia. Artificial respiration should be continued for at least an hour. Failure to detect the pulse does not mean that the heart has

emia. The hypoglycemia after some anesthetic agents is said to be due to a cessation of liver function due to anoxemia. Restoration is brought about by inhibition of adrenal cortical secretion and increased production of adrenaline.

Other effects are reduced renal function, acidosis due to lack of bicarbonate shift, which in turn is due to permeability of red cell walls to anions as well as cations; and decreased function of adrenal cortex with disturbances in potassium sodium ratio and which in turn affects water balance, interstitial fluid, and blood sugar level.

Bone marrow effects vary with the degree of anoxemia which is a stimulant to erythrocytosis when mild. Severe degrees of anoxia, however, produce atrophic changes in the marrow resulting in anemia.

Compensatory changes take place in anoxemia as in other bodily injuries, and as in other general traumas (dehydration, acidosis, hemorrhage, shock) the compensatory mechanisms are manifested in a greater or lesser degree, depending upon the time limit. In high altitudes, for example, there is a compensatory polycythemia and erythremia which is first due to a contraction of the spleen, later to anoxic stimulation of the bone marrow. At first there is also a decrease in blood volume and an increased blood flow through the heart. Thus, more red cells pass through the lungs for oxygenation per minute. Yet there has been no actual great increase in the number of cells except those thrown out by the spleen. By the fifth day in high altitude there is an actual increase in red cells and the cardiac output decreases concomitantly with the actual increase in hemoglobin and erythrocytes. Other compensatory mechanisms are: hyperpnea with increased elimination of carbon dioxide, increased amount of glucose in the blood, increase in blood supply to those organs most sensitive to oxygen want.

Symptoms and Signs of Anoxia.—The symptoms and signs of anoxia depend on the type but, in general, are much the same. Symptoms of anoxemia usually begin when the alveolar partial pressure falls to 60 mm. of mercury—the normal being about 100 to 110 mm. of mercury. However, in pathological states where there is a great demand for oxygen, such as hyperthyroidism, infections with high fever, etc., or where it cannot be quickly transported, requirements may be higher and alveolar pressure and oxygen concentration must be kept to high levels in the blood to avoid symptoms and signs of anoxia. In the obstructive type the patient makes futile attempts to breathe, using all accessory muscles of respiration. He becomes alarmed quickly and very early manifests mental disturbances such as extreme restlessness, irritability, exhilaration, delirium, delusions, or he may become maniacal. In other types, breathing is at first stimulated and there is an increase in rate and amplitude and then becomes slower, gasping, and finally ceases. In most types there is at first a slight decrease in pulse rate, with a rise in systolic pressure (stimulation of the cardioinhibitory and vasomotor centers). Soon the

7. Direct mouth-to-mouth breathing, using a handkerchief or piece of gauze, will deliver about 16 per cent oxygen—a method quoted in the Bible and useful in dire emergencies, especially in the newborn.

8. The Sylvester supine position.

Anemic Anoxia.—Anemic anoxia requires blood transfusion. A sufficient amount of blood must be given to transport the oxygen. A common observation is to see a postoperative patient in an oxygen tent, dying of anoxia. There is no cyanosis, but all other symptoms are present. Obviously, hemoglobin, not oxygen is needed.

Stagnant anoxemia means a "standstill" of the blood. Here attention to the heart and plasma to relieve hemoconcentration is the treatment of choice.

Histotoxic varieties of anoxemia may be helped by chemical antidotes, plus oxygen and artificial respiration.

The Use of Oxygen Therapy.—The supply of oxygen controls the sensitivity of the respiratory center. Slight deficiency increases its sensitivity, extreme deficiency diminishes it. However, oxygen deficiency is not the respiratory *stimulus*—this is carbon dioxide, acting through the pH of the blood. The use of carbon dioxide by inhalation in asphyxia is logical because it restores the normal amount of blood bicarbonate and increases breathing. Severe anoxemias will require more carbon dioxide; those less severe require less, because the center is more sensitive. Oxygen therapy in all types of anoxia is an adjunct after the primary cause has been eliminated. It is also indicated in many other states not associated with anoxia, such as coronary occlusion, fevers, migraine, polycythemia, hyperthyroidism; also to eliminate nitrogen from the body, to prevent decompression, sickness or to combat intestinal obstruction.

Oxygen may be administered by the *oxygen tent* or *chamber.* We have a chamber in the Riley hospital with two rooms. It is very efficient but is expensive and requires careful supervision. The tent is equally effective and will deliver up to 60 per cent oxygen. In both types air must be circulated by a fan or the patient will be uncomfortable; also the atmosphere must be cooled. It is difficult to regulate the temperature accurately. The *oronasal* catheter will deliver anywhere from 40 to 70 per cent oxygen, with a flow of 5 to 8 liters per minute. It has the disadvantage of being unreliable and of causing extreme dryness of the upper respiratory passage as well as irritation. The Boothby-Lovelace-Bulbulian (B.L.B.) mask is very efficient and will deliver up to 100 per cent oxygen.

The use of 100 per cent oxygen by inhalation is useful in intestinal obstruction along with decompression; also, at the time of operation, it may quickly restore the normal color of the bowel. Following surgery, oxygen inhalation should not be used as a last resort and for serious complications only. It is useful to minimize postoperative distention

stopped beating, for sometimes its beat is so feeble that it can scarcely be heard with the stethoscope; therefore, the necessity for perseverance.

Where temporary paralysis of the respiratory or cardiac centers occurs, as in electrocution, artificial respiration is urgently needed. If the muscles of respiration are crippled, as in higher anterior poliomyelitis, prolonged artificial respiration is necessary. Here the "iron lung" (the Drinker respirator) must be used. In laryngeal diphtheria an intubation tube, such as the O'Dwyer tube, may be used until such a time as the patient can breathe or tracheotomy should be performed.

The most commonly employed method of artificial respiration is Schafer's method. The patient lies in a prone position, with face to one side. A blanket or coat is placed underneath the abdomen. The tongue is pulled out and, if the patient is unconscious, the jaw will collapse and the tongue will stay out. The operator straddles the patient, with his knees on either side of the patient's knees, and presses with both hands firmly upon the back, over the lower ribs, forcing air and water out of the lungs; then he raises his body slowly and at the same time relaxes the pressure with his hands, allowing the chest wall to relax, thereby creating a negative pressure and causing air to be inspired. This forward and backward movement should be done about every four seconds, or fifteen to sixteen times a minute. Experiments with radioactive sodium show that artificial respiration moves the blood through the vascular system. It has been suggested the heparin be used so that blood will not clot in asphyxia, because as long as blood is moved and artificial respiration is continued, oxygenation may occur.

Other types of artificial respiration are:

1. Manual pressure on a 5-liter rubber bag may be used postoperatively or during surgery with an endotracheal tube. In this way the patient is made to breathe regularly with an adequate supply of oxygen. Too much pressure should not be used because of the danger of atelectasis, congestion, hemorrhagic infiltration, and bronchial spasm—the pressure exerted should not exceed 35 to 40 mm. of mercury, which gives about 29 to 36 mm. of mercury in the bronchiolar system. This may also be accomplished by the automatic machine devised by Craaford and also by Mautz.

2. A two-phase (positive-negative pressure) resuscitator.

3. The Kreeselman bellows.

4. The Neff-Ling apparatus.

5. Drinker respirator.

6. The Eve rocker method—particularly useful in drowning—where Eve believes the helpless diaphragm may be raised and lowered by tilting—10 rocks per minute with a tilt of 50 degrees to ventilate 600 c.c. per rock (normal is 500 c.c.). In favor of this idea is the fact that the lungs of drowned persons often float in autopsy. Much of the water is in the stomach.

significance, although the latter may interfere with function. Rarely the sternum is absent, sometimes it is bifid. *Funnel chest* is the opposite of pigeon breast and instead of a protruding deformity there is a funnel-shaped depression of the anterior chest wall. Other names for this condition are *pectus excavatum, trichterbrust,* and chonechondrosternon. The effect of the deformity on the thoracic viscera is that of compression. The cause of the condition is unknown but is thought in part to be due to obstruction to breathing necessitating an increased amount of pull by the diaphragm, thereby increasing negative pressure and it may also be caused by actual shortening of the diaphragm. Treatment is indicated when symptoms are present. However, if the deformity is pronounced and progressive, surgery is indicated. Early, this consists of resection of the lowest costal cartilages (fused sixth and seventh), division of the xyphoid from the gladiolus, severance of the substernal ligament, and severance of the diaphragmatic attachments from the resected portion of the costal cartilages. This allows the sternum to spring up to its normal position. Late, after the deformity has been present to adult age, the costal cartilages are resected and a wedged transverse osteotomy of the sternum at the level of the second costal cartilage is then performed. The sternum is elevated and then the costal cartilages resutured.

Hernia of the lung (a protrusion of the lung through the endo thoracic fascia together with the pleura) may be congenital or acquired as a result of trauma. The protrusion may not be covered by pleura (evisceration or false hernia). Congenital types may occur in the apices due to funnel chest or anywhere from thoracic defect. One lung may herniate into the other chest due to absence of part of the mediastinum (internal hernia). Rarely, in twins the two chests are connected (thoracopagus) with or without lung hernia.

Treatment consists of correcting the primary deformity as in funnel breast. In congenital absence of part of the chest wall, subperiosteal resection of the ribs may be done and these set at angles in criss-cross fashion to correct the defect.

Injuries of the Chest Wall (Nonpenetrating)

Injuries to the chest wall are common. The danger, as in head injuries, is that of injury to the vital organs within. Contusions and lacerations are dealt with by the same methods as are used for other parts of the body. However, should a laceration penetrate the pleura or lung, the wound should be cautiously cleaned and closed tightly at once in order to preserve the intrathoracic pressure and prevent mediastinal shifting. *Fractures* of the ribs are extremely common; they are sometimes produced by blunt force and often by muscular action, as by sneezing or coughing. If the lung is punctured, it will collapse and give definite symptoms and signs (q.v.). The x-ray will demonstrate fractures but

and postoperative headache. In shock it helps overcome the stagnant anoxia. Pulmonary complications, such as postoperative pneumonia, atelectasis, pulmonary edema, and pulmonary embolism, are greatly helped by the administration of oxygen. Lastly, the inhalation of oxygen is useful in anaerobic infections such as tetanus and gas gangrene.

Oxygen therapy may be dangerous if improperly used. One hundred per cent oxygen given to normal persons at 1 atmosphere for five to six hours may cause pulmonary congestion and edema, a reduction of vital capacity, substernal pain, nose and throat irritations, impaired vision, and rise in blood pressure. If continued for twenty-four hours, it may even cause collapse, and in experimental animals death occurred after thirty-nine hours with pleural effusions and severe injury of the lungs, liver, spleen, and kidneys. Therefore, 100 per cent oxygen should be used for only two to three hours at a time, if at all.

Although it is stated that 100 per cent oxygen may be given for twenty-four hours at a time in severe anoxia, it is perhaps unwise to use it because in such states lungs are already damaged and will react unfavorably. It is also stated that 40 to 50 per cent oxygen is of no value. I am sure that if there is need for it and the primary cause has been eliminated that 40 to 60 per cent oxygen will be very helpful. In severe cases it should be given at 85 per cent concentration under slight (35 mm. of mercury) pressure.

Drugs and Other Agents in Anoxia.—Glucose prolongs consciousness in anoxia due to high altitude flying. Carbon dioxide, 5 to 7 per cent, with 93 to 95 per cent oxygen may be helpful in severe anoxia due to carbon monoxide and for brief periods. Carbon dioxide is useful in anoxia for the following reasons: (1) it is a respiratory stimulant; (2) it increases the depth of respiration and therefore tends to prevent atlectasis; (3) because of the depth of respiration, venous return is augmented; (4) it increases dissociation of carbon monoxide from the hemoglobin.

Drugs such as Adrenaline may be useful in certain kinds of shock (spinal anesthesia, anaphylaxis). Drugs are not readily absorbed as a rule due to the accompanying shock, and respiratory stimulants should be given intravenously if at all (caffeine, sodium benzoate).

In asphyxia neonatorum, the airway must be cleared, spontaneous respiration initiated, and oxygen given. If oxygen is given by endotracheal tube and the blood does not become red, an arteriovenous shunt or massive pneumonia is probably present. If spontaneous respiration does not start, cerebral injury or deep anesthesia of the respiratory center is present.

DISEASES AND INJURIES OF THE CHEST WALL

Congenital anomalies of the chest wall are rare. The more common conditions such as fused or forked ribs, *pigeon breast*, have little clinical

organ within the thorax or the abdomen. In addition, important abnormalities in physiology of respiration may ensue.

Effects of Thoracic Injuries.—The pathological and abnormal physiological effects of the chest wounds may be divided into the following categories: (1) Pathological effects due to the increase in air pressure within the pleural cavity or elsewhere. This air may be merely present or may be present under tension and is known as (a) traumatic pneumothorax, (b) mediastinal emphysema, (c) pneumopericardium, (d) subcutaneous emphysema. If the air in the pleural cavity is under pressure, it is known as a tension pneumothorax. (2) Abnormal mobilities giving rise to (a) mediastinal flutter, (b) paradoxical respiration, (c) mediastinal shift. (3) Abnormal collections of fluid. This may be serum, blood, or pus. If serous, it is hydrothorax; if bloody, it is a hemothorax; and if pus, it is a pyothorax or empyema. The serous fluid is either transudate or exudate. The bloody fluid is due to hemorrhage from intercostal vessels, internal mammary arteries or veins, blood vessels of the lung, or, rarely, major vessels within the thorax. (4) Combinations of the foregoing may produce hydropneumothorax or hemopneumothorax or pyopneumothorax. (5) Injury to thoracic viscera. Lacerations of the lung are not infrequent following nonpenetrating wounds and have been recently well described during World War II as blast injuries to the lung. Syncope and heart damage may occur from nonpenetrating wounds but are more apt to result from those which penetrate. These have been described under the subject of heart injury. Any organ or organs may be injured by penetrating or perforating wounds. (6) Injury to the diaphragm, although far more common with penetrating wounds, rarely may occur in a nonpenetrating injury. (7) Thoracico-abdominal injuries due to gunshot wounds of the chest or stab wounds may injure blood vessels and viscera above and below the diaphragm.

Effects of Abnormal Pressure or Increase in Pressure Within the Thorax.—Air may be present, as has been noted, within the pleurae, the mediastinum, the pericardium, or under the skin. It is also sometimes encountered free in the abdominal cavity from the perforated viscera or from a thoracico-abdominal injury, rarely by finding its way from the thorax into the abdomen along the great vessels. The mere presence of air in an abnormal position is not serious and is only important because of its diagnostic value. However, when air accumulates under pressure in any of the situations mentioned, serious symptoms may result. In the chest such accumulations of air are known as a tension pneumothorax (pressure pneumothorax) or a tension mediastinal emphysema. If the air is in the pleural cavity, it may get there by: (1) An open wound which sucks air; that is, the wound is small or at least smaller than the diameter of the trachea and permits air to be drawn in with each inspiration and to be forced out only partially with each expiration. It is, therefore, a building up of pressure. The same effect could be produced by a flap of

will not show cartilaginous tears at the chondrosternal articulations. These may result in dislocations or slipping ribs. These may be very painful. If anteroposterior pressure is made on the ribs, pain will be referred to the site of injury. The *treatment* consists of blocking the intercostal nerves with 1 per cent Novocain and the use of an elastic binder about the chest. This forces the patient to breathe with the diaphragm, putting the ribs at rest. In complete or multiple fractures with displacement, the fragments should be wired. The sternum is rarely fractured but may embarrass respiration or cause internal injury if much deformity exists. The treatment consists of rest with a sandbag between the shoulders.

If the sternum is so deeply depressed that vital functions are hampered, operative reduction is necessary. The sternum may be held in place by wiring the fragments. Extensive fractures of the ribs and sternum may produce great deformity (stove-in chest) and may be accompanied by severe complications such as mediastinal emphysema, tension pneumothorax, hemorrhage, mediastinal flutter, paradoxical respiration due to flapping chest wall, laceration of lungs, mediastinal hematoma, acute gastric dilatation, an embolism, and, if the trachea or bronchi become obstructed with blood or mucus, massive atelectasis. In all such injuries it is better to wire the fragments together by open operation.

INJURIES TO THE CHEST

The results obtained in thoracic centers during World War II were splendid. In civilian practice the same results have been obtained. At the outset we must take cognizance of the fact that most injuries are combined ones, including head, thorax, abdomen, and lacerations and fractures of the extremities. Therefore, the composite picture produced by the effects of an automobile accident upon a patient may be extremely difficult to interpret. We have touched upon the matter previously in the discussison on shock, head injuries, hemorrhage, and injuries to the blood vessels and the heart. Chest injuries may be divided into three types: (1) nonpenetrating. Such injuries have no external wound and are due to contusions, birth injuries, severe straining, or violent coughing. Although there is no penetration of the chest cavity, serious and dire effects may ensue. (2) Penetrating wounds of the chest which do not have an external opening. Such wounds are usually the result of a fractured rib being driven inward with resultant injury to the pleura, lung, large vessels, thoracic duct, heart, or diaphragm. (3) Penetrating and perforating wounds which are open. Such injuries are produced by bullets, shrapnel, knives, or other implements; also by compound fractures of ribs due to severe contusions with lacerations of the chest wall. The effect of penetrating open wounds depends upon the position of the wound or trajectory of the bullet or foreign body and may involve any

sucking wound must be closed, but, in addition, the tension must be relieved immediately. In civilian practice this is accomplished by the use of a large bore needle to which is attached a long tube which goes beneath a water level at the side of the bed. It is our custom to introduce two such needles, one posteriorly so that fluid as well as air may emerge, the other anteriorly so that air which rises to the top in a patient lying on his back may easily find egress through the large bore needle. The water seal arrangement of course prevents air from being sucked in but permits air to get out. During World War II this same treatment was used but a mobile piece of equipment, namely, a small (No. 16 French) catheter, was introduced into the chest and sealed with adhesive and collodion. Over the end of this tube was the thumb of a rubber glove with its end cut out. This was tied to the tube so that it acted like a flutter valve, permitting air to get out but collapsing during inspiration, thus preventing air from getting in. In this way soldiers with chest injuries could be safely transported to the large hospitals for definitive treatment. Of course, air may be sucked out by actual suction or by other devices, by negative pressure such as Wangensteen suction, water valve suction, etc.

Effects of Abnormal Mobility of the Mediastinum, Shifts of the Mediastinum, and Paradoxical Respiration.—The mediastinum is normally a movable structure which stays in the midline because air pressures within the two pleural cavities are equal even though they may vary during inspiration and expiration. However, should pressure within one side of the thorax vary from that of the other, shifts in the mediastinum may ensue. This is seen clinically in such conditions as massive atelectasis, in which the mediastinum is pulled toward the affected side, and in collections of fluid, blood, pus, or air on one side, pushing the mediastinum toward the normal side. In chest injuries the chief cause for changes in the mediastinum are collections of air or fluid or extensive injuries to the chest wall. With pneumothorax, the mediastinum is pushed over to the normal side and is pulled somewhat by the negative pressure on that side. As we have seen, when air enters the pleural cavity, the lung collapses not only because of the air pressure, but also because of the elastic recoil of the lung. The mediastinum will be pushed to the opposite side and remain more or less in this position. This is known as mediastinal shift. The results of this shift may produce anoxemia for two reasons: (1) It may interfere with respiration on the normal side and (2) it may prevent blood from reaching the right heart due to a twist on the large veins. The latter is probably due to the fact that the mediastinum, in shifting, rotates slightly. With mediastinal shift, during inspiration air rushes into the good lung but cannot enter the affected one. During expiration, air leaves the normal lung and the mediastinum may be pushed to the affected side slightly by an increase in intrapleural pressure in the uninjured half of the chest. In tension

skin or muscle which points inward, permitting air to come in but not to get out. (2) An opening anywhere in the bronchial tree or lung which may permit air to enter the pleural cavity and to build up pressure. The effects of tension pneumothorax are as follows: As a result of the increase in intrapleural pressure and due to the elasticity of the lungs, there is a complete collapse of the lung on the affected side. In addition, the mobile mediastinum is pushed over to the opposite side due to the fact that pressure is much greater in the injured pleura and also because a negative pressure is present on the unaffected side. This is known as *mediastinal shift.* Sometimes there is enough air pushed out with every expiration and enough sucked in with inspirations that tension pneumothorax does not occur. In this case the opening is larger than the trachea and air gets in and out with respiration. However, the air pressure within the pleural cavity is equal to atmospheric pressure, whereas the pressure in the unopened pleura is below atmospheric pressure. The effects of this situation are a collapse of the lung on the open side and a shift of the mediastinum which moves back and forth, moving toward the intact half during inspiration and toward the open pleura during expiration. This is known as *mediastinal flutter.* The effects of mediastinal shift and flutter will be discussed in some of the following paragraphs.

The physiology of respiration with changes in air pressure in the pleural cavity is altered as follows: With pneumothorax, air goes into the good lung with inspiration but does not get into the collapsed lung because the intrapleural pressure is increased and the lung is collapsed even more, so that any air which may be present in this lung is shifted over to the other side. With expiration, air leaves the good lung and some air leaves the pleural cavity of the affected side, therefore lessening the intrapleural pressure; thus some air from the unaffected lung finds its way into the opposite lung. This is paradoxical respiration and will be discussed further in subsequent paragraphs. It should be said here, however, that the little air which is exchanged under the conditions described in the lung on the affected side is impure and therefore does not contribute to the oxygenation of the blood. In tension pneumothorax, with every inspiration, air pressure within the pleural cavity becomes greater, collapsing the lung completely and pushing the lung far toward the unaffected side. In this case no air gets into the collapsed lung, and due to the great shift of the mediastinum, there is a diminished amount of air entering the normal side. If the mediastinum or lung is fixed by adhesions, the effects would be minimized. Mediastinal emphysema is important because it prevents the blood from returning to the right heart. In this way stagnant anoxemia is produced and shock develops very rapidly due to diminished return of blood to the heart, with resultant cardiac inadequacy. Pneumopericardium behaves very much as cardiac tamponade. This has been discussed previously under heart injuries. The treatment of pneumothorax depends upon its cause. Obviously a

anoxemia. The treatment for abnormal mobilities is to correct the cause. Open wounds should be closed and flail chests supported by padding and elastic straps. In addition, the patient should be on the affected side to delimit movement. Should symptoms persist, open operation with wiring of rib fragments should be done.

Abnormal Collections of Fluid.—Following injuries to the chest, transudates and exudates may appear within the lung or the pleural cavity or both. In addition, hemorrhage may occur.

Fluid Within the Lung.—Fluid within the lung or pulmonary edema is so common following chest injuries that it has been termed traumatic wet lung. Many theories have been advanced to account for this phenomenon. No doubt many different factors are at work, depending upon the type of injury. It is easy to understand how blast injuries, contusions, and penetrating and perforating wounds of the lung may cause transudation and exudation of the fluid and blood. The uninjured lung is wet also; this has been thought to be due to immobility and stasis with passive congestion; also bronchial and tracheal occlusions with mucus and blood, causing partial atelectasis with dyspnea. To prevent these factors from operating, the intercostal nerves are injected with Novocain along the injured area to stop reflex respiratory inhibition, and frequent tracheal aspirations and bronchoscopy are used to remove mucous plugs. Anoxemia, whether anoxic or stagnant, may invite transudation in the lung. Unconscious patients who lie in one position invite hypostatic congestion which may be conducive to wet lungs. Furthermore, they develop tracheobronchial obstruction due to mucous plugs. For this reason tracheotomy is frequently done in head injuries. One more factor is that of a very tight thoracic bandage which prevents expansion.

Fluid in the Pleural Cavity.—In the pleural cavity very much the same factors are at work. In addition, most chest wounds are accompanied by some form of intrathoracic injury which gives rise to hemothorax. The presence of blood in the pleural cavity or of fluid interferes with respiration on the affected side and causes a collapse of that lung. If large enough, the mediastinum may be pushed over to the opposite side, and since usually fluid is associated with air as a hemopneumothorax or hydropneumothorax, the combined effect is one of great pressure.

It was formerly thought that blood in the chest did not clot. This is still true, but it is supposed that the reason blood does not clot in the chest is due to the fact that it is defibrinated and that the fibrin is whipped out by respiration and deposited on the visceral and parietal pleurae. Thus the defibrinated blood does not clot. Bleeding in the chest may occur from various sources; namely, intercostal vessels, the lung, internal mammary vessels, and large thoracic vessels. Physical signs and symptoms and x-ray examination reveal the presence of fluid. Thoracentesis tells us whether the fluid is primarily serum or blood.

pneumothorax the mediastinum may be pushed over so far to the opposite side that aeration cannot take place in the good lung due to compression by this structure and, moreover, blood cannot enter due to air pressure or to a shift in the position of the large veins. It is apparent that in the latter condition, if the tension pneumothorax is on the right side, pressure of the air alone may occlude the vena cavae which may also be compressed by the shift. If the pneumothorax is on the left side, the shift and the twist mechanically occlude the large veins. In either event, there results anoxemia which is both anoxic and stagnant, and early shock and death will ensue unless the condition is promptly corrected.

If the mediastinum shifts from side to side with respiration, a condition known as *mediastinal flutter* results. This is seen chiefly in two conditions: (1) open chest wounds in which the diameter of the wound is as large or larger than that of the trachea and (2) stove-in or flail chest. In the previous discussion we described the effects of these conditions. Here we are interested chiefly in the effects on the mediastinum. With an open wound in the chest, with inspiration the good lung will expand. The injured pleural cavity, filled with air at atmospheric pressure, will draw in more air. The effect of this is to collapse the lung on the injured side and to shift the mediastinum to the opposite chest. During expiration the uninjured lung contracts as air leaves the lung. Air also leaves the injured pleural cavity, and the mediastinum is thereby permitted to swing back toward the injured side of the chest; air leaves the injured lung during inspiration and crosses to the good side, whereas air leaves the good lung to enter the injured lung during expiration, slightly inflating the latter. The to-and-fro shift in the mediastinum is known as mediastinal flutter. This may be very serious because of interference with circulation or the return of blood to the heart and interference with respiration. The second cause of flutter is due to paradoxical respiration, the result of a crushed chest, in which with every inspiration the chest wall is sucked in and with every expiration it is expanded. On the uninjured side normal movements prevail. The chest wall expands during inspiration and contracts during expiration. The effect of the paradoxical movement on the injured lung and mediastinum is as follows: During inspiration there is a contraction of the injured side, compressing the lung and pushing the mediastinum over toward the normal half of the chest which expands normally. Very little air enters the collapsed lung; in fact, air leaves it and crosses over to the normal lung. During expiration the injured chest expands due to increased intrapleural pressure, but the lung is inflated very little and this is due to air passing over from the good lung, which has just contracted, pushing the mediastinum over toward the injured side. Mediastinal flutter is not as pronounced as in open wounds of the chest, but the combined effects of the flutter and lack of air on the injured side with a decrease in respiration of the normal side (due to the abnormal mediastinal movements and the to-and-fro movement of air which is not oxygenated) will produce

anoxemia. The treatment for abnormal mobilities is to correct the cause. Open wounds should be closed and flail chests supported by padding and elastic straps. In addition, the patient should be on the affected side to delimit movement. Should symptoms persist, open operation with wiring of rib fragments should be done.

Abnormal Collections of Fluid.—Following injuries to the chest, transudates and exudates may appear within the lung or the pleural cavity or both. In addition, hemorrhage may occur.

Fluid Within the Lung.—Fluid within the lung or pulmonary edema is so common following chest injuries that it has been termed traumatic wet lung. Many theories have been advanced to account for this phenomenon. No doubt many different factors are at work, depending upon the type of injury. It is easy to understand how blast injuries, contusions, and penetrating and perforating wounds of the lung may cause transudation and exudation of the fluid and blood. The uninjured lung is wet also; this has been thought to be due to immobility and stasis with passive congestion; also bronchial and tracheal occlusions with mucus and blood, causing partial atelectasis with dyspnea. To prevent these factors from operating, the intercostal nerves are injected with Novocain along the injured area to stop reflex respiratory inhibition, and frequent tracheal aspirations and bronchoscopy are used to remove mucous plugs. Anoxemia, whether anoxic or stagnant, may invite transudation in the lung. Unconscious patients who lie in one position invite hypostatic congestion which may be conducive to wet lungs. Furthermore, they develop tracheobronchial obstruction due to mucous plugs. For this reason tracheotomy is frequently done in head injuries. One more factor is that of a very tight thoracic bandage which prevents expansion.

Fluid in the Pleural Cavity.—In the pleural cavity very much the same factors are at work. In addition, most chest wounds are accompanied by some form of intrathoracic injury which gives rise to hemothorax. The presence of blood in the pleural cavity or of fluid interferes with respiration on the affected side and causes a collapse of that lung. If large enough, the mediastinum may be pushed over to the opposite side, and since usually fluid is associated with air as a hemopneumothorax or hydropneumothorax, the combined effect is one of great pressure.

It was formerly thought that blood in the chest did not clot. This is still true, but it is supposed that the reason blood does not clot in the chest is due to the fact that it is defibrinated and that the fibrin is whipped out by respiration and deposited on the visceral and parietal pleurae. Thus the defibrinated blood does not clot. Bleeding in the chest may occur from various sources; namely, intercostal vessels, the lung, internal mammary vessels, and large thoracic vessels. Physical signs and symptoms and x-ray examination reveal the presence of fluid. Thoracentesis tells us whether the fluid is primarily serum or blood.

The treatment of hemothorax and of serous collections is that of aspiration which may be repeated. Fresh hemorrhage is not caused unless strong negative pressure is produced. This should be done early and not replaced with air. If blood is present, it may be aspirated and retransfused into the patient after mixing it with citrate solution. Following aspiration the patient is watched carefully. If blood accumulated quickly and if there is a fall in the hematocrit, it may be assumed that a large vessel has been torn. This would demand *thoracotomy*. If, however, the lung expands after aspiration and no signs or symptoms of shock appear, the bleeding has stopped and further interference will not be necessary. In those cases of hemothorax with a persistent shadow on the x-ray film, fever, and negative results from aspiration, it may be assumed that a thick fibrinous exudate is present over the lung, preventing its expansion. This would require visceral *decortication* which permits re-expansion of the lung and prevents chronic empyema.

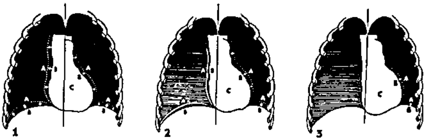

Fig. 213.—Diagrams illustrating fluoroscopic movements in the thorax.

1. Normal movements of the diaphragm and mediastinal border during (a) expiration diaphragm elevated and mediastinal shadow widened) and (b) inspiration (diaphragm lowered and mediastinal shadow narrowed).

2. *Empyema before localization has occurred. Movements normal on the* unaffected side. Movements exaggerated on the affected side, with movement of the lower lung margin if the empyema is not massive. If part of the fluid is aspirated, these movements are more easily observed.

3. After localization the diaphragm, mediastinum, and lower lung margin do not move, whereas movement on the unaffected side is exaggerated. In massive empyema some of the pus is aspirated, so that fixation by pressure may not be mistaken for localization by a pyogenic membrane. (From Berman, J. K.: J. Indiana M. A. 29: 419, 1936.)

The operation of visceral decortication was popularized during World War II. Extensive studies on patients with *fibrinous hemothorax* have shown that this deposit of fibrin, infected or uninfected, should be removed. The operation is done through the sixth interspace. After the chest has been opened, the pleural cavity will be found to contain blood clot, pus, and shaggy purulent fringes hanging from the pleura. A line of cleavage is easily established and the deposit on the visceral pleura is removed. The parietal pleura deposit is also removed so that two pleural surfaces may adhere. The lung can be easily expanded by the anesthetist through the endotracheal tube. Any lacerations which are encountered in the lung are sutured. The optimum time for this procedure is between ten and twenty-five days. Earlier than this the decortication may start bleeding again. Later than this the fibrinous coat becomes organized with a layer of granulation tissue beneath it so that stripping leaves a raw bleeding surface which may be conducive to a recurrence of the hemothorax. *After the chest*

is closed, two small tubes are inserted, one in the third interspace anteriorly, the other in the seventh interspace in the posterior axillary line for underwater seal drainage. These are removed after about forty-eight hours.

Injury to the Viscera.—In Chapter 18 we discussed injuries to the heart. In this discussion we spoke of syncope and heart damage from contusions; also perforating wounds of the heart were discussed; therefore, heart injuries will not be included in this résumé. The lung is frequently injured and usually does not require suture. However, large lacerations would require open thoracotomy with suture. Infrequently, large vessels are torn which may require suture or even ligation. Smaller vessels are tied. The thoracic duct may be injured and this may result in chylothorax. This has been discussed in Chapter 18. Last, abdominal injuries frequently occur in connection with thoracic wounds. In civilian practice we have encountered perforations or lacerations to the following abdominal organs in connection with thoracic injuries: stomach, pancreas, liver, kidney, spleen, hepatic flexure of the colon, and inferior vena cava. In most of these injuries transthoracic approach was used. The diaphragm was opened widely and the injured organ sutured or removed. The diaphragm itself is frequently torn. This occurs sometimes in nonpenetrating injuries and is probably due to strong abdominal force together with a compression of the lower chest. Usually, however, the injury is produced by projecting ribs or by a knife wound, resulting in a large opening in the diaphragm with protrusion of abdominal viscera into the thoracic cavity. Such injuries require thoracotomy and repair of the diaphragm. Sometimes it is advantageous temporarily to interrupt the phrenic nerve by the injection of Novocain or by crushing so that the diaphragm may be immobilized to facilitate repair and healing.

Anesthesia.—One of the most important persons of the team doing thoracic surgery is the anesthetist. Endotracheal anesthesia is employed in all thoracic or thoracico-abdominal injuries. The anesthetic agent may be cyclopropane or nitrous oxide and curare or ether. We prefer the latter. In fact, it is the best all around anesthetic agent for injured persons. This, added to the fact that most of these patients have had great loss of blood, producing severe anemia, makes ether the only anesthetic which can give full relaxation. (See Chapter 13.)

Complications and Sequelae of Chest Injuries.—We have already seen that the chest wall may be deformed or destroyed, permitting in the latter case hernia of the lung. This complication can be corrected by using portions of adjacent ribs to bridge the gap and stabilize the chest wall. Inside the chest the pleura may become infected with resultant empyema. When due to hemothorax, decortication should be done. If, however, the empyema is a late development or has been neglected over a long period of time, open drainage may be necessary as described under the subject of empyema. Should this form of treatment

fail to obliterate the cavity, visceral and parietal decortication may be tried to permit reexpansion. If this fails, the parietal pleura is removed and the cavity filled in by skin and muscle flaps obliterating it.

Another complication of chest injuries is lung abscess. This will be discussed later. However, here should be mentioned the possibility of this disease resulting from penetrating wounds, contusions, aspiration of foreign bodies, and atelectasis due to obstructions. Abscess is treated by outside drainage as soon as it is discovered. Should the lung abscess become chronic, lobectomy or segmental resection may be necessary.

In open perforating wounds, bronchopleural fistula may result. These usually close spontaneously. Rarely it is necessary to close them surgically. Another type of fistula occurs very infrequently. This is the

Fig. 214.—Hemothorax with fibrinous empyema treated by visceral and parietal decortication. The patient was a man 45 years of age who received a gunshot wound of the right chest. On admission to the hospital the patient was in a moderate state of shock. Physical examination showed the presence of a large amount of fluid in the right chest. This was confirmed by x-ray studies. The patient was treated by blood replacement for forty-eight hours and then 1,500 c.c. of bloody fluid were aspirated from the right thorax. This was repeated at intervals over a period of four weeks. After this time no fluid could be obtained by thoracentesis; however, the patient had a septic type of fever. X-ray examination at this time showed the presence of a fibrinous type of empyema. *A*, Preoperative x-ray film. *B*, Postoperative x-ray photograph taken after visceral and parietal decortication. The lung has almost completely re-expanded.

It is not necessary to do a parietal decortication in the early cases, that is, the hemothorax cases with secondary fibrinous empyema which are within the six to eight-week period. Here a visceral decortication followed by re-expansion of the lung will give good functional results and the lung will remain out. In older cases and in those due to tuberculosis where the visceral and parietal pleurae are thickened, particularly the latter, it is desirable, although oftentimes it cannot be accomplished, to remove the parietal as well as the visceral pleura. The reasons for this are (1) it is easier to get a line of cleavage and (2), if the visceral pleura is removed and the lung is re-expanded, it may not stick to a hard, sclerotic, thickened pleura which has the consistency of cartilage.

The function of the re-expanded lung in chronic cases, whether tuberculous or nontuberculous, is not as good as might be expected from the x-ray picture. Its respiratory function is greatly decreased although it does have a space-filling function which obliterates dead space and thereby, eliminates chronic infection. Therefore, it is a desirable procedure.

In the tuberculous varieties of empyema the lung will re-expand after decortication although it may not regain its respiratory function. Furthermore, the old lesions may be activated by the expansion of the lung. A combination of decortication and thoracoplasty may be desirable in some of these cases.

tracheoesophageal communication due to a perforating wound. This complication tends to heal spontaneously but is usually accompanied by an empyema. Sometimes surgery is necessary to effect a closure. Obviously, if such an injury is discovered early, it should be closed at once. In all fistulas and in abscesses the presence of a foreign body should be suspected and if present should be removed.

Summary of Chest Injuries.—From the foregoing discussions one may see that the correct diagnosis and treatment of chest injuries is by no means a simple matter. The difficulties arise in part from the fact that the diagnosis may be very complicated. This in turn is due to the fact that chest injuries are rarely the only injuries that have been sustained. In civilian practice the automobile shows no distinction between the head, thorax, abdomen, and extremities. Head injuries, as we have seen, are accompanied during the stage of stimulation from increased intracranial pressure by a slowing pulse and a rising blood pressure. Contrast this with shock, due to loss of blood, interference with circulation, or anoxemia. In all of these conditions there is a rise in pulse rate and a fall in blood pressure. Yet in patients with concomitant head injuries clinical symptoms and signs may be confusing. In thoracic injuries very often there is an ipsilateral spasticity of the rectus muscle. This may lead to the erroneous conclusion that there has been a thoracicoabdominal injury. Therefore, thoracic injuries must be viewed in the light of the patient as a whole. In order to arrive at a correct diagnosis and to give the correct treatment, the following routine should be observed: (1) thorough and complete physical examination; (2) careful watching of the patient for all changes in temperature, pulse, blood pressure, state of consciousness, control of emunctories, and respiration; (3) hematocrit and plasma protein determinations at frequent intervals; (4) x-ray examinations of the chest and abdomen; (5) thoracentesis and, if indicated, paracentesis; (6) explorations if indicated.

A summary of the treatment would be a summary of the injuries. In general, however, there must be the closest observation to determine proper treatment. A general rule to follow is to arrest hemorrhage first and then treat the patient for shock. Since in chest injuries the hemorrhage may be concealed and shock may result not only from hemorrhage but also from interference with respiration and circulation, it becomes necessary to differentiate the type of hemorrhage and the kind of shock; consequently it is our custom to try to stop external bleeding and to replace blood lost in the chest by autotransfusion. Should bleeding persist as shown by repeated aspirations and progressive fall in hematocrit, an open operation to arrest hemorrhage becomes imperative. In addition, since shock may be caused by tension pneumothorax, mediastinal shift and flutter, and large accumulations of serum or blood, these conditions must be corrected as previously indicated.

Our routine is as follows: Sucking wounds are closed. If tension pneumothorax is present, needle aspiration and drainage are instituted and plasma is started. From this point definitive treatment depends upon the type of injuries present. In all cases, multiple transfusions are given and careful attention is given to water balance and oxygen requirements. Thoracotomy is indicated in large lacerations going into the chest, thoracico-abdominal injuries, uncontrolled hemorrhage, large lung lacerations, and removal of foreign bodies. Following operation or primary treatment we attempt to improve tracheobronchial drainage to prevent atelectasis and pneumonitis. This is done by catheter suction, bronchoscopy, and intercostal nerve block with procaine (to permit normal breathing) and by encouraging the normal cough reflex; also by the use of oxygen and antibiotics.

INFECTIONS OF RIBS

Infections of the ribs may occur as complications. Osteomyelitis may be part of a multiple osteomyelitis (see Chapter 21) or an empyema. Tuberculosis of the ribs and sternum, involving the cartilage, is usually secondary to the disease elsewhere. Its "cold" and insidious development makes diagnosis difficult until draining sinuses appear. The rare typhoid rib is usually a complication of a milder "walking" type of the disease. The treatment is conservative unless sequestra form, in which case they are removed. X-ray is useful in the treatment of tuberculous ribs.

TUMORS OF RIBS

Tumors are benign, such as chondroma, which may be removed; malignant, such as multiple myeloma, in which many bones are involved; or metastatic carcinoma, especially from the breast. In these, x-ray is the only available treatment.

THE PLEURA

Injuries to the pleura have been discussed previously.

Inflammations of the Pleura

Mesothelial structures have many similar characteristics as well as a common origin. Such structures as the pleura, pericardium, peritoneum, synovial membranes (mesenchymal epithelium), bursae, and tendon sheaths line cavities. This lining is one cell layer thick and rests on a basement membrane around which is a layer of fat which is liberally supplied with blood vessels and especially with lymphatics. Mesothelial membranes secrete a thin protein fluid which varies in density (the density is greater in joints and bursae, less in pleura and peritoneum). The capillaries are more permeable than elsewhere and therefore lose more protein, but the lymphatics are well able to absorb this material normally.

The reaction of mesothelial tissues to trauma and infection is rapid and extensive, accounting for the relatively high immunity which they possess. In fact, the entire pleura on the affected side or the entire peritoneum takes part—not a limited area. Any tissue that is traumatized is stimulated to react, and such stimulation to *these* tissues causes an increased secretion of fluid. *This is a protective mechanism, causing immobilization, separation of raw surfaces, dilution of toxins, and, because, of excessive osmotic index, prevention of absorption.* Should injury continue, there would be decreased stimulation and slow absorption of fluid, and the dry, raw surfaces would ultimately become adherent.

In infections of mesothelial tissue the same defense mechanism present elsewhere asserts itself: plasma is lost, due to increased capillary permeability; the osmotic index of the tissue fluid increases, preventing reabsorption; the blood capillaries and lymphatics become thrombosed; cellular exudates form an extensive pyogenic membrane; and local immunity becomes established. In addition, the volume of exudates is prodigious, diluting toxins; floating cells give rise to macrophages, also small lymphocytes, which in turn may give rise to fibroblasts.

Therefore, the treatment is the same as elsewhere in spreading inflammations: rest, waiting for localization, incision, and drainage. In the case of these cavities, the excessive pus and exudates make an excellent irrigating fluid. If untreated, absorption begins after clot retraction in the lymphatics; however, this occurs after eight to ten days, when the exudate is practically sterile and therefore not as harmful. Mesothelial tissues heal very quickly. In the peritoneum, a protective exudate is present within thirty minutes. This prevents leakage in intestinal surgery, for no sutures would be close enough to be watertight and airtight.

Inflammation of the pleura is known technically as *pleuritis,* or *pleurisy,* and may occur as a distinct entity or in connection with diseases of the lung or injuries to the chest. Not all fluid in the chest is due to an inflammation of the pleura (exudate). Hemothorax and chylothorax, from injuries to the large blood vessels or the thoracic or right lymphatic duct and, in the latter instance, malignancy, may play a role, giving rise to blood and lymph within the thorax. Indeed the esophagus may be injured or eroded, giving rise to saliva or food within the chest. In any case, the pleura soon becomes inflamed too and thus hemothorax may be difficult to distinguish from hemorrhagic pleurisy with effusion, especially when there has been no penetrating wound. Last, transudates constitute another cause for fluid in the chest, as seen in cardiac decompensation or constrictive pericarditis, nephritis with edema, mediastinal tumors—this fluid is known as hydrothorax. It is perhaps safe to say that in pneumonia or pulmonary tuberculosis the pleura is usually inflamed. However, these inflammations are a part of the underlying disease and usually improve with it. *Dry* pleurisy (sicca or fibrinous) produces a friction rub which

is heard through the stethoscope and which causes pain with every inspiration. Here the two layers are covered with a fibrinous exudate which rubs and irritates the sensitive visceral pleura. It is usually associated with or is the forerunner of pneumonia or pneumonitis, often with bronchitis or upper respiratory infections, rarely as a distinct and separate entity. It may be tuberculous in origin as discussed in Chapter 8. The causative organisms are pneumococcus, streptococcus, staphylococcus (rarely), and the tubercle bacillus. *Wet* pleurisy is probably a further development of dry pleurisy and is a conservative act on the part of nature, separating the pleural surfaces and in a measure putting the lung at rest. The causes of wet pleurisy (pleurisy with effusion) are variable and the type of fluid is not always indicative of the etiological agent. We have repeatedly shown that with the advent of penicillin, the sulfonamides, and streptomycin, fluid which might have been purulent remains clear. However, it is convenient to classify effusions according to their characteristics which may be as follows:

1. Serous serosanguineous, serofibrinous. These are exudates with specific gravity above 1.012 and transudates are due to (1) the spread of an inflammatory process in the lung, (2) obstruction of a bronchus, (3) obstruction of an artery supplying a pulmonary segment. The inflammatory lesions causing serosanguineous fluid are usually streptococcal but may be due to mixed infections, virus pneumonia, tuleremia, and pyogenic organisms, although the latter usually give rise to purulent or serofibrinous effusions. Serous effusions may be due to nonspecific organisms which have been inactivated by penicillin but almost always a clear straw-colored effusion is due to *tuberculosis until proved otherwise.*

Obstructions to a bronchus may be due to carcinoma, primary or secondary, lymphoblastoma, bronchial adenoma or other endobronchial neoplasms, inflammatory exudate or stricture (tuberculosis, nonspecific as seen in bronchiectasis), foreign bodies. In other words, occlusion from within the bronchus or disease of its walls or external pressure may cause a pleural effusion.

Carcinoma: The intrathoracic carcinomas are bronchiogenic or mediastinal. Secondary growths are due to carcinoma of the breast, ovary, kidney, stomach, colon, etc.

An artery may be obstructed by embolism or neoplasm, giving rise to serosanguineous effusions. Transudates which are all serous may be due to congestive heart failure, constrictive pericarditis, cirrhosis of the liver, and chronic nephritis with nephrosis.

A final group are due to trauma with or without penetration and perforation and also that which follows artificial pneumothorax in the treatment of tuberculosis.

2. Hemorrhagic fluid may be due to injuries or spontaneous hemopneumothorax (due to tuberculosis) or neoplasm of the pleura. Some-

times it is seen in lymphoblastoma, congestive failure, cirrhosis of the liver, pneumonia, and infarction.

3. Chylous fluid is seen in injuries to the thoracic or right lymphatic duct or carcinoma involving them, rarely to congenital anomalies, filariasis, Hodgkin's disease, tuberculous glands, aortic aneurysm, and thrombosis of the subclavian vein. (See Chapter 18.)

4. Purulent fluid (empyema) is due to nonspecific organisms, rarely to tuberculosis or mixed infections (tuberculous and pyogenic). Breath sounds are diminished, there is dullness on percussion, and vocal fremitus is diminished or absent. As the underlying lung condition improves, the pleurisy usually improves also. Occasionally the fluid accumulates in such quantities that respiration is embarrassed by its presence. In this case, *thoracentesis*, or aspiration of the chest, is done with a syringe and needle. X-ray is of help in diagnosis.

Diagnosis of the cause of the effusion is made by a careful examination of the patient after recording his history and then x-ray examination. After this, thoracentesis is done. The fluid is examined carefully. This includes smears, cultures, centrifuging for cells (button), and guinea pig inoculation. Immediately after thoracentesis, x-ray and fluoroscopic studies are continued to determine whether or not the primary disease is in the lung or mediastinum.

The treatment of pleural effusions will depend upon their cause. Tuberculous effusions are discussed in Chapter 7. Those due to other types of inflammation are treated by aspiration or drainage as described in the following discussion on empyema. Fluid due to bronchial obstructions and carcinomas will persist unless the primary cause is eradicated. However, repeated aspiration relieves the patient greatly, permitting him to breathe and thereby relieving the anoxemia. Transudates from other causes are aspirated to relieve respiratory distress and to prevent empyema. Traumatic effusions have been discussed and chylous effusions are described in Chapter 18. In general, it is unwise to leave fluid within the pleural cavity because it interferes with respiraiton and may become secondarily infected and whether it does or not, fibrinous deposits with thickened pleurae result. In tuberculosis, obliterative pleuritis (adhesion between visceral and parietal pleura) is undesirable, and therefore partial aspiration is done. In addition, removal of fluid permits more accurate diagnosis by (1) x-ray and fluoroscopic examination of the lung and mediastinum and (2) careful analysis of the fluid. Pleural effusions decrease plasma proteins and invite dehydration. Hemothorax means loss of blood. Therefore, it is necessary that careful attention be given to fluid and protein balance as well as to blood volume. Empyema is a special type of pleural effusion and is discussed in the following paragraphs.

Empyema.—Sometimes the pleural disease overshadows in importance the causative lung condition. The pleura becomes inflamed and suppuration occurs. This disease is known as empyema thoracis. It is

usually acute and may occur as a complication of pneumonia (synpneumonic) or as a sequel (metapneumonic or postpneumonic). Since the introduction of penicillin and the sulfonamides, the incidence of the disease seems to be less, and, when it occurs, it is less virulent. It is caused by various organisms. The most virulent is the streptococcus (in the synpneumonic form), which invades connective tissue planes within the lung and continues out into the pleura, causing a spreading cellulitis (see Chapter 5). The pneumococcus usually causes the metapneumonic form and is much less virulent. *The staphylococcic form is fortunately* very rare; when it occurs, it is extremely virulent. In any of these the pleura becomes inflamed and edematous, and soon the entire pleural cavity is filled with thin (streptococcic) or thick (pneumococcic) pus. Should the pus burrow to the outside, or into other organs, it is called *empyema necessitatis*. The diagnosis is not difficult in the metapneumonic types but is in the synpneumonic. In the former the history is clear.

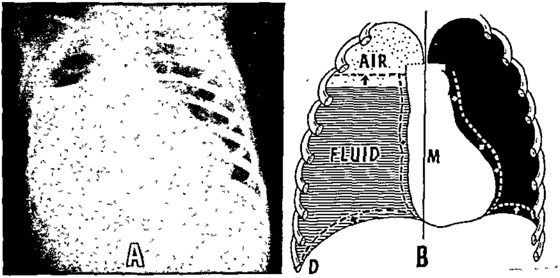

Fig. 215.—The diagnosis of empyema by fluoroscopic examination. Empyema of right pleural cavity. The child is in the upright position. Fixation has not occurred. *A*. X-ray photographs, posteroanterior. *B*. Diagram illustrating fluoroscopic observations. Both leaves of the diaphragm and both sides of the mediastinum move with respiration. As the diaphragm descends on inspiration, the fluid level moves down, and on *expiration* it moves upward. (From Berman, J. K.: Surg., Gynec. & Obst. 76: 183, 1943.)

There has been a pneumonia. The patient's temperature *had returned* to normal but has risen again, assuming a septic character. Percussion reveals dullness, absence of vocal fremitus (which had been increased during the pneumonia, due to consolidation), and absence of breath sounds. The x-ray is indispensable in diagnosis, as is also the aspiration of some pus for smear and culture to determine the type of organism at fault. The prognosis is good in pneumococcic empyema but is more serious in the streptococcic variety and most serious in *the staphylococcic type*.

The *treatment of empyema* will vary, depending on (1) its cause (traumatic or *nontraumatic*), (2) the causative organism (nontubercu-

lous, tuberculous, anaerobic), (3) the type of exudate (serous, hemorrhagic, purulent), (4) the extent of involvement (unilateral, diffuse, interlobar, localized, and bilateral).

Before discussing the various types and their treatment, it is well to consider the behavior of fluid in the chest. The systemic effects result from (1) the infection, (2) anoxemia, (3) anemia, (4) hypoproteinemia, (5) dehydration, all of which have been previously discussed in infections in general and also in diseases and injuries of the chest. The local effects are due to: (1) Fibrinous, purulent, or other deposits on the visceral or parietal pleura, more on the latter, but more important, the former, which compresses the lung, making it atelectatic. No matter what type of exudate, the fluid compresses the lung by its quantity. However, very soon a fibrinous deposit on the pleura prevents re-expansion, even if the fluid is withdrawn. (2) The formation of pockets due to the conversion of granulation tissue into fibrous tissue—inflammatory cysts. (3) Adhesive pleurisy, complete or partial.

Medical Treatment.—Medical treatment of empyema includes repeated aspirations, the introduction of penicillin or streptomycin or both into the empyema cavity, relief of atelectasis by bronchoscopic aspiration, systemic penicillin and sulfonamide therapy, attention to water and protein balance, and blood transfusion as indicated. As soon as fluid is discovered in the chest, it is aspirated and studied as outlined in preceding paragraphs. Then x-rays of the chest are made again. Fluoroscopic observation as outlined below is invaluable for diagnosis and for treatment. Daily thoracentesis should be done with the injection of 5 to 10 c.c. penicillin, 1,000 units per cubic centimeter, depending on the size of the cavity. By this method an empyema may be rendered sterile and if done early with persistence, the lung may expand and the cavity thereby obliterated. Thoracentesis without the injection of penicillin has been used for many years with good results in some cases. However, the cavity must be obliterated or it will become reinfected. Thus an inflammatory cyst might remain following what appears to be a complete cure of the inflammatory process. That has been a common observation. Here is what happens. When an empyema exists for just a short time and it is aspirated and penicillin has been used, complete resolution may occur; there are many authentic reports of such cases. However, in such patients it might have occurred without the use of penicillin due to repeated aspiration, or it might have occurred without any surgical treatment if we exclude aspiration as a surgical maneuver. But if any length of time transpires between the onset of the disease and the evacuation of the pus, then a pyogenic membrane or a leucocytic barrier is built up. That is granulation tissue, and the longer the delay in healing, the greater amount of this tissue. Granulation tissue goes through stages and finally becomes fibrotic. It becomes a scar, a very thick scar. That scar contracts; nature will not tolerate dead space so that dead space fills up with some-

usually acute and may occur as a complication of pneumonia (synpneumonic) or as a sequel (metapneumonic or postpneumonic). Since the introduction of penicillin and the sulfonamides, the incidence of the disease seems to be less, and, when it occurs, it is less virulent. It is caused by various organisms. The most virulent is the streptococcus (in the synpneumonic form), which invades connective tissue planes within the lung and continues out into the pleura, causing a spreading cellulitis (see Chapter 5). The pneumococcus usually causes the metapneumonic form and is much less virulent. The staphylococcic form is fortunately very rare; when it occurs, it is extremely virulent. In any of these the pleura becomes inflamed and edematous, and soon the entire pleural cavity is filled with thin (streptococcic) or thick (pneumococcic) pus. Should the pus burrow to the outside, or into other organs, it is called *empyema necessitatis*. The diagnosis is not difficult in the metapneumonic types but is in the synpneumonic. In the former the history is clear.

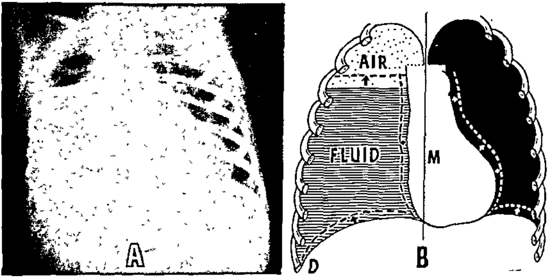

Fig. 215.—The diagnosis of empyema by fluoroscopic examination. Empyema of right pleural cavity. The child is in the upright position. Fixation has not occurred. *A*. X-ray photographs, posteroanterior. *B*. Diagram illustrating fluoroscopic observations. Both leaves of the diaphragm and both sides of the mediastinum move with respiration. As the diaphragm descends on inspiration, the fluid level moves down, and on expiration it moves upward. (From Berman, J. K.: Surg., Gynec. & Obst. 76: 183, 1943.)

There has been a pneumonia. The patient's temperature had returned to normal but has risen again, assuming a septic character. Percussion reveals dullness, absence of vocal fremitus (which had been increased during the pneumonia, due to consolidation), and absence of breath sounds. The x-ray is indispensable in diagnosis, as is also the aspiration of some pus for smear and culture to determine the type of organism at fault. The prognosis is good in pneumococcic empyema but is more serious in the streptococcic variety and most serious in the staphylococcic type.

The treatment of empyema will vary, depending on (1) its cause (traumatic or nontraumatic), (2) the causative organism (nontubercu-

atelectasis which is due to compression by the fluid as well as bronchial obstruction. If atelectasis persists, a residual cavity may be prevented by a pulling in of the chest wall and pulling over of a labile mediastinum. If the mediastinum is fixed, a space will remain between the atelectatic lung and the chest wall which will result in a chronic empyema if not detected. The treatment for an acute empyema which does not readily respond to medical management as determined by daily fluoroscopic studies is open drainage. The same is true for the persistent cavity.

Surgical Treatment.—A pleural infection behaves very much like pyogenic infections elsewhere, and as we shall see after the peculiarities of thoracic physiology are discussed, is amenable to the same forms of treatment as govern the foregoing. "A study of the pathology teaches one lesson in particular—that if the functional value of the lung is to be retained the septic process must be relieved at as early a stage as possible." (Fraser). Resolution may occur and does so in many instances. More commonly, localization takes place, in which event an abscess cavity is formed. Less often the infection is disseminated, giving rise to general septicemia and death.

During normal inspiration the diaphragm descends and the mediastinum is slightly narrowed. During expiration the reverse is true. In the child the mediastinum is a very movable structure easily affected by changes in intrathoracic pressure. The child also has a lower vital capacity than the adult. The child's lungs almost fill the entire pleural cavity. Normally the thorax grows away from the lung with increase in age, leaving a small pleural space. Consequently, the elastic recoil of the lung will be less in the child than in the adult, and therefore intrapleural tension in the child rises to zero at the end of expiration, whereas in the adult it remains below zero.

Dr. John Fraser, of Edinburgh, has demonstrated intrapleural pressure in a conclusive manner. He introduced a hollow aspirating needle of large bore (15 gauge) into the pleural cavity and attached it by a tube to a manometer. In this way he could accurately record pressures. He found that normally in a child of five years there is a range from minus 2 mm. Hg with expiration to minus 6 mm. with inspiration. In adults it is *more negative. In an empyema without walling in, and therefore without fixation of the mediastinum, the diaphragm, and the lower lung, there is a very wide fluctuation, the pressure varying from minus 5 mm. at inspiration to plus 10 mm. at expiration. However, after localization has occurred, the intrapleural pressure remains positive, with very little fluctuation, the pressure ranging from plus 5 mm. Hg to above plus 8 mm.*

This is a very important observation and clearly explains the surgical pathology of empyema. The intrathoracic space is increased by the displacement of the mediastinum and the descent of the diaphragm. This mediastinal displacement occurs very early in children and is due not only to a pushing over, but also to a "sucking" over by the heavily breathing lung of the other side. But after fixation occurs, there is little or no move-

thing and that "something" in this case is usually serum. It is sterile but it is apt to be infected over and over again and it is a menace. Although we may sterilize the cavity, the cavity does remain and will continue to be reinfected until it is obliterated. By "dead space" we mean space that has been produced by a disease process which was not there before. The body is full. We speak of pleural and peritoneal spaces. They are potential in that they are occupied or not, as physiological processes require them. Here is a space that was formerly occupied by lung; surrounding this lung was a thin pliable pleura. Now a space has been created which is surrounded by a thick scar, sometimes a half an inch thick, and we have seen them as much as two inches thick. Inside of this scar is an empty cavity. In it is serum, pus, or mucus, as a rule. In osteomyelitis or any chronic abscess or infected cavity, "dead space"

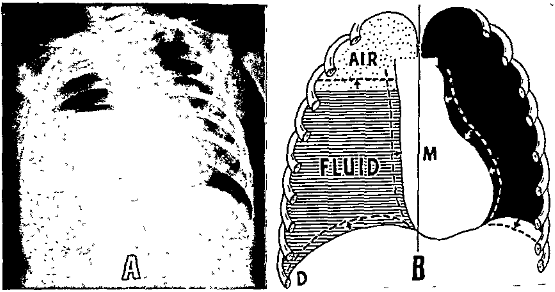

Fig. 216.—Patient in upright position. Empyema thoracis (right) after fixation. Paradoxical movement with deep inspiration; the left diaphragm descends and the left mediastinal shadow moves mesially. The right diaphragm ascends and the fluid level moves upward. *A*. X-ray photograph. *B*. Diagram illustrating movement. (*From* Berman, J. K: Surg., Gynec. & Obst. 76: 183, 1943.)

will exist unless the cavity is obliterated. In the chest it might be termed an inflammatory cyst. Such cavities or spaces are "dead" insofar as any normal function is concerned. Nature will not tolerate an empty space; it fills up with something. If sterile, it will fill with plasma from which serum exudes, thus forming an inflammatory cyst. If infected, it will fill with pus which may become sterile or be reinfected. Such spaces may be filled with air as seen in the brain (aerocele) or pleura, but the space does not remain empty. It has to fill with granulation tissue and turn into scar tissue, or it fills up with an exudate or a transudate. This is the reason for decortication operations in chronic empyema. The cavity is unroofed, and muscle and skin are transplanted to fill the void.

We shall discuss chronic empyema later. However, it should be added now that another cause for the persistence of a cavity is pulmonary

ment. The practical importance of this is obvious, for a patient can tolerate thoracic section in direct proportion to his vital capacity. If the mediastinum is not stabilized by adhesions, the normal lung suffers as much as the collapsed one. Furthermore, "mediastinal flutter" may compromise the circulation through the large venous trunks and the right auricle and may cause a kinking of the inferior vena cava as it passes through the diaphragm. The latter would be more apt to occur in right-sided empyema. But after localization occurs, so far as the thoracic mechanics are concerned, the empyema is a walled-in abscess and even with atmospheric pressure (760 mm. Hg or 14.7 pounds to the square inch) no harm occurs to the lungs or mediastinum. And, of course, as soon as the tube is removed, the opening immediately decreases in size until it is smaller than the main bronchus and negative pressure begins.

This walling in also implies that immunological localization has taken place. According to Thorsness and Higgins, this occurs for colloids after the first day and for crystalloids after the sixth day. By injecting aleuronat into the pleural cavity, this localizing process was well demonstrated by them. It is no doubt due to the formation of a pyogenic membrane with fibrin and clot occlusion of the lymphatics and later of the capillaries. An empyema, after localization has occurred, may be regarded as an abscess of the pleural cavity. If this is true, it should be treated as such. The next problem, then, was to evolve a method whereby one could find the proper time for surgical intervention by open drainage, for it was our belief that as soon as localiza*tion had occurred, operation was indicated, regardless of the consistency* of the pus or any other consideration than the ability of the patient to withstand surgical procedure.

Fraser's method for determining localization is not suitable for routine use and therefore a more practical way had to be found. We decided to use the fluoroscope as an aid. First, we observed normal subjects and we found that the mediastinal shadow is narrowed during inspiration and widened during expiration. The diaphragm descends during inspiration and ascends during expiration. With fluid, even though the mediastinum is pushed over and the diaphragm is down, there is still movement, as previously described, before walling-in occurs. However, *after localization* there is very little or no movement of the mediastinum, diaphragm, or compressed lung margin on the affected side and increased movement on the normal side. Using this method to determine the proper time for surgery, we have operated upon our patients as soon as fixation occurs. Fluoroscopic examination is made on all patients upon admission and then every other day until surgery is indicated. Other criteria such as height of fever, dyspnea, displacement of mediastinum, etc., are also used.

After localization, the second most important consideration in the treatment of an abscess is adequate drainage. In septicemia, if an acute focus can be removed or drained (all things being favorable), the patient

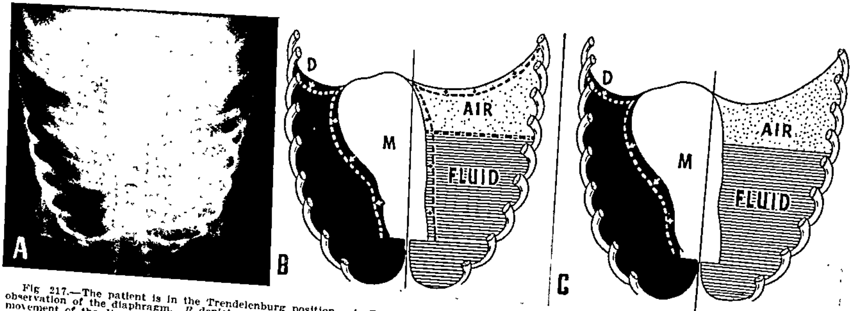

Fig. 217.—The patient is in the Trendelenburg position. *A*. Posteroanterior x-ray photograph. *B* and *C*. Diagrams illustrating fluoroscopic observation of the diaphragm. *B* depicts movement of the diaphragm cephalad (arrows) during expiration; air space decreased. It is the movement of the diaphragm that is observed. *C* shows fixation of the diaphragm. Note the band of adhesion to the diaphragm in the roentgenogram. (From Berman, J. K.: Surg., Gynec. & Obst. 76: 183, 1943.)

quired but always as infrequently as possible, for we believe with Paracelsus that "nature and not the surgeon heals wounds." We felt, too, that the tube acts as a foreign body and would actually perpetuate a cavity if left in too long. Therefore, after the seventh day the silkworm-gut suture is cut and the tube is allowed to "work its way out." This occurs due to rapid filling in of granulation tissue and some lung expansion.

If the tube is not out by the tenth day, a fluoroscopic examination is made. This will disclose fluid levels, or "pockets" with fluid, if any are present. By gently moving the patient, as *he stands upright behind the* fluoroscope, the fluid is clearly seen to move about due to the presence of air. If no fluid is present and if the drainage is thin, the tube is promptly removed. It should be remembered that the time required for the *obliteration of an empyema cavity may be exceedingly variable.* One cannot be dogmatic about the length of time that drainage should be continued. This depends upon the fluoroscopic examination and the character of the pus.

In treating our empyema cases we do not forget the patient as a whole. We have found adequate fluid intake and blood transfusions very helpful allies.

The surgical treatment of empyema is never an emergency, and in the case of streptococcic empyema, a long time is required for walling-in. Since most empyemas occur in children, we recently studied the problem and published a review describing the method of treatment which we have found successful. The treatment does not differ in adults. It should be said, however, that some authorities do not accept the "open" method of treatment (rib resection, or the removal of a small section of the sixth or seventh rib in the posterior axillary line), preferring the "closed" method, which consists of inserting a small catheter through a trocar introduced in the intercostal space. The trocar is re*moved and the catheter "sealed" in position by collodion. Some attach* a suction apparatus to the tube; others wash it at frequent intervals, aspirating the pus and then clamping again. The purpose is to maintain a negative pressure. Some authors advise repeated aspirations instead. It is perhaps better to wait for localization as determined by fluoroscopy and the character of the pus, then perform a thoracostomy by rib resection and introduce a large tube. No irrigations are done and the tube is removed in about two weeks. Breathing exercises are important if complications are to be avoided. These are outlined by Harken as originally described by Edwards. They are based on the idea that pressure over the lower and upper ribs, abdomen, and back (with the aid of a band) used successively will establish an afferent pathway whereby the patient can become conscious of the area during inspiration. During expiration the pressure *should be firmer and aids in expiration.*

No matter which method is employed in the treatment of empyema, a fundamental maxim is *the earlier the diagnosis, the sooner fluid may be*

probably will recover. Such is usually the case in metapneumonic empyema. Obviously, if a pneumonia is present (as in the synpneumonic form), the acute focus is in the lung, but if localization of the empyema has occurred, adequate drainage is indicated.

An abscess cavity properly drained must also be kept free of foreign bodies. This is done at the time of operation and any fibrinous masses which may form, later plugging the tube, are removed from it by forceps. The next step in the treatment of an abscess is obliteration of the dead space, to permit "healing from the bottom up." In empyema, healing takes place by granulations from the visceral pleura, which fuses with the parietal pleura, and by the ascent of the diaphragm. The lung expands because of (1) the contractile force of adhesions which pull it out, (2) positive pressure within the collapsed lung, because of air driven into it by forced expiration from the normal side, (3) the stretching effect of forced inspiration on the adhesions of the parietal pleura, which tend to inhibit expansion, and (4) negative pressure in the empyema cavity during inspiration, when the drainage opening is smaller than the main bronchus.

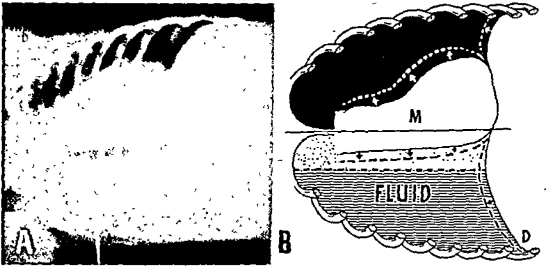

Fig. 218.—Empyema thoracis (right) observed with patient in lateral decubitus position. *A*. Roentgenogram showing the fluid level after aspiration and injection of air. *B*. Illustration depicting the movement of the diaphragm and mediastinum. With expiration the diaphragm moves upward and the mediastinal shadow widens (see arrows). The air space is narrowed. It is the movement of the mediastinal shadow that is observed. After fixation there is no mediastinal movement on the affected side.

Although massive empyema is uncommon now, the methods herein described are useful in determining the condition of the thorax, the amount of fluid, and the size of the cavity in empyemas and effusions of various types. Therefore, the maneuvers are those that will be very helpful in the diagnosis and treatment of various types of fluid accumulations. (From Berman, J. K.: Surg., Gynec. & Obst. 76: 183, 1943.)

If an abscess is to heal, the part must be put at rest and given a chance. Our study shows that prior to 1935, 77.2 per cent of these patients received daily irrigations with various solutions. Two nurses on Ward B of the Riley Hospital were kept busy giving this treatment. We have now discontinued all irrigations. Dressings are changed as re-

removed, and the sooner it is removed, the less the chance for complications or sequelae. It follows that in all types of empyema aspiration should be done first and may be continued if the amount decreases and the consistency remains thin. If purulent exudates are present, open drainage should be instituted unless the exudate may be removed as in fibrinous hemothorax (secondarily infected), where thoracotomy followed by closed drainage is indicated. Frequent fluoroscopic examinations are indispensable.

Complications and Sequelae.—Complications and sequelae result from: (1) Incomplete evacuation due to the following: (a) the disease was unrecognized and not treated. The empyema was walled in and remained as a cavity filled with serum or pus. (b) The disease was recognized

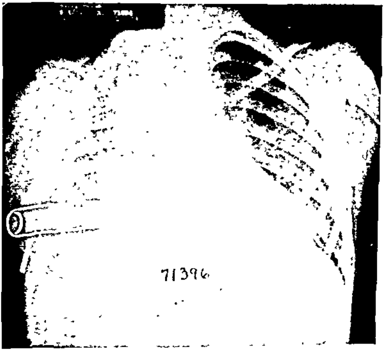

Fig. 219.—Empyema thoracis showing the tube in place after rib resection. The lung has collapsed. The chest is filled with air and a small amount of fluid. X-ray photograph retouched. This variety of empyema is uncommon now since the advent of antibiotic and chemotherapeutic agents.

and treated with a tube which was too small as in closed drainage methods, a tube large enough but removed too early, a tube improperly placed, allowing a pool of pus at the bottom of the cavity; encapsulated pockets were unrecognized at the time of operation and left behind; a foreign body may have been left, such as a piece of tubing, safety pin, piece of rib; persistent atelectasis due to the pressure of residual empyema or pain with incomplete expansion of the affected side. (c) Nature attempts to obliterate the cavity left by the disease by spontaneous drainage as in bronchopleural fistula by increased thickening of the pleura or by adhesions between visceral and parietal pleura even at the expense of pulling the labile mediastinum over or the chest wall in. Sometimes a classical deformity

Interlobar empyema is becoming more common along with many bizarre types which localize in unusual situations such as the apex and vertebral gutter. Diagnosis is usually not difficult, although lung abscess may resemble it and indeed may often be the forerunner of an interlobar accumulation. Thoracentesis, in addition to fluoroscopic examination as previously described, will usually reveal the diagnosis. Treatment by aspiration is often successful; the injection of penicillin is helpful.

Bilateral empyema is rare but requires early treatment, particularly in children whose vital capacity may be reduced to a critial level quickly. The diagnosis is made as in other types. Early aspiration is done and continued with the use of penicillin on one side at a time. Should open drainage be necessary, this may be safely done after localization.

Fig. 220 —Localized empyema. Interlobar empyema in fissure between middle and lower lobes at the level of the fifth rib. This is the type of empyema which is encountered more commonly at present, no doubt due to the effects of antibiotics and chemotherapeutic agents. *A*. Posteroanterior x-ray photograph. *B*. Lateral view.

Putrid empyema gets its name from the character of the pus which is malodorous due to the mixed flora of aerobes and anaerobes—chiefly the latter. Fusiform bacilli, spirochetes, and anaerobic streptococci are the chief offenders in the latter group. Putrid empyema is usually secondary to pulmonary abscess but is sometimes seen secondary to bronchiectasis and suppurative pneumonia. Other causes are perforation of esophagus, contamination of the pleural cavity following lobectomy, pneumonectomy or drainage of the pulmonary abscess, penetrating wounds of the thorax and mediastinum, gangrene of lung, and necrotizing pneumonitis. The symptoms and signs resemble those of other forms of empyema but

necessitatis, or bronchopleural fistula, it is enlarged. The cavity is explored, the visceral pleura removed insofar as possible or "criss-crossed" by incisions to let the lung expand if it will, and the parietal thickened pleura removed; adjacent ribs are also removed subperiostealy to give a bevelled rather than a sharp edge. If foreign bodies are present they are removed and secondary cavities are opened and unroofed. If the cavity is large, this operation must be done in stages because the patient will not stand the complete procedure in one stage. Furthermore, due to the presence of large numbers of microorganisms in the poorly drained cavity, any type of closure is apt to fail. Therefore, the unroofing is done in stages, and then three to four weeks later the closure is effected. This is more important in chronic tuberculous empyema, where the closure should not be done as long as tubercle bacilli are present, than in the nontuberculous variety. Closure is done as follows: The saucerized wound is held open and bronchopleural fistulae are closed by muscle flaps. Since proper cardiac and respiratory function are not possible without a rigid chest wall, the defect must be closed with firm tissue. Bone and cartilage would be best, but since these cannot be used, whole thick muscle transplants are employed—anteriorly the pectorals, laterally the pectoralis major, latissimus dorsi, and serratus anterior, and posterolaterally the sacrospinalis, latissimus, trapezius, supra- and infraspinatus, teres major, and minor. The muscles are sutured to the remaining visceral pleura. Then the skin is closed *loosely* over the defect, leaving a one-half inch gap. No drains or packing is used. A pressure bandage is applied.

The old Délorme operation was a decortication of the visceral pleura. Recently it has been used successfully in acute posttraumatic empyema and fibrinous hemothorax as previously described in this chapter. To peel the thick adherent visceral pleura off the lung in chronic empyema is difficult without tearing the lung with the danger of severe bleeding, bronchopleural fistulas, air embolism, and forbidding shock. The operation therefore is used only in selected cases in chronic empyema. Partial removal of this layer by light scraping may make it thinner, or criss-crossing may help by permitting some re-expansion of the underlying lung.

The treatment of lung complications associated with chronic empyema include lung exercises as described and may demand segmental resection if chronic abscess or bronchiectasis results.

Special Types of Empyema.—Although special types of empyema require recognition for proper treatment, their management does not differ greatly from the general treatment of empyema. The more common varieties which require special considerations are (1) interlobar empyema, (2) bilateral empyema, (3) putrid empyema, (4) tuberculous empyema.

Interlobar empyema is becoming more common along with many bizarre types which localize in unusual situations such as the apex and vertebral gutter. Diagnosis is usually not difficult, although lung abscess may resemble it and indeed may often be the forerunner of an interlobar accumulation. Thoracentesis, in addition to fluoroscopic examination as previously described, will usually reveal the diagnosis. Treatment by aspiration is often successful; the injection of penicillin is helpful.

Bilateral empyema is rare but requires early treatment, particularly in children whose vital capacity may be reduced to a critial level quickly. The diagnosis is made as in other types. Early aspiration is done and continued with the use of penicillin on one side at a time. Should open drainage be necessary, this may be safely done after localization.

Fig. 226.—Localized empyema. Interlobar empyema in fissure between middle and lower lobes at the level of the fifth rib. This is the type of empyema which is encountered more commonly at present, no doubt due to the effects of antibiotics and chemotherapeutic agents. *A.* Posteroanterior x-ray photograph. *B.* Lateral view.

Putrid empyema gets its name from the character of the pus which is malodorous due to the mixed flora of aerobes and anaerobes—chiefly the latter. Fusiform bacilli, spirochetes, and anaerobic streptococci are the chief offenders in the latter group. Putrid empyema is usually secondary to pulmonary abscess but is sometimes seen secondary to bronchiectasis and suppurative pneumonia. Other causes are perforation of esophagus, contamination of the pleural cavity following lobectomy, pneumonectomy or drainage of the pulmonary abscess, penetrating wounds of the thorax and mediastinum, gangrene of lung, and necrotizing pneumonitis. The symptoms and signs resemble those of other forms of empyema but

usually there is an associated productive cough with foul sputum due to lung abscess or bronchiectasis. If a general empyema instead of a localized type develops, the cough may cease but all other symptoms are aggravated. In those cases with little cough the symptoms resemble those of pneumonia. The diagnosis is made as in other forms of empyema and is definitely established by the aspiration of foul pus. *Early open drainage* is imperative. This is possible because of extensive adhesions and fixation of the mediastinum and diaphragm and is necessary because the bacteria are anaerobes and, if left in situ, will necrotize the adhesions and cause a widespread dissemination of the infection, including a cellulitis of the chest wall at the sites of thoracentesis. The mortality is high, up to 13 per cent in some statistics, due to the associated lesions and virulence of the organisms; another type of putrid empyema is that due to *Escherichia coli* which follows perforated appendicitis or other intra-abdominal infections or perforations with subphrenic abscess. The colon bacillus is a gas producer and may cause confusion in diagnosis. Usually bronchopleural fistula is thought of when the x-ray film is first seen. However, the history, associated disease, fluoroscopic examination (which is particularly helpful in distinguishing between supra- and subdiaphragmatic accumulations of air and fluid), and thoracentesis will make the diagnosis. Open drainage is indicated. In the anaerobic variety of putrid empyema, penicillin, streptomycin, and sulfadiazine are used. In the colon bacillus type, streptomycin is added up to 4 Gm. daily, given intramuscularly.

Tuberculous empyema has been discussed in Chapter 8 but should be considered here due to the commonness of the mixed types. Tuberculous pleural effusions are common. In fact, a clear straw-colored fluid which on microscopic examination shows only a few lymphocytes and no tubercle bacilli is often seen in the absence of any demonstrable pulmonary lesion. This fluid should be aspirated and injected into a guinea pig for diagnosis. The fluid should be aspirated at frequent intervals as previously described. *Empyema implies the active growth of tubercle bacilli* in the fluid. Three types are seen: (1) a thin cloudy fluid without pus but with demonstrable tubercle bacilli, (2) a more purulent type without pyogenic organisms, and (3) a mixed type with frank pus and pyogenic bacteria as well as tubercle bacili. In all types the primary consideration is the general care of tuberculosis by medical means. At present this includes the use of streptomycin for short periods of time. In addition, the first type may be controlled by repeated aspiration. If thoracoplasty seems indicated, it should be done. In the second type a thickened pleura may be present and thoracoplasty may not cause a collapse of the pleural cavity. Decortication may be done in early cases; however, there is danger of a mixed type of empyema. In the third or mixed type open drainage should be done promptly. Here the Eloesser flap may be used to avoid tubes (which act as foreign bodies) and yet produce prolonged drainage. This is accomplished by turning in a flap of skin

after thoracotomy and suturing it to the parietal pleura. Should a chronic empyema cavity result, as will usually occur, it should be saucerized and closed as previously described. We have recently done combined visceral and parietal decortication in several cases of this type with encouraging results. This procedure is useful in cases without active intrapulmonary disease. In the presence of active parenchymal lesions or cavities, decortication would mobilize the lung and disseminate the infection inside as well as outside the lung in the pleural cavity.

PNEUMOTHORAX

We have already considered pneumothorax under Injuries to Chest and in Chapter 8 under Tuberculosis. The term is ordinarily used to mean *intrapleural* collections of air. Extrapleural pneumothorax does occur in connection with penetrating injuries and subcutaneous emphysema, extrapleural infections with gas-producing organisms, and also as a result of the injection of air extrapleurally for therapeutic reasons in the treatment of tuberculosis. *Intrapleural* pneumothorax may be due to an open or penetrating wound, traumatic pneumothorax, or, under tension, tension pneumothorax. Spontaneous pneumothorax usually is associated with pulmonary tuberculosis, and artificial pneumothorax is used to produce a lung collapse in the treatment of the disease (see Chapter 8).

Pneumothorax may be associated with extraneous air in the tissue (interstitial emphysema, subcutaneous emphysema), in the mediastinum (mediastinal emphysema), and in the abdomen (pneumoperitoneum). Other causes for acute pneumothorax are cystic disease of the lung, emphysema, blebs due to emphysema of the "giant" variety or cysts associated with "giant" emphysema, and in the so-called "chronic" types of spontaneous pneumothorax, bands in addition to blebs cause repeated attacks. The treatment of spontaneous pneumothorax depends upon the cause. If not under tension, it is probably best left severely alone until it is absorbed; then careful x-ray and bronchoscopic studies may be done to determine the underlying lesion. If it persists, it should be aspirated and diagnosis of the morbid anatomy of the lung made. If no lung disease is found, no active treatment is instituted. In cystic disease, lobectomy or segmental resection may be necessary, whereas in emphysema, unless of the bulbous type, surgery is not necessary. Sometimes it is difficult to differentiate between a giant cyst and a spontaneous pneumothorax, especially if it is a hydropneumothorax. Aspiration under such circumstances may be unwise because of the danger of empyema. Spontaneous pneumothorax is not uncommon after major surgery in the abdomen or elsewhere. It may be very serious and result in death from anoxemia even though unilateral and almost always when bilateral in spite of any treatment.

THE LUNGS

Within the pleural cavities lie the lungs (pulmones) with which we breathe. Impure blood is brought to the right auricle by the superior vena cava (from the head and neck) and by the inferior vena cava (from the rest of the body). From here it goes

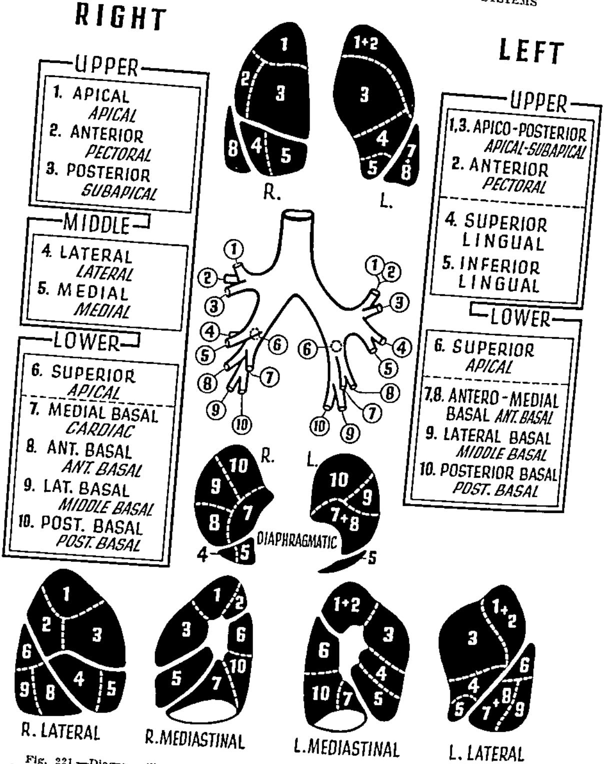

Fig. 221.—Diagram illustrating the tracheobronchial branching correlated with subdivisions of the lungs after Jackson and Huber. (Nomenclature based upon studies of Jackson, C. L., and Huber, J. F.: Correlated Applied Anatomy of the Bronchial Tree and Lungs With a System of Nomenclature Dis. Chest 9: 319, 1943; Boyden, E. A.: A Synthesis of the Prevailing Patterns of the Bronchopulmonary Segments in the Light of Their Variations, Dis. Chest 15: 657, 1949; Brock, R. C.: The Anatomy of the Bronchial Tree, London, 1946, Oxford University Press [also personal communication]; Scannell, J. G.: An Anatomic Approach to Segmental Resection, J. Thor. Surg. 18: 64, 1949.)

through the tricuspid valve to the right ventricle which pumps it to the lungs through the pulmonary artery. In the lungs the impure blood releases its carbon dioxide and takes its oxygen and then hurriedly rushes through the pulmonary vein to the left auricle, through the mitral valves to the left ventricle and out into the aorta to be carried to all parts of the body. To make this purification possible the lungs are composed of tiny air sacs (alveoli) which are made up of epithelial cells fused into thin, structureless plates of tissue. Immediately adjacent to these plates are the endothelial cells of the capillaries. In addition, there are elastic fibers which allow the alveoli to

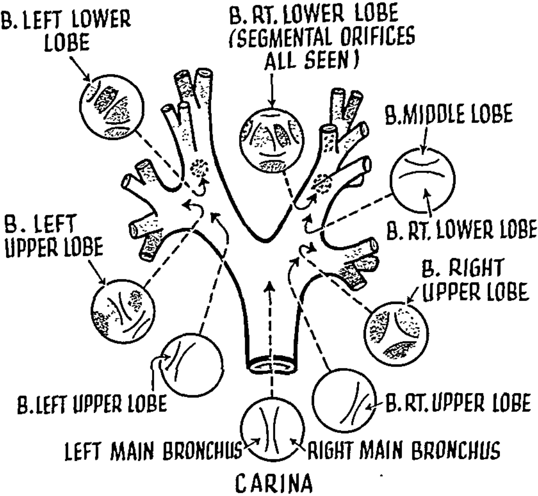

Fig. 222.—Diagram of the bronchi to the lobes and their segmented branches with endoscopic landmarks as seen through the bronchoscope when the patient is examined in the dorsal recumbent position. (Redrawn from Jackson and Huber: Correlated Applied Anatomy of the Bronchial Tree and Lungs With a System of Nomenclature, Dis. of Chest 9: 1, 1943.)

become greatly distended and some macrophage cells (dust cells) to engulf foreign bodies, such as soot, thus making the adult lung gray. Respiration takes place by the transfer of gases through the alveolar plates and endothelial cells. The alveoli are gathered about the bronchioles. These lead to the bronchi, which lead ultimately to the trachea. The entire lung is divided into lobes: three in the right and two in the left. These in turn are subdivided into segments (Fig. 221) with names as indicated by Jackson and Huber. The general scheme of division is based upon a broncho-

vascular distribution, making possible segmental resection in bronchiectasis and other diseases for which only a portion of the lobe need be removed. At surgery the lobe is deflated, the bronchus temporarily occluded and then reinflated by positive pressure through the endotracheal tube. In this manner avascular planes are found between segments, allowing for a bloodless dissection between these units. The divisions of the lung on the right are upper, middle, superior lower, and basal lower; on the left there are the upper, lingular, superior lower, and basal lower. These are subdivided into segments as shown in Fig. 221. In addition, there may be extra lobes such as the azygos lobe, caused by an abnormal position of the vein, producing a septum in the right upper lobe covered by two layers of parietal and visceral pleura because the vein is extrapleural. Another is an extra lobe in the space between the pericardium and diaphragm on the right or left side.

We have already studied the mechanics of respiration. It remains to be said that respiration is under the control of the respiratory center in the medulla. This center is affected by (1) voluntary impulses, (2) gases—carbon dioxide, and, to a lesser degree, oxygen, and (3) nervous impulses by way of the vagi and sensory nerves, which may have a pressor or depressor effect (discussion under Physiology of Respiration).

Congenital Anomalies of the Lungs

In addition to the extra lobes which are occasionally seen, there may be other anomalies. We have recently seen a case of complete agenesis of the left lung with a blind left main stem bronchus. Pericardial deficiency with bronchiogenic cyst has been called iter venosum since it is due to abnormal development of the left duct of Cuvier.

Cystic Disease of the Lungs.—Cystic disease of the lungs may be congenital or acquired. Sometimes the distinction is very difficult and cannot be made even by microscopic study. This is due to the fact that abscess cavities become epithelialized and cyst cavities become infected. In the newborn true cystic disease is suspected. Widespread cystic disease consisting of hundreds of various-sized cysts involving one or more lobes or even both lungs is practically always congenital. Other names given to cystic diseases are pulmonary cysts, bronchogenic cysts, pneumocysts, and pneumatoceles. Some authors include cystic bronchiectasis which may be present at birth or acquired later in life. However, mediastinal cysts of bronchogenic type, parasitic, hydatid cysts, tuberculous cavities or cavitary infections, or carcinoma should not be included.

True Congenital Cystic Disease.—True congenital cystic disease includes some bronchogenic or bronchoalveolar cysts. The cysts are found in the pulmonary parenchyma and sometimes are attached to the trachea or a main stem bronchus. They are lined with bronchial epithelium, but their walls contain cartilage, smooth muscle, elastic tissue, and glands in more or less disorderly arrangement. Therefore, some pathologists have called them cystic teratomas. Pulmonary abscess and simple bronchial dilatation usually have a different picture but may be similar. Clinically and pathologically, two types are seen: the large solitary cyst seen in infancy and childhood as a rule and the multiple cystic disease composed of multilocular or unilocular cysts. The latter type may be associated with polycystic disease of the kidneys and liver. Complications of congenital cystic disease include accumulations of fluid, hemorrhage,

secondary infection, hemopneumothorax, pneumothorax, empyema, acquired cysts, bronchiectasis, pneumatocele, pneumonia, and all of the other complications of chronic pulmonary suppuration.

Acquired types include pneumatoceles, which have no epithelial lining and therefore tend to disappear spontaneously, abscess cysts, emphysematous blebs, and bullae. Other cysts include bronchogenic cysts and pulmonary cysts resulting from infection, penetrating wounds, hemorrhage and noxious gases.

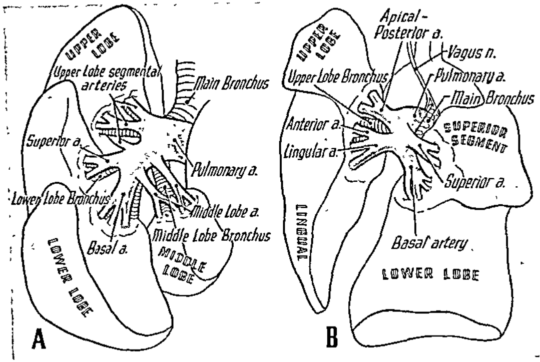

Fig. 223.—Diagram illustrating the pulmonary arteries with their branches. *A*, Right pulmonary artery as seen anteriorly with the lobes widely separated. The middle lobe has been rotated medially; its arteries run posterior to the bronchus although the diagrams make them appear anterior because of the retraction of the lobe. The main artery descends below the upper lobe bronchus. The first branch is usually the common stem superior pulmonary trunk which separates into the apical and anterior segmental arteries. The third artery usually supplying the upper lobe is the posterior segmental branch which arises from the inferior trunk opposite the middle lobe branches and ascends into the posterior portion of the upper lobe. The inferior pulmonary trunk is found anterior to the intermediate bronchus. The medial and lateral arteries to the middle lobe arise from the anterior aspect of the inferior trunk. Sometimes they begin as a common trunk and split into medial and lateral and often other branches. The basal branches follow the corresponding bronchi. The first branch is the superior segmental artery and it arises at the same level and posterolateral to the middle lobe branches. The arteries to the basal segments arise from the inferior pulmonary trunk independently. They are the medial, anterior, lateral, and posterior basal segmental arterial branches.

B. The left pulmonary artery lies above the left main bronchus and the superior pulmonary vein just beneath the aortic arch. This diagram shows the branches with the lobes widely separated. The artery winds around and behind the upper lobe bronchus. The first branch is the apical-posterior segmental artery which divides into an ascending or apical and posterior segmental branch. Sometimes the two branches originate independently. The next branch to the upper lobe is the anterolingular trunk which gives rise to the anterior segmental branch and the two lingular branches. The latter may come off as a common trunk and then divide, or they may come off the anterolingular trunk independently as illustrated. They supply the superior and inferior lingular bronchopulmonary segments.

Branches to the lower lobe come off the interlobar portion of the artery. The superior segmental branch arises at a higher level than the lingular arteries. It divides into two or three branches. The arteries to the basal segments lie anterolateral to the bronchi and are four in number—anterior, medial, lateral, and posterior basal. (Modified from Overholt, R. H., and Langer, L.: Surg., Gynec. & Obst. 84: 257-268, 1947.)

Diagnosis.—Diagnosis is made by the history and symptoms and signs. The latter include cough which may or may not be productive, depending upon whether or not there is a communication with a bronchus. Hemoptysis may be present. Any of the findings of chronic pulmonary disease may be present, making the differential diagnosis difficult. Such lesions as dermoid cysts or other neoplasms, abscess, localized empyema, cavitary tuberculosis, hydatid cyst, and diaphragmatic hernia must be taken into consideration. X-ray examination and bronchography with Lipiodol are of great help.

Treatment.—Treatment depends upon the type of cyst encountered. In general it is surgical and includes the complete removal of the cystic portion of the lung, conserving as much lung tisue as possible. Partial or complete lobectomy or pneumonectomy may be required. Age is no contraindication to surgery.

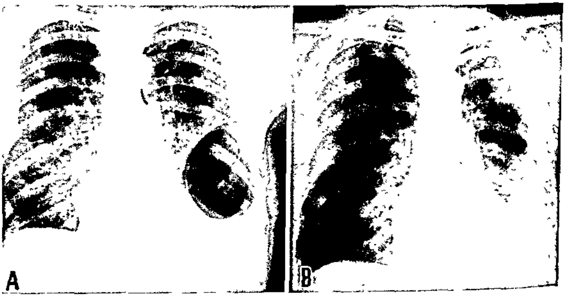

Fig. 224.—Pulmonary cyst of the lung. *A.* Pulmonary cyst of the left lower lobe. T. U. C., a man aged 50 years, first noticed symptoms after a severe blow on left chest by a falling post. These consisted of persistent cough, dyspnea, and pain in the left lower chest and left shoulder. They were thought to be due to possible rupture of smaller cysts into the larger one. The patient is emphysematous as disclosed by the decrease in peripheral markings and hyperillumination of lung fields with accentuation of the hilar markings. The differential diagnosis included bullous emphysema (pneumatocele, pneumocyst, balloon cyst) due to giant bullae formation, pneumothorax localized due to previous adhesions; congenital cystic disease because of the small cyst in the right lower lobe, and inflammatory cyst (old lung abscess which had sealed off the previously communicating bronchi with gradual absorption of retained exudate). Final diagnosis was acquired lung cyst due to lobular emphysema with check valve obstruction of the bronchial lumina. Left lower lobectomy was done. Microscopic examination showed pulmonary cyst, fibrosis, patchy pneumonitis, and anthracosis of pulmonary tissue. *B.* Postoperative film. There is still some pleural reaction in the left costophrenic angle. Patient made an uncomplicated recovery. (Case referred by Dr. R. Henry and Dr. D. Stone.)

Arteriovenous Fistula of the Lung.—Arteriovenous fistula of the lung may be congenital or acquired. The latter is rare. Congenital types are really large cavernous hemangiomas which are found anywhere in the lung and may include the mediastinnm. They lead to anoxemia with cyanosis, polycythemia, osteoarthropathy, and other symptoms, due

to the interference with respiration and poor oxygenation, because impure blood is shunted from the pulmonary arteries to the pulmonary veins. On auscultation a continuous murmur is heard. The x-ray examination shows the shadow which may be seen to pulsate under the fluoroscope. Angiography aids greatly in the diagnosis. The treatment is lobectomy or, in rare cases, pneumonectomy.

Injuries.—Injuries to the lung result from fractured ribs, punctured wounds, gunshot wounds, or blast injuries. The effects of such injuries are collapse of the lung and hemorrhage. The patient coughs up bright red blood, is dyspneic, and may go into shock. Soon the pleural cavity may fill with blood, or if the injury is less extensive, blood fills the alveolar spaces, producing consolidation with dullness, increased vocal fremitus, and tubular breathing. The treatment consists of closure of the wound at once and wiring or otherwise immobilizing rib fragments, morphine for sedation, and blood transfusion. Dyspnea is relieved by the administration of oxygen. Thoracotomy may be necessary. (See discussion under Injuries to the Chest.)

Infections of the Lung

Pneumonia.—Perhaps the most common *inflammatory* lesion is pneumonia. Pneumonia may be defined as an infectious inflammatory lesion of the lung caused by pathogenic bacteria and characterized by exudation with more or less consolidation. It may be classified as lobar, broncho pneumonia, lobular or patchy, central, interstitial, aspiration or postoperative, and hypostatic. It may be caused by the pneumococcus, streptococcus, staphylococcus, Friedlander's bacillus, *Hemophilus influenzae*, tubercle bacillus, virus, and miscellaneous infections such as influenza, tularemia, coccidioidomycosis, moniliasis, and histoplasmosis. The surgeon is particularly interested in those types of pneumonia due to aspiration, bronchial obstruction, and hypostasis. To avoid this, every provision is made for keeping the trachea and bronchi free from foreign material. The stomach is aspirated in pyloric occlusions; the esophagus is emptied in esophageal occlusions; frequent aspirations are done if there has been any vomiting. The patient is placed in the head-down position and, after all lung operations, the anesthetist sucks out the trachea through the endotracheal tube and again after its removal at the conclusion of the operation. Early mobilization, deep breathing, holding the chest and forcing the patient to cough after chest operations prevents and relieves bronchial obstruction and hypostasis. The pre- and postoperative use of the sulfonamides and penicillin also help to prevent these complications and to control pneumonia after it occurs. Oxygen is used after chest operations and others as indicated with reservations as previously outlined in this chapter. Postoperative pneumonia is more common after spinal than inhalation anesthesia. The latter does cause bronchial irritation; the former is accompanied by small emboli

Diagnosis.—Diagnosis is made by the history and symptoms and signs. The latter include cough which may or may not be productive, depending upon whether or not there is a communication with a bronchus. Hemoptysis may be present. Any of the findings of chronic pulmonary disease may be present, making the differential diagnosis difficult. Such lesions as dermoid cysts or other neoplasms, abscess, localized empyema, cavitary tuberculosis, hydatid cyst, and diaphragmatic hernia must be taken into consideration. X-ray examination and bronchography with Lipiodol are of great help.

Treatment.—Treatment depends upon the type of cyst encountered. In general it is surgical and includes the complete removal of the cystic portion of the lung, conserving as much lung tisue as possible. Partial or complete lobectomy or pneumonectomy may be required. Age is no contraindication to surgery.

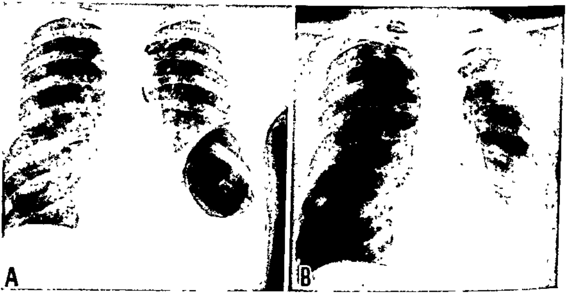

Fig. 224.—Pulmonary cyst of the lung. *A.* Pulmonary cyst of the left lower lobe. T. U. C., a man aged 50 years, first noticed symptoms after a severe blow on left chest by a falling post. These consisted of persistent cough, dyspnea, and pain in the left lower chest and left shoulder. They were thought to be due to possible rupture of smaller cysts into the larger one. Arteriovenous Fistula of the Lung.—Arteriovenous fistula of the lung may be congenital or acquired. The latter is rare. Congenital types are really large cavernous hemangiomas which are found anywhere in the lung and may include the mediastinum. They lead to anoxemia with cyanosis, polycythemia, osteoarthropathy, and other symptoms, due

(1) penetration from outside; (2) blood stream infections (septicopyemias) and phlebothrombosis, which rarely causes a pulmonary abscess in our experience; (3) aspiration, such as foreign bodies spill from esophageal obstruction, etc., (4) extension from subphrenic or perinephric or retropharyngeal abscess. The causative organisms are variable, including aerobes and anaerobes, pneumococci, staphylococci, fusiform bacilli, hemolytic streptococci, *Micrococcus catarrhalis*, spirochetes and many others.

Pathology.—The pathology varies with the cause and the organisms found. Abscesses may be single or multiple, unilateral or bilateral, in the upper or lower lobe (about equal), and if in the lower, it is in the posterior basal or apical portion. Every lung abscess begins with a localized pneumonitis which is often thought to be a lobar pneumonia. The mechanism of infection is due to an obstruction of the bronchus or bronchiole in aspiration types (putrid abscess) or by embolism, in which the pulmonary artery branches are obstructed. In either instance we note the element of obstruction first. In the former, atelectasis results which makes the area suitable soil for bacterial growth because of interference with the blood supply; in the latter, infarction results from vascular occlusion and local anoxemia and then the infection begins. We have seen that the lobes of lungs are divided into bronchovascular segments. It is in the periphery of these segments that abscess is most apt to occur. The so-called central abscess may appear to be central but is usually at the periphery of a segment or facing a fissure, the diaphragm, mediastinum, or pericardium. This is important because if true, abscesses will be peripheral with only a little margin of lung between them and the pleura; moreover, there will be early adhesions between the visceral and parietal pleura. The reaction of the tissue to the bronchial or vascular insult will result in (1) no infection or, if infection occurs, resolution may and does occur; (2) necrosis with absorption as in infections elsewhere; (3) necrosis with sloughing; or (4) suppuration which may occur within two weeks from the time of onset. After about six weeks, other lesions may appear; secondary abscess, multilocularity, due to spilling over into adjacent bronchi or through intercommunicating bronchi, spread of infection peripherally along bronchovascular segment, interstitial pneumonitis, fibrosis and bronchiectasis, epithelialization, hemorrhage, rupture of the abscess with empyema, bronchopleural fistula, involvement of surrounding lung with thickening and fibrosis of septa and complete obliteration of alveoli, and metastatic abscess in the skin, kidneys, spleen, and, rather commonly, in the brain. The abscess may be simple (early) or complicated (late). Very late there may be clubbing of the fingers and amyloid disease. The abscess may break into an open bronchus or bronchi and be coughed up, or it may rupture into the pleural cavity; in either instance the abscess may then heal, but in the latter a residual empyema may remain.

with pneumonia. Bronchial irritation and occlusion with mucous plugs is a common cause of pneumonia and atelectasis. The pernicious habit of keeping patients so narcotized that their respirations are shallow and they are immobile for long periods of time is perhaps the greatest cause of this complication.

Lipoid Pneumonia.—Lipoid pneumonia occurs after fractures of the long bones, due to fat emboli. Recently some have thought that it may occur as a result of the use of oil in the nose, or even in the eyes, through aspirations of the fatty droplets.

Above all, the old debilitated patient is a ready host for bacteria due to his weakened resistance, and he must be watched carefully and moved early. The surgeon is called upon not infrequently to care for lung abscess and empyema following pneumonia.

Pulmonary Abscess and Gangrene.—Lung tissue may be infected by many organisms and reacts in many different ways. What might be said to be a general infection of the lung is seen in pneumonia. The local type of infection, which may follow, is seen in abscess and gangrene.

Etiology.—Experimentally it is difficult to produce an abscess by the injection of infected material into the bronchial tree because of the cough reflex and the normal action of the cilia. If the bronchus is blocked by a foreign body or if infected emboli are used, abscess results. The cause of lung abscess is not clearly understood; perhaps it is better to say there are probably many causes. A lung abscess may occur after an acute upper respiratory infection or pneumonia but is more commonly seen postoperatively. In general, the infection has two ways of entering. The first is by the bronchial tree. After operations done under general anesthesia, infected mucus or blood is aspirated and even bits of tonsil or other tissue may lodge in a bronchiole. This produces an atelectasis of a small lobule or lobe, with subsequent infection. (Closure of the outlet traps virulent bacteria.) This type sets up a gangrenous bronchopneumonia of the bronchopulmonary segment with liquefaction and abscess formation. Since we see this condition after operations other than those performed on the nose or throat, and when local or spinal anesthesia has been used, we must assume that the second way infection enters the lung is by embolism (see Chapter 17). In either case, an area of infarction ensues, with destruction of lung tissue and subsequent suppuration. The history is usually typical. An operation was performed a week before; then the patient developed a dry cough. There was fever, which became septic in type. Soon the cough became productive, with foul-smelling sputum. Then there was dullness on percussion and râles were heard.

Other causes for abscess are foreign bodies, subphrenic abscess, congenital cystic disease, penetrating wounds, retropharyngeal abscess, spillover from esophageal obstruction due to carcinoma, diverticulum, or achlasia. In general, the causes may be summarized into four avenues:

chronic types it may help in the differential diagnosis between bronchogenic carcinoma, lung cyst which is secondarily infected, bronchiectatic cavity, localized empyema, interlobar empyema, and tuberculosis. Repeated sputum examinations and thoracentesis may aid in the diagnosis. Fluid levels on x-ray examination are seen in only one-half of the cases. The presence of multiple types of lesions is an ever-present possibility; abscess with carcinoma (about 5 per cent in our cases) or with tuberculosis is not uncommon. Carcinoma and abscess are common enough to warrant comment. The combination may be due to the carcinoma itself which is secondarily infected or due to the obstruction of bronchi by the growth causing abscesses distally; if the neoplasm is in the upper lobe, there may be spill over with subsequent abscess in the lower lobes.

Treatment.—Prophylactic treatment includes care of the mouth prior to any elective surgery but no radical "clean up" which may disseminate infection. The anesthetic and early postoperative periods are important in the prevention of lung abscess. Vomiting with aspiration of food particles, if the patient has some type of gastric obstruction, may be prevented by gastric aspiration. This is done routinely in pyloric obstruction from any cause not only because of vomiting but because decompression is necessary for successful surgery. Emesis of liquids may be equally disastrous if aspirated. Foreign bodies such as teeth, bits of tonsil, blood, and mucus may act as the nidus for an abscess. The same factors are true during the early postoperative periods. Here deep breaths and encouragement to cough are most important. If coughing is too painful, enough sedation is used to make it possible or the pharynx and upper trachea are aspirated with a catheter attached to a suction machine. Aspiration by bronchoscopy should be done after long deep anesthesia and thoracic operations where endotracheal anesthesia has been used. Strong sedatives and narcotics are used sparingly. The patient is mobilized early and encouraged to cough.

Medical treatment should be given a trial for six to eight weeks. Sulfadiazine in large doses, penicillin intramuscularly, 100,000 units every three hours, streptomycin, 0.25 Gm. every six hours, and postural drainage and bronchoscopic aspiration should be given a trial.

Later, after adhesions have formed (three to four weeks), the abscess cavity may be aspirated and pencillin with streptomycin injected. This will be coughed up as a rule because there are usually two to three bronchi which open into the cavity. Bronchoscopy is very helpful and is imperative if a foreign body is suspected. It should be given a trial.

Surgical treatment consists of drainage of the abscess cavity or removal of the affected lung segments. If medical treatment fails after six to eight weeks, thoracostomy may be done. We do not use the two-stage operation because adhesions are present early between the visceral or parietal pleura and the two-stage operation cripples the lung unnecessarily. The abscess having been located by x-ray, one or two rib sections

Symptoms and Signs.—The earliest and most persistent symptom is cough, unproductive at first, then odorless sputum, and finally foul sputum. Hemoptysis in about one-half the cases, chills and fever, rapid weight loss, dullness on percussion, suppressed breath sounds, and râles

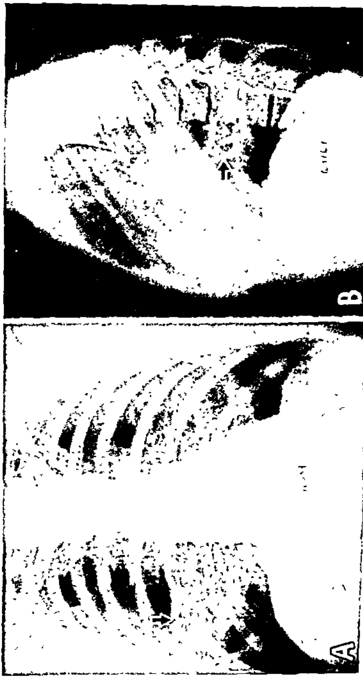

Fig. 225.—*A*, Lung abscess, right middle lobe. There is thickening of the interlobar pleura between the middle and the upper lobe. A fluid level may be seen in the abscess cavity, which is surrounded by a rather large inflammatory zone. *B*, Lateral view. The arrow points to the abscess cavity. Lobectomy of right middle lobe was done.

over the abscess area are present. X-ray examination (posterioranterior, lateral, and oblique films) is necessary for diagnosis and exact location of the abscess. Bronchoscopic examination is helpful but bronchography with Lipiodol is useless in the acute phase because it will not enter the cavity because of bronchiolar obstruction and may be dangerous. In the

chronic types it may help in the differential diagnosis between bronchogenic carcinoma, lung cyst which is secondarily infected, bronchiectatic cavity, localized empyema, interlobar empyema, and tuberculosis. Repeated sputum examinations and thoracentesis may aid in the diagnosis. Fluid levels on x-ray examination are seen in only one-half of the cases. The presence of multiple types of lesions is an ever-present possibility; abscess with carcinoma (about 5 per cent in our cases) or with tuberculosis is not uncommon. Carcinoma and abscess are common enough to warrant comment. The combination may be due to the carcinoma itself which is secondarily infected or due to the obstruction of bronchi by the growth causing abscesses distally; if the neoplasm is in the upper lobe, there may be spill over with subsequent abscess in the lower lobes.

Treatment.—Prophylactic treatment includes care of the mouth prior to any elective surgery but no radical "clean up" which may disseminate infection. The anesthetic and early postoperative periods are important in the prevention of lung abscess. Vomiting with aspiration of food particles, if the patient has some type of gastric obstruction, may be prevented by gastric aspiration. This is done routinely in pyloric obstruction from any cause not only because of vomiting but because decompression is necessary for successful surgery. Emesis of liquids may be equally disastrous if aspirated. Foreign bodies such as teeth, bits of tonsil, blood, and mucus may act as the nidus for an abscess. The same factors are true during the early postoperative periods. Here deep breaths and encouragement to cough are most important. If coughing is too painful, enough sedation is used to make it possible or the pharynx and upper trachea are aspirated with a catheter attached to a suction machine. Aspiration by bronchoscopy should be done after long deep anesthesia and thoracic operations where endotracheal anesthesia has been used. Strong sedatives and narcotics are used sparingly. The patient is mobilized early and encouraged to cough.

Medical treatment should be given a trial for six to eight weeks. Sulfadiazine in large doses, penicillin intramuscularly, 100,000 units every three hours, streptomycin, 0.25 Gm. every six hours, and postural drainage and bronchoscopic aspiration should be given a trial.

Later, after adhesions have formed (three to four weeks), the abscess cavity may be aspirated and pencillin with streptomycin injected. This will be coughed up as a rule because there are usually two to three bronchi which open into the cavity. Bronchoscopy is very helpful and is imperative if a foreign body is suspected. It should be given a trial.

Surgical treatment consists of drainage of the abscess cavity or removal of the affected lung segments. If medical treatment fails after six to eight weeks, thoracostomy may be done. We do not use the two-stage operation because adhesions are present early between the visceral or parietal pleura and the two-stage operation cripples the lung unnecessarily. The abscess having been located by x-ray, one or two rib sections

are removed, and if adhesions are found, aspiration is done, and then the abscess cavity is opened and drained with soft rubber dam tissue. If the abscess is not adherent as in the interlobar type, the normal lung may be sutured to the parietal pleura, then aspirated, and a small Penrose drain inserted. The two greatest dangers from open drainage are hemorrhage and brain abscess due to septic emboli. Some will not heal and the remaining abscess must be removed with the lung segment. Such cavities are usually lined with epithelium. Sometimes the cavity may be closed by muscle flap transplants. Open drainage is not often employed by us except when associated with empyema.

Complicated (multiple abscess, bronchiectasis) and late abscess cavities will not heal by open drainage in most cases. For these we use segmental resection or lobectomy. If multiple and disseminated abscesses are present, pneumonectomy may be necessary to effect a cure. Following lobectomy, closed drainage is employed anteriorly and posteriorly.

Abscess with empyema requires open drainage and additional opening of the abscess cavity so that it will drain properly. Thus the abscess and bronchopleural fistula will fill in as the empyema heals. Chronic empyema is treated by the Schede thoracoplasty with closure of the cavity by muscle flaps from the pectoralis anteriorly in upper lobe cavities, latissimus in lower lobe and sacrospinalis in paravertebral cavities. By this method the decortication is held to a minimum and the bronchopleural fistula will close. We recently reviewed 28 cases of lung abscess which we treated in the following ways: (1) medically with the aid of bronchoscopic aspiration. Two cases, both recovered. (2) Aspiration without injection of penicillin or streptomycin into the cavity, but with their aid intramuscularly. Two cases, both recovered. (3) Open drainage, seven cases. Two were chronic and complicated by localized empyema. They recovered. One was chronic and uncomplicated (cystic type). This patient recovered but returned nine weeks later with a brain abscess and died. One man was dismissed from the hospital and later had an exsanguinating hemorrhage from the drainage site and by hemoptysis. Two cases later required lobectomy. (4) Lobectomy. Fifteen cases. One was an acute complicated type with gangrene. (This followed an anesthetic given during childbirth in a primipara aged 41 years. A tooth broke off and was aspirated.) Two cases subsequently developed empyema with bronchopleural fistula and were treated by open drainage. (5) Lobectomy and pneumonectomy. Two children. One had a lower lobectomy and then developed bronchiectasis in the upper lobes and was subjected to pneumonectomy on the operated (right) side. The other had the primary abscess in the lingula with secondary abscess in the upper lobe and bronchiectasis in the lower. Pneumonectomy was done. Both recovered. Thus in our limited group of recent cases, 61 per cent ultimately required lobectomy or pneumonectomy. Al-

most 50 per cent of all open drainage cases later required lobectomy. Late cases with localized empyema responded well to open drainage.

Pulmonary Tuberculosis.—Pulmonary tuberculosis is discussed in Chapter 8. Since the disease may require lobectomy or even pneumonectomy, the indications for these procedures should be enumerated. They are as follows: (1) bronchial stenosis, especially with febrile attacks and positive sputum from this area, if the remainder of the lung is quiescent. (2) Areas of tuberculous bronchiectasis. (3) Hemorrhages from bronchiectatic area. (4) Atelectatic lobes. (5) Cavities that persist in spite of pneumothorax although thoracoplasty in the upper lobe may be tried first. (6) Tuberculosis confined to the lower or middle lobe when,

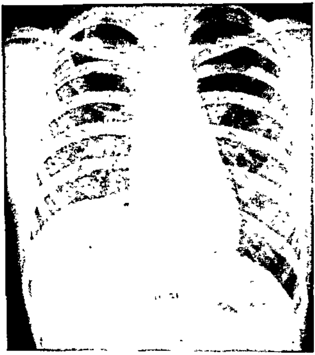

Fig. 226.—Paralysis of the diaphragm on the right, due to phrenectomy. The diaphragm is in the position of extreme expiration.

because of adhesions, pneumothorax or phreniclasia does not control it. (7) Solitary large tuberculomas which will cause dissemination, if not removed. (8) Massive tuberculosis in one lung which has been considered by some to be an indication for pneumonectomy—this is doubtful. (9) In the young if thoracoplasty is indicated, lobectomy may be preferable because it obviates the resultant scoliosis. (10) In chronic case with limited disease that does not respond to other forms of treatment yet does not spread.

In addition to lobectomy, the general treatment of tuberculosis should be carried out because the removal of a focus does not mean that the disease is entirely arrested.

Massive Collapse.—Massive collapse of the lungs occurs as a result of the obstruction of a bronchus by a plug of mucus and subsequent absorption of the air trapped in the obstructed alveoli, with resulting atelectasis. Massive collapse occurs more frequently after gas anesthetics. These are quickly absorbed from the alveoli. It is more common after spinal anesthesia than after inhalation anesthesia. Prolonged anesthesia of any kind increases the chance for accumulation of secretion. Therefore, light anesthesia which is stopped as soon as possible is best. The incidence is higher in men, in smokers, after surgery in the upper abdomen, in patients with acute or chronic respiratory infections, in the old, and in patients undergoing long operations. This is due to a sharp

Fig. 227.—Massive collapse of the lung (right). Note the mediastinal shifting toward the affected side, the narrowing of the intercostal spaces, and the diminished aeration on this side.

reduction in vital capacities, a decrease in subtidal volume of the lungs, and decreased excursion of the diaphragm. In the presence of an obstructed bronchus, atelectasis quickly occurs. Pneumonia, lung abscess, or fibrosis may follow massive collapse. This is not uncommon postoperatively in the small bronchioles; obstruction of the large bronchi is less common and produces the most marked symptoms. The clinical picture is one of pneumonia. There is rapid distressing respiration, with pain and cough. Some cyanosis exists and the temperature rises to about 101 to 102° F. The condition is distinguished from pneumonia by the distant breath sounds and by the displacement of the heart and mediastinum *toward the affected side.* A bedside roentgenogram clinches the diagnosis, in massive cases, not in lobar or lobular types. If fever and toxemia continue, it is probably bronchopneumonia.

Prevention.—Heavy smokers are asked to stop for one week prior to surgery, and all patients with chronic respiratory irritation are asked to cough before anesthesia is given. Atropine as a preanesthetic agent helps. The anesthetist may hyperventilate the lung with carbon dioxide and oxygen during the surgery; however, this does not always prevent the complication. The patient after operation must move about frequently and be forced to take deep breaths. The best time to encourage this is immediately after morphine has been administered, for there is no doubt that shallow respiration results from pain and not from reflex paralysis of the diaphragm, although the latter may play a secondary role. While it is true that morphine depresses the respiration, it also relieves pain and thereby makes deep breathing and early motion possible. The *treatment* of massive collapse after it has occurred is also deep breathing, early mobilization, and holding the patient's affected side to help cough up the plug of mucus. Inhalation of 5 to 10 per cent carbon dioxide stimulates deep breathing and is sometimes effective. The bronchoscope may be passed in rare cases. Sulfadiazine and penicillin are given to reduce infection. The prognosis is good.

Pulmonary Embolism.—Pulmonary embolism has been mentioned in Chapters 6 and 17. As was pointed out then, pieces of thrombi or fat or air bubbles may be carried to the pulmonary vessels. By far the most common are bits of thrombi, which, if small, produce infarcts, and, if large enough, completely occlude the pulmonary artery, causing an entire lobe, or even lung, to be deprived of blood and, because of the sudden onset, resulting in death from asphyxia. The condition usually occurs seven to ten days after operation and manifests itself by pain and cough, with blood-tinged sputum. Local signs of dullness, friction rub, and harsh sounds may be elicited. Sometimes the patient is cyanotic and dyspneic. The outcome of an embolism depends on its extent and infectivity; usually it ends in resolution. Sometimes pneumonia, pulmonary abscess, empyema, and even death may occur. Often successive emboli occur, singly or in showers. The *treatment* consists primarily in prevention. This is discussed under phlebothrombosis and thrombophlebitis (see Chapter 17). Deep breathing exercises, turning of the patient, early mobilization in old people, and adequate intake of fluid all are designed to prevent thrombosis, which may presage embolism. The surgeon must handle tissues gently, especially where large plexuses of veins are present. Should embolism occur, the treatment resolves itself into treating whatever effect the embolism has produced (q.v.). The Trendelenburg operation which consists of pulmonary arterial embolectomy has occasionally been done with success.

Pulmonary embolism has long been recognized as a surgical complication. Recently its importance in medical patients has led to early ambulation in heart and other medical diseases. Air embolism is rarely due to intravenous medication since 5 to 10 c.c. have been injected rapidly in man without producing clinical symptoms. A gaping wound in

a large vein (internal and external jugular or axillary) with fixed facial coverings preventing collapse may cause fatal pulmonary embolism. Entrance of air into the pulmonary vein following pleural punctures, pneumothorax, or operations on the lung causes obstruction of the arterial tree. Should air embolism occur, 100 per cent oxygen is administered. While the cause is controlled, rarely the knee-chest position following delivery, tubal insufflation, or the injection of air about the adrenals for diagnosis may cause air embolism.

Fig. 228.—Lung with multiple areas of infarction. Arrows point to three such wedge-shaped areas. Post-mortem specimen.

Nontuberculous Infections of the Lungs

Actinomycosis.—Actinomycosis has been discussed in Chapter 7. The pulmonary form is probably secondary to aspiration from the mouth. The diagnosis can only be established by finding actinomycotic granules in the excised tissue from draining sinuses or persistently in the sputum.

Encouraging reports have been given from the treatment of the disease by sulfadiazine, penicillin, lobectomy, and pneumonectomy.

Coccidioides Immitis.—*Coccidioides immitis* may produce an infectious granuloma in the lung following the inhalation of infected dust. The infection is usually mild, involves the lungs and mediastinal nodes, and soon disappears, leaving a scar. Exceptionally an abscess may form which may break into a bronchus or cause secondary lesions. Rarely the infection gains entrance into the blood stream causing death. The differential diagnosis includes tuberculosis, residual pneumonitis, fibrosis, healed abscess, bronchitis, bronchiectasis, Boeck's sarcoid, and metastatic carcinoma or sarcoma. Skin tests with coccidioidin study of the sputum and blood help in the diagnosis. There is no specific treatment although chemotherapy and antibiotics may be used.

Histoplasmosis.—Histoplasmosis in the lungs is far more common than was formerly believed. Furthermore, it is not always fatal but may be present in a mild form. Its chief interest at present lies in the fact that it explains pulmonary calcification, which was thought to be tuberculous but which gave a negative tuberculin test. The disease is caused by the *Histoplasma capsulatum* or an immunologically related organism. Skin tests with histoplasmin help make the diagnosis. With antigens derived from fungi, there is a possibility of crossed immunological response to coccidioidin and antigen derived from Haplosporangium.

Blastomycosis.—Blastomycosis may be caused by (1) Saccharomycetaceae and (2) Blastoporinae which are Hyphomycetes, the so-called Cryptococcus. *Cryptococcus capsulatus* of Darling is histoplasmosis. *Cryptococcus histolyticus* may involve the lung or may cause a cerebrospinal meningitis. A third variety pathogenic for man is *Cryptococcus hominis.*

If the disease is limited to a lobe or lobes or is present as a solitary tumor, lobectomy or pneumonectomy may be done. Iodides in increasing doses are given pre- and postoperatively.

Echinococcus Disease of the Lung (Hydatid Cyst).—Hydatid cysts are usually single. The cause is a small tapeworm, *Taenia echinococcus,* found in the intestinal canal of the dog, wolf, or jackal, which they ingested by eating organs of intermediate hosts—sheep and pigs. The ova are transmitted to human beings by handling infected dogs or ingesting uncooked, contaminated water or vegetables. A sac grows around an implanted embryo, forming a cyst. The embryo is usually implanted first in the liver. Here it forms a vesicle with an inner germinal layer and an outer laminated layer. From the germinal layer, vacuolated masses of cells (brood capsules) protrude into the vesicle's cavity. These in turn give rise to scolices. Daughter cysts are usually sterile and, without scolices or proliferaitng vesicles, are generally the result of mechanical infectious or toxic influence. If the cyst ruptures, it may be implanted in any organ in the body. Diagnosis is made by finding hooklets in the sputum. The x-ray findings are not characteristic. Aspiration is danger-

ous because of implanting cysts in the pleura and the so-called allergic reaction which may occur. There is usually an eosinophilia.

Treatment.—Formerly marsupialization was done and the cyst treated with 2 per cent formalin and packed with gauze. Now, after adequate preparation with penicillin and sulfadiazine, lobectomy is done.

Amebiasis.—Amebiasis may result in liver abscess (see Chapter 7). Pleuroperitoneal complications, though usually responsive to medical treatment (emetine and Diodoquin), may require surgical intervention. The indications for surgery are (1) bronchobiliary fistula; (2) empyema; (3) persistent amebic abscess of the lung; (4) collapsed lung. The surgical treatment is in general that of similar entities caused by other organisms plus the medical treatment of the disease. However, drainage is preferable to extirpation wherever possible even more so than in other conditions. This is because the organisms reside in the wall of the abscess and dissemination may result from radical surgery.

Neoplasms of the Lungs and Bronchi

Since many neoplasms of the lung originate in the bronchi, it is necessary that we consider lungs and bronchi together. Neoplasms of the lung may be benign or malignant, primary or secondary. They vary greatly in their structure because of the complexity of tissues, which embryologically make up its component parts. The following is a classification of the more common varieties:

I. Benign neoplasms (usually originate in the bronchi)
   1. Adenoma
   2. Papilloma
   3. Fibroma
   4. Lipoma
   5. Chondroma
   6. Osteoma
   7. Neurinoma
   8. Dermoid cysts
   9. Teratoma
   10. Cylindroma
   11. Hamartoma
   12. Hemangioma

II. Malignant neoplasms
   A. Primary
      1. Sarcoma
         (a) Spindle cell
         (b) Small round cell
         (c) Lymphosarcoma
         (d) Chondrosarcoma
         (e) Osteosarcoma
      2. Carcinoma nearly always bronchiogenic in origin; may be classified as to origin, distribution, and microscopic variety
         (a) Origin: [illegible] ic, from bronchial adenoma (adenocarcinoma, or oat cel[illegible]), from large bronchus, from small bronchi, from

blood vessels, from alveoli (alveolar cell carcinoma or pulmonary adenomatosis (see Chapter 15)

(b) Distribution: May be hilar (here in large bronchus, growth more or less restricted) diffuse infiltrative peripheral (here in small bronchus without cartilaginous walls grow fast and give rise to early metastases), miliary carcinosis, superior pulmonary sulcus of Pancoast (probably not a special type, but because of its location causes pain in shoulder girdle, Horner's syndrome, paralysis of hand muscles—Pancoast syndrome), alveolar cell carcinoma may be lobar or general.

(c) *Microscopic varieties:* May be *squamous cell, small cell (oat cell),* reserve cell carcinoma; adenocarcinoma; carcinoma simplex, hemangioendothelioma, alveolar cell.

B. Secondary neoplasms—may occur by *direct extension* from pleura or mediastinum or mediastinal nodes; metastasis more common way of transmission

(a) Lymphatic as from carcinoma of breast, lymphosarcoma, Hodgkin's, and lymphomas of leucemia

(b) Vascular as in sarcoma and carcinoma of thyroid, hypernephroma and chorioepithelioma; as part of a generalized carcinoma

Pathology of Benign Tumors.—The principal effect of benign tumors is that of obstruction which in turn may give rise to atelectasis, secondary infection (bronchitis, abscess, bronchiectasis). If the tumor is in the trachea and is sessile, it may give rise to stridor due to narrowing. If, however, it is on a pedicle, it may swing down, occluding the bronchus so that air cannot enter, but it can leave, giving rise to atelectasis, or it may swing up, allowing air to enter but it cannot leave, causing emphysema.

Lipomas arise from fat, which is a normal component of the major bronchi, that is present in the submucosal adipose tissue in the center of groups of bronchial glands and around them. Lipomas in the parenchyma of the lung or beneath the pleura arise from subpleural fat or fat in the smaller bronchi.

Adenomas arise from bronchial glands or their ducts in the larger bronchi. Graham suggests they be called "mixed tumors" because of the occasional presence of fat, cartilage, bone, or muscle (like the mixed tumors of the salivary glands). Often the adenoma resembles bronchiogenic carcinoma. Indeed it is a slow-growing, locally invasive neoplasm, which may at times metastasize or extend to regional nodes. Histologically mitotic figures and degenerative changes (pyknosis karyorrhexis) are not found in adenoma, but they are present in carcinoma. It is best to regard adenomas as slow-growing malignant neoplasms in most cases.

Cylindromas resemble the cylindromas of the salivary glands. Microscopically the tumor cells form tubules or cylinders filled with mucus. The main point of differentiation from bronchial adenoma, which cylindromas resemble very closely, is the presence of a mucoid secretion, apparently produced by the epithelial cells. They are as potentially malignant as the adenomas.

Fibromas are not common. As elsewhere, they are frequently associated with other cells, such as fat, muscle, and angiomatous tissue.

Chondromas and osteomas are rare and usually contain other elements.

Hamartomas are those tumors containing the normal components of an organ in an abnormal quantity, arrangement, and degree of differentiation. These are seen in the liver and other organs, including the lung. In the latter they are seen on microscopic examination to contain fat, bronchial mucosa, smooth muscle, and cartilage.

Symptoms and Signs.—Symptoms and signs are variable. Usually there is a cough which soon becomes productive and which may be accompanied by bleeding (adenomas). If atelectasis occurs, there is secondary infection, much sputum, and recurrent attacks of pneumonia. Often there is an asthmatic type of wheeze, particularly in sessile growths which do not move but partly obstruct the trachea or bronchus. Finally, bronchiectasis, pulmonary abscess, gangrene, or empyema may develop in neglected cases. The diagnosis is made by careful x-ray studies and bronchoscopic examination. Sometimes the growth will be shown by tomographic studies. More often an unexplained area of atelectasis leads to the supposition that the bronchial obstruction causing it is due to an endobronchial tumor, which is confirmed by bronchoscopy and bronchography.

Treatment.—Fibromas, chondromas, hamartomas, and lipomas should be removed by bronchoscope forceps, surgical diathermy, and implantation of radon seeds if necessary. If there are complications such as abscess or bronchiectasis, lobectomy may be necessary. Adenomas near the carina, those on narrow pedicles, freely movable adenomas, and those in poor-risk patients should be removed with the bronchoscope. If there is associated pulmonary disease, if the growth has recurred, if it is not accessible to the bronchoscope, or if there is seen to be adenomatous peribronchial infiltration, lobectomy or pneumonectomy is the safest treatment.

Pathology of Primary Carcinoma.—The pathology of primary carcinoma has been discussed in the classification of malignant neoplasms of the lung. The cause of pulmonary carcinomas is unknown. The miners of Schneeberg and Joachinetal are particularly susceptible. These mines contain radon, especially where pitch blend is mined. However, radon is not the sole cause. Contributing causes are pneumonoconiosis, chronic irritation, arsenic, radioactive substances, and, perhaps, hereditary susceptibility, since it is a father to son trade as well as much intermarriage.

Since practically all primary carcinomas originate in bronchial epithelium, it is proper to speak of bronchiogenic carcinoma. It is not rare and constitutes about 10 per cent of all carcinomas. The most frequent variety is the squamous-cell carcinoma. The next is the adenocarcinoma variety and the small-cell (oat-cell) type. The latter are thought to arise from bronchial adenoma. Since the growths start in the

bronchus, one of the first effects is bronchial obstruction which leads to atelectasis and secondary infection. Thus there are frequently such complications as pulmonary abscess, bronchiectasis, and pneumonia. These complications are often diagnosed while the carcinoma is missed. Biopsy sections do not always give a good guide to prognosis or operability. This is due to the fact that tissue sections vary from place to place. Ordinarily the squamous-cell type offers the best prospect of cure because its growth and metastasis are slower. Adenocarcinoma and the undifferentiated types are much more rapid in their progress and spread. Karsner believes that the hilic type, the diffuse infiltrative form,

FIG. 229.—Bronchiogenic carcinoma of the lung. Woman aged 48 years. Arrow points to a portion of the tumor mass which is projecting into the bronchus.

the peripheral form, and miliary carcinosis may represent, in part, different stages of the same process. Carcinomas that are grade 4 (Broders) are not so prone to spread by direct extension as are those of grade 3, but no predictions can be made on this basis alone. Alveolar cell carcinomas are extremely rare and the prognosis is poor although the tumor is slow growing.

Metastases of bronchial carcinoma are very frequent in the cerebrum. It is said that out of every nine tumors of the brain, one is metastatic and about one-third of these are from bronchiogenic car-

Since practically all primary carcinomas originate in bronchial epithelium, it is proper to speak of bronchiogenic carcinoma. It is not rare and constitutes about 10 per cent of all carcinomas. The most frequent variety is the squamous-cell carcinoma. The next is the adenocarcinoma variety and the small-cell (oat-cell) type. The latter are thought to arise from bronchial adenoma. Since the growths start in the

cure patients of this disease, it should be suspected in any person who develops a chronic cough or wheeze with or without blood-streaked sputum if he does not have tuberculosis. *Aids in diagnosis* include: sputum examination, x-ray studies, bronchoscopy, bronchography, biopsy secured through the bronchoscope, or suspected supraclavicular lymph nodes, thoracentesis, and exploratory thoracotomy. Pneumothorax, punch biopsy, or thoracoscopy have been used as an aid to diagnosis. Sputum examinations should be done to rule out tuberculosis and to look for cancer cells which are found frequently if a careful search is made. X-ray examination and fluoroscopic studies are indispensable. The shadow of a central or a peripheral tumor mass, localized expiratory emphysema, localized atelectasis, mediastinal shift (usually toward the lesion due to atelectasis, rarely away, due to emphysema) are all indications of bronchiogenic carcinoma. Tomography: posteroanterior, lateral, and oblique views are necessary on some occasions. Bronchoscopy is done routinely in all suspected cases except (1) positive biopsy from a peripheral metastasis, (2) advanced state of the disease, (3) carcinoma cells in the sputum or pleural effusion, or (4) symptoms and signs sufficient to make the diagnosis, although with the latter instance corroborative evidence is usually obtained. Bronchography is usually not indicated, obscures the lesion, and may be the cause of extensive pneumonitis if the opaque oil is trapped beyond the growth.

Bronchoscopic washings often reveal cells stained by special technique (see Chapter 2); moreover the actual location of the growth may be more accurately ascertained by the site from which the washings were obtained.

The differentiation of primary and secondary carcinoma is sometimes difficult. The history of previous carcinoma elsewhere is by no means evidence that the lung lesion is secondary. If carcinoma is present in other organs, the logical conclusion is that of metastasis. More important are the "concealed" primary sites such as the kidney and adrenal which give little evidence of their presence until the lung lesion is found. In the rare case of metastasis to a bronchial wall, differential diagnosis may be very difficult. Peripheral, spherical lesions and multiple lesions are apt to be metastatic. In any event a careful examination should be made with gastrointestinal x-rays, pyelography, and gall bladder studies as indicated. Pulmonary resection may be indicated in solitary metastasis or even multiple metastases in one lobe. Therefore, if the *diagnosis is uncertain, exploratory thoracotomy* is in order.

The frequency with which carcinoma occurs in the presence of lung abscess, bronchiectasis, and tuberculosis makes one wary of accepting a final diagnosis on x-ray findings alone. However, the routine use of chest films as procured by state boards of health has been of inestimable value in detecting early lesions, thereby *allowing for early differential* diagnosis.

cinoma. Therefore, it is routine in some hospitals to make an x-ray study of the lungs in every case of brain tumor. Metastasis to the cerebellum is rare. Metastases may occur anywhere in the body but are usually seen in the regional nodes first. Other frequent sites are the pleura, mediastinum with recurrent nerve paralysis, cervical lymphatics with Horner's syndrome, phrenic nerve paralysis, vena cava obstruction, chest wall, esophagus, skin, peripheral nodes, liver, and lungs. Pleural effusion usually means pleural involvement and cancer cells are often found in this fluid.

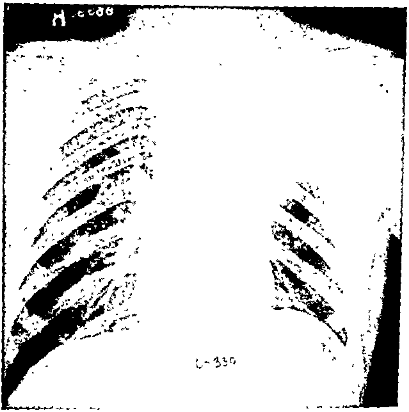

Fig. 230.—Carcinoma of the lung (primary). Superior sulcus tumor (Pancoast). Ultimately there are erosion of the ribs and a Horner's syndrome. The latter was present in this case. Note the elevation of the left leaf of the diaphragm. This may be due to phrenic narve involvement or to pulmonary atelactasis.

Symptoms and Signs.—Symptoms and signs are usually typical. There is a cough or wheeze or both with little sputum which is frequently blood streaked. There is often pain due to atelectasis. Later there are severe pains due to involvement of bronchial plexus, parietal or mediastinal pleura, bloody pleural fluid, loss of weight, paralysis of corresponding half of the diaphragm, paralysis of the left vocal cord (in the left-sided carcinoma) because of the proximity of the recurrent laryngeal as it passes around the arch of the aorta, brain symptoms due to metastases, and pulmonary osteoarthropathy. The late symptoms of carcinoma of the lung, like those of carcinoma of the breast, are of academic interest insofar as the probability of cure is concerned. Therefore, if we are to

(200,000) units of penicillin are left in the pleural cavity and the chest is closed in layers without drainage. The dead space is obliterated by organizing exudate and displacement of the mediastinum, diaphragm, and chest wall. Postoperatively the patients are placed in an oxygen tent for twenty-four to forty-eight hours. They are encouraged to sit up and cough by holding the chest.

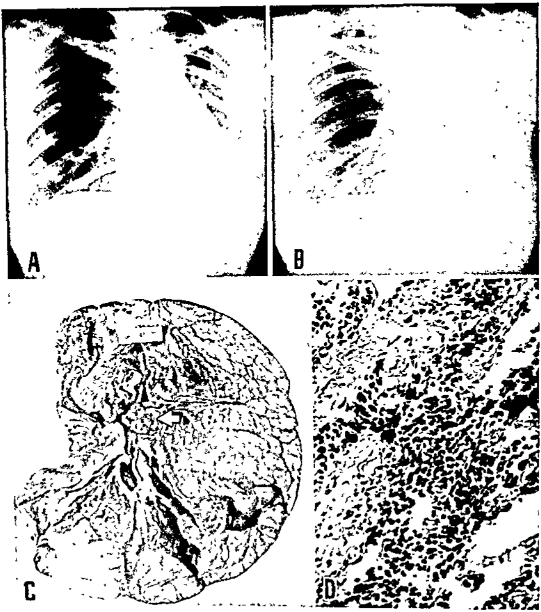

Fig 231 —Carcinoma of the left lung treated by pneumonectomy. R. F., a white woman aged 40 years, was admitted to the hospital complaining of a productive cough and dyspnea. *A.* X-ray photograph of the lung prior to operation. *C.* Photograph of gross specimen removed at operation. The arrow indicates the small cauliflower-like lesion *D.* Photomicrograph showing anaplastic carcinoma of the "oat-cell" variety. *B* Postoperative film. This patient has remained well to the present date which is now four years after surgery. (Case referred by Dr. R. R. Beach.)

Treatment.—Pneumonectomy in early cases. Every doubtful case should have an exploratory thoracotomy. Graham performed the first successful pneumonectomy in April, 1933. Unfortunately in our experience only about one-sixth of the cases are resectable when first seen. This rate will increase as diagnoses are made earlier. The mortality rate for the operation is about 10 per cent. The five-year "cures" are very few at present, averaging about 15 per cent or less as nearly as can be estimated. Lobectomy is rarely indicated but may be advisable for purely palliative reasons, or in doubtful cases of peripheral lesions with no nodal involvement.

Indications of inoperability are as follows: (1) Extensive pleural involvement evidenced by a bloody pleural effusion containing cancer cells. The fluid may be removed and replaced with air and then x-ray pictures taken to show pleural nodules; or punch biopsy with the thoracoscope may be done. We have preferred a small thoracotomy to the latter. (2) Extension to lymph nodes (supraclavicular, cervical and axillary). The nodes are easily removed for biopsy under local anesthesia. (3) Lymphatic dissemination as demonstrated by x-ray showing small nodules beneath the visceral pleura or by thoracotomy. (4) Hematogenous spread to liver, bones, and brain as determined by physical signs or x-ray. (5) Pain down the arm, Horner's syndrome (see Chapter 18), and erosion of first and second ribs which is known as Pancoast's syndrome or superior sulcus syndrome. (6) Nerve paralyses such as the recurrent laryngeal and phrenic which may be operable but usually not curable. (7) Small-cell types which should be given the benefit of surgery although the prognosis is poor. (8) Extension to the chest wall renders the lesion hopeless so far as cure is concerned, but palliation may be obtained by resection of the intercostal nerves or chordotomy or resection of the involved chest wall along with pneumonectomy.

The patient is prepared for operation by using penicillin by inhalation and intramuscularly. Sulfadiazine is given by mouth. Blood transfusions are given or indicated and blood is given by ankle vein during surgery. Intratracheal anesthesia is used but first the trachea and bronchi are aspirated and then kept clean throughout the operation. Ether and oxygen are used and at the conclusion of the operation the trachea and bronchi are again aspirated. A posterolateral incision is made and the fifth and sometimes the sixth ribs are resected. The patient's head is lowered to promote drainage. After freeing the lung, when adhesions are present the hilus is dissected out, the pulmonary artery and veins are individually ligated with No. 2 silk, and then the main stem bronchus is divided close to the carina and the lymph nodes and the lung are then removed. The bronchus is closed with interrupted silk sutures, approximating the membranous to the cartilaginous portion. Bronchial vessels are tied with silk. If possible, the mediastinal pleura is used to cover the bronchial stump. Two hundred thousand

the pharynx. The probe is pushed through and the fistula everted into the pharynx and then tied off.

True branchial cleft fistulas are lower than the hyoid bone and are lined with skin, hair follicles, and sebaceous and sweat glands. They should be excised.

Thyroglssal duct cyst will be discussed in Chapter 22 in conjunction with aberrant thyroids.

Submaxillary and submental inclusion cysts form from the small budlike lobules which go to form the gland. Should these tubules become obliterated, cysts will occur which should be removed with the gland, if necessary.

Infections of the Neck.—Infections of the neck are discussed in the paragraphs on mediastinitis which follow this chapter.

New Growths of the Neck.—New growths of the neck are many and varied. The persistent branchial cleft or thymic duct may rarely become the seat of squamous carcinoma. The lymph nodes are often a part of the lymphoblastic group of diseases discussed in Chapter 17.

Adamantinomas belong to the oral cavity and are reviewed in Chapter 19. Salivary gland and thyroid neoplasms are important and will be described in Chapter 22. Sarcomas and carcinomas of the mandible, metastatic growths in the lymph nodes, and secondary involvement of the neck from a malignant growth in the pharynx must be kept in mind in all tumors in the neck.

The Larynx

The voice box is a cartilaginous chamber in the neck, often referred to as the "Adam's apple." At its entrance are the two vocal cords, between which is an opening (the glottis), through which we breathe. The entrance of food into the larynx is prevented by the contraction of the thyrohyoid muscle which raises the organ, bringing the glottis under the shelter of the epiglottis and the base of the tongue. The latter is not essential since after its removal food still does not enter the larynx. The epiglottis stands erect and food passes over its posterior (not anterior) surface. The elevation of the larynx is important and if fixed by disease, food finds its way into the larynx. At the same time that the larynx is pulled up, the vocal cords are approximated due to the contraction of the arytenoid cartilages which are thereby drawn forward against the posterior pharyngeal wall and rotated medially. This has the effect of closing the glottis and opening the upper end of the esophagus. When the constrictors contract on a bolus of food, it follows the path of less resistance and goes down the esophagus.

The chief nerves supplying the larynx are the superior and inferior laryngeal (recurrent) nerves. The latter is unusual in that it is composed of two sets of fibers carrying impulses which produce opposing muscles action—abduction and adduction and also coordinated impulses concerned with speech and breathing. Paralysis of both recurrent nerves results in inability to abduct or adduct the vocal cords. When the recurrent laryngeal nerves are injured, the cords are lax and cannot be abducted or adducted. There is no difficulty in breathing, but there is inability to speak. Within three to six months the voice returns due to atrophy and the resultant fibrosis which tends to pull the cords together as the scar contracts. This continues until the cords are brought almost into approximation. Then there is difficulty in breathing on the slightest exertion and actual air hunger, if large amounts of air are necessary. This is often

X-ray treatment of pulmonary carcinoma is used as a palliative measure but is not curative. Secondary carcinoma is not treated by resection, although when the primary lesion can be removed, as in carcinoma of the stomach, and when there is one or more metastatic nodules, in one lobe, lobectomy has been done. This may prolong life.

THE UPPER RESPIRATORY TRACT

Embryology

About the second week of fetal life, *the foregut develops five pouches from the* interior lateral walls. These are known as the branchial pouches. At the same time the ectoderm becomes indented over the corresponding pharyngeal pouches. These are known *as the branchial* grooves. The pouches and grooves *come together so* that ectoderm and entoderm are in contact, the contracting area being the closing membrane which disappears in animals with gills, forming gill clefts, which open from the pharynx *to the exterior*. The mesoderm is thus pushed aside into six cylinders, *the* branchial arches, of which the first two partially telescope over the remainder, forming the cervical sinus. Each arch contains a cartilaginous bar and in each is the forerunner of the primitive aortic arches. (See Chapter 17.) The following is a list of the arches and their ultimate structures: *First*, or mandibular, arch—muscles of mastication, lower lip, mandible, anterior part of tongue; from the cartilaginous portion comes part of middle ear and mandible; *second*, or hyoid, arch—structures of upper part of the neck and *from* its cartilage the styloid process, styloid ligament, lesser cornu of the hyoid bone, and, with the third arch, the body of the hyoid and posterior part of the tongue; *third*, *fourth*, and *fifth* arches—structures in the vicinity of the *hyoid*, whereas, the *sixth arch* gives *origin* to the *cricoid*, arytenoid, and tracheal cartilages.

All the branchial grooves disappear except the first, which gives origin to portions of the auricle and external acoustic meatus.

The *four pairs of pharyngeal pouches are important* for they form, respectively, the following adult structures: (1) the auditory (eustachian) tubes and tympanic cavity and tympanic membrane, (2) the palatine tonsils, (3) the thymus anlages, (4) the parathyroids and epithelial bodies (*see Chapter 22.*)

The Neck

Congenital Anomalies of the Neck.—From the third pouch, two tubes descend into the mediastinum to form the thymus. They course downward and medially along in the anterior *border of the sterno-mastoid, lateral to the thyroid, and anterior to* the carotid sheath. Sometimes these tubes persist as a sinus, a cyst, or a fistula, depending on whether their distal end is open, ending a short way up, or both ends are closed or both ends are open, the internal end opening in the tonsillar fossa. This branchial cyst or fistula is probably the thymic ducts. The tract is lined with ciliated and squamous epithelium and surrounded by connective tissue. Mucoid or milky material or pus exudes from the branchial sinus or fistula. If there has been a tonsillectomy, liquids ingested may in part drool from the fistula. The treatment is complete excision. The tract may be injected with methylene blue but *this is* rarely necessary. A probe is *introduced and the dissection* carried up to

opposite side. Inferiorly it passes down on the surface of the bodies of the vertebra into the posterior mediastinum. From the sheath of the vessels outward beyond the posterior edge of the sternomastoid muscle the prevertebral fascia covers the scalene muscles, the brachial plexus, and the subclavian artery. On reaching the clavicle, the fascia is attached to its upper surface where it blends with the superficial layer, and then it is continued down over the subclavian muscle, forming its sheath, and ends in the costocoracoid membrane. The part over the subclavian artery and vein is continued over them and the brachial plexus and follows them into the axilla. This layer of fascia forms the floor of the posterior cervical triangle, and the roof of this triangle is formed by the superficial layer of the deep cervical fascia. Between these two layers the subscapular artery and veins run. The descending branches of the cervical plexus, the spinal accessory nerve, the omohyoid muscle, some fat, and lymph nodes are found here.

The pretracheal layer passes from side to side in front of the trachea. Laterally it, too, blends with the sheath of the vessels and is continued posteriorly behind the pharynx and esophagus as the buccopharyngeal fascia. In front it blends in the median line with the superficial fascia and is attached to the hyoid bone and cricoid cartilage. It splits to enclose and form a capsule for the thyroid gland and the inferior thyroid veins, and thense it passes to the arch of the aorta to be continuous with the pericardium. Laterally, it passes under the sternohyoid, omohyoid, and sternothyroid muscles to blend with the sheath of the vessels.

The buccopharyngeal fascia which was mentioned above lies between the pharynx in front and the vertebral column behind. This is known as the retropharyngeal space. The fascia forming the posterior wall of this space is the prevertebral fascia. Forming its anterior wall is a thin layer of connective tissue called the buccopharyngeal fascia. It invests the superior constrictor of the pharynx and is continued downward on the buccinator muscle. It is continued downward behind the pharynx and esophagus into the posterior mediastinum. Laterally, it blends with the sheath of the vessels and is continuous with the pretracheal fascia around the larynx, trachea, and thyroid gland.

Collections of fluid and pus superficial to the deep fascia tend to perforate the skin and to be discharged externally. Exudates in the supersternal notch or the space of Burns bulge anteriorly but may perforate posteriorly. The sternothyroid and sternohyoid muscles are attached to the posterior surface of the sternum, but the layer of fascia on their anterior surface is very thin so that pus may pass between the muscles or perforate them and go down in front of the pretracheal fascia close to the undersurface of the sternum. It would then tend to show itself in the upper intercostal spaces close to the sternum. Exudates between the pretracheal and superficial layers as may occur from an abscess of the thyroid gland tend to work their way downward. The pretracheal fascia at the sides blends with the sheath of the vessels and the fascia covering the posterior surface of the sternomastoid muscle. Pus can follow the posterior surface of the muscles behind the sternum in front of the innominate veins and arch of the aorta. Transudates and exudates between the pretracheal and prevertebral layers cannot go further to one side than the sheath of the vessels; therefore, they follow the trachea and esophagus down into the posterior mediastinum. This space between these layers is sometimes called the visceral space because it contains the esophagus, trachea, and thyroid gland. Pus in this space may also perforate into the trachea, pharynx, or esophagus, or even externally and involve the great vessels. If the anterior portion of the thyroid gland suppurates, the pus may perporate the thin pretracheal fascia covering it and pass down behind the sternohyoid and sternothyroid muscles into the anterior part of the superior mediastinum.

Exudates posterior to the prevertebral fascia, as from caries of the vertebrae if high up, bulge into the pharynx, forming a retropharyngeal abscess. Such exudates may follow the scalinae muscles and brachial plexus down around the axillary artery into the axilla. In the neck they show themselves posterior to the carotid arteries and to the outer edge of the sternomastoid muscle. Exudates in the sheath of the great vessels, when originating from lymph nodes may, first raise the sternomastoid muscle and show along its anterior border. They may perforate the vessels or pass down along the vessels into the superior mediastinum or may bulge into the visceral space between the prevertebral and the pretracheal layers and follow the trachea and esophagus down into the chest. Should they tend outwardly, they may break into the posterior cervical triangle between the prevertebral and superficial layers and show above the clavicle.

Retropharyngeal abscess comes from diseases of the vertebrae or from lymph nodes which are suppurating or from contiguous spaces as outlined in the text. An abscess here may point into the pharynx or, pushing its way outward, pass behind the great vessels and show itself behind the outer edge of the sternomastoid muscle. When originating in the retropharyngeal space it lies in front of the prevertebral fascia and behind the buccopharyngeal fascia. It either points into the pharynx or going down follows the posterior surface of the esophagus into the posterior mediastinum. It may also perforate the esophagus. Pus in the posterior cervical triangle, if above the prevertebral layer, bulges directly forward and tends to open through the skin. Its progress downward is obstructed by the attachment of the superficial layer to the top of the clavicle as it blends with the prevertebral layer. If pus is beneath the prevertebral layer, it may then follow the brachial plexus and subclavian artery down beneath the clavicle and appear in the axilla. The attachments of the costocoracoid membrane tend to direct the pus laterally under the pectoralis minor muscle into the axilla rather than to allow it to come forward on the anterior portion of the chest.

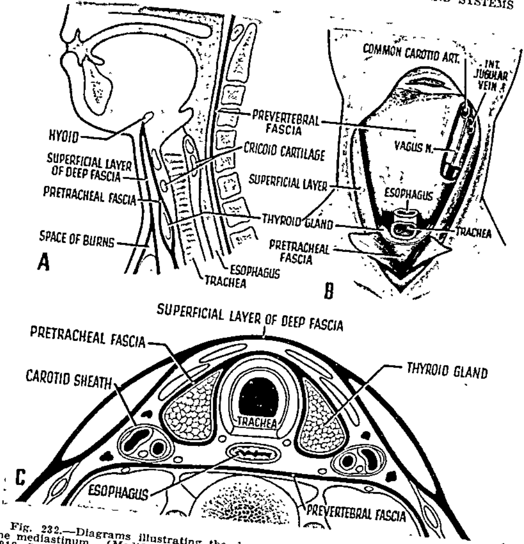

Fig. 232.—Diagrams illustrating the deep cervical fascia and its prolongations into the mediastinum. (Modified from Davis, G. B.: Applied Anatomy, ed. 5, Philadelphia, 1918, J. B. Lippincott Co., and Cunningham: Manual of Practical Anatomy [revised by Robinson, A.], ed. 6, New York, 1914, William Wood & Co.)

A, Sagittal section illustrating continuity of deep cervical fascia and pharyngeal spaces.

B, Longitudinal section showing the superficial layer, the pretracheal layer, and the prevertebral layer of the deep cervical fascia as it is prolonged down into the mediastinum.

C, Transverse section of the neck through the sixth cervical vertebra showing the compartments.

The cervical fascia may be divided into three layers: the superficial, which completely encircles and envelops the neck, the prevertebral, which passes from side to side in front of the spinal column, and the pretracheal layer, which passes from side to side in front of the trachea.

The superficial layer is attached above to the occipital bone and the mastoid process, and it blends with the capsule of the parotid gland, then passes to the angle of the jaw and along the body of the mandible to the symphysis, where it proceeds in the same manner to the opposite side. Below, it is attached to the sternum, the under edge of the clavicle, the acromion process, the spine of the scapula, and then across the vertebral spines and to the ligamentum nuchae and is attached to the external occipital protuberance. In the front of the neck it passes from the mandible down to be attached to the hyoid bone and then down to the sternum and clavicle. About 3 cm. above the sternum the fascia splits into two layers, one to be attached to the anterior and the other to the posterior edge of the sternum in front of the sternohyoid and sternothyroid muscles. Between these two layers is the space of Burns. It contains the lower ends of the anterior jugular veins with the branch that joins them, some fatty tissue and lymph nodes, and the sternal origin of the sternomastoid muscles.

The prevertebral layer passes from side to side in front of the bodies of the vertebrae. It covers the muscles attached to the spine. On reaching the carotid artery and jugular vein, it helps to form their sheaths. Its upper edge is attached to the base of the skull at the jugular foramen and carotid canal and thence across the basilar process to the

nels. The causes of obstruction within the lumen of the bronchi may be listed as endogenous or exogenous. The former may be due to (1) tenacious sputum, (2) fibrinous casts, (3) broncholiths, (4) ruptured lymph nodes, (5) postoperative retention of secretions, (6) the entrance of a foreign body of any type occluding the lumen of the bronchus, the most important exogenous cause.

Obstruction due to changes in the bronchial wall may be listed as follows: (1) congenital anomalies of the bronchi; (2) inflammatory diseases of the bronchi which may be nonspecific or specific; the former are inflammations of the bronchial mucosa or cicatrization following chemical burns or ulcers—the latter may be due to tuberculosis, syphilis, leprosy, and rhinoscleroma; (3) new growths which may be benign or malignant; (4) distortion of bronchi by kinking or twisting as the result of a pulmonary disease, vertebral disease, or intrathoracic dislocation of the viscera following pneumothorax, thoracoplasty, pneumonectomy, or lobectomy.

The extrabronchial causes for obstruction are (1) enlarged lymph nodes of inflammatory or neoplastic origin, (2) mediastinal suppuration, mediastinal emphysema, mediastinal neoplasms or cysts, (3) vertebral disease which may be inflammatory or neoplastic, (4) neoplasms of the lungs, esophagus, or intrathoracic goiters which may produce an obstruction, (5) cardiovascular disorders such as aneurysms of the aorta or the pulmonary arteries; also congenital anomalies of the cardiovascular system producing pressure upon the trachea. (Chapter 17.)

The results of bronchial obstruction are variable. If the obstruction is complete, no air will get into the lung, which is supplied by the bronchi, and atelectasis will result. If it is incomplete, there may be great dilatation beyond the point of obstruction and there may be great hypertrophy of the muscular elements, or if a ball valve type or flap door type of obstruction is present, cavitation may result. Such cavities will not collapse spontaneously by external pressure or drainage. Furthermore, after obstruction to the bronchus, the portion distal to the occlusion not only dilates but also retains secretion which becomes a favorable medium for the growth of bacteria, so that it is not uncommon to see such complications as pneumonitis, lung abscess, bronchiectasis, or bronchiectatic cavitation. This is also true in tuberculosis, as we have seen in Chapter 8. See Chapter 15—Cohnheim's laws.)

Bronchial obstruction may be compared in a general way with obstructions elsewhere in the human body. When the obstruction is sudden and complete, there is usually atelectasis distal to the obstruction, and this may be permanent and may produce changes, as we have seen, due to the atelectasis. When it is incomplete, there may be dilatation distal with retention of secretions and a great amount of fibrosis and hypertrophy of muscular elements. When it is of an incomplete and ball valve nature, there will be great dilatation and formation of all types of cavities.

accompanied by a crowing or roaring sound. The treatment is nerve suture if discovered early. Later the arytenoid muscles may be shortened on one side, making the glottis larger.

Diseases and Injuries of the Larynx.—*Foreign bodies* are frequently aspirated into the larynx. This is dangerous because asphyxia may occur. Removal of these bodies is often carried out through the use of the *laryngoscope.* Sometimes their removal may be accomplished with the fingers or a hemostat or by turning a child "upside down" to facilitate extrusion by cough. Should all methods fail, or should the larynx be obstructed by new growth or stricture, a tracheotomy must be done. *Intubation* was formerly used in laryngeal diphtheria or edema for temporary help. It is safer and less irritating to do a tracheotomy. Inflammations may be simple (laryngitis) or specific (tuberculosis, syphilis). *Laryngitis* is treated by steam inhalations, such as compound tincture of benzoin; specific infections are treated by specific treatment (syphilis) or general treatment (tuberculosis). Recently a few cases of laryngeal fibrosis and scarring have been reported from the use of the duodenal tube. This is due to irritation of the cricoid with resultant perichondritis. It may be avoided by using small, soft tubes, which should be removed at frequent intervals and then reinserted if necessary.

New Growths may be benign (papilloma) or malignant (carcinoma). These may be removed locally, or, if extensive, the entire larynx must be extirpated (*laryngectomy*) after a permanent tracheotomy has been established. Electric speaking devices are available for such patients.

The Trachea and Bronchi

The trachea and bronchi are the tubes through which we breathe. The trachea can be easily felt in the neck just above the manubrium sterni and below the cricoid cartilage. It is surrounded by cartilaginous rings except posteriorly, where it lies on the esophagus. The mucus membrane is made of columnar epithelium bearing small hairlike cilia, which help trap foreign bodies, such as dust, until they may be coughed up. The trachea begins in the larynx and divides into the right and left main bronchi at about the level of the fifth thoracic vertebra. These bronchi are smaller than the trachea but much like it in structure. The right is in more direct line than the left. The bronchi lose their cartilaginous nature as they divide and subdivide into bronchioles.

Bronchial Obstruction

Bronchial obstruction is important not only because of the intrinsic factor which is causing the obstruction, but more because of its effects on the bronchi and lungs. As in all hollow tubes, the obstruction may be within the lumen of the tube or it may be outside the tube, producing pressure. We have used this same general classification in obstructions of the bowel, blood vessels, common bile duct, ureters, and other chan-

nels. The causes of obstruction within the lumen of the bronchi may be listed as endogenous or exogenous. The former may be due to (1) tenacious sputum, (2) fibrinous casts, (3) broncholiths, (4) ruptured lymph nodes, (5) postoperative retention of secretions, (6) the entrance of a foreign body of any type occluding the lumen of the bronchus, the most important exogenous cause.

Obstruction due to changes in the bronchial wall may be listed as follows: (1) congenital anomalies of the bronchi; (2) inflammatory diseases of the bronchi which may be nonspecific or specific; the former are inflammations of the bronchial mucosa or cicatrization following chemical burns or ulcers—the latter may be due to tuberculosis, syphilis, leprosy, and rhinoscleroma; (3) new growths which may be benign or malignant; (4) distortion of bronchi by kinking or twisting as the result of a pulmonary disease, vertebral disease, or intrathoracic dislocation of the viscera following pneumothorax, thoracoplasty, pneumonectomy, or lobectomy.

The extrabronchial causes for obstruction are (1) enlarged lymph nodes of inflammatory or neoplastic origin, (2) mediastinal suppuration, mediastinal emphysema, mediastinal neoplasms or cysts, (3) vertebral disease which may be inflammatory or neoplastic, (4) neoplasms of the lungs, esophagus, or intrathoracic goiters which may produce an obstruction, (5) cardiovascular disorders such as aneurysms of the aorta or the pulmonary arteries; also congenital anomalies of the cardiovascular system producing pressure upon the trachea. (Chapter 17.)

The results of bronchial obstruction are variable. If the obstruction is complete, no air will get into the lung, which is supplied by the bronchi, and atelectasis will result. If it is incomplete, there may be great dilatation beyond the point of obstruction and there may be great hypertrophy of the muscular elements, or if a ball valve type or flap door type of obstruction is present, cavitation may result. Such cavities will not collapse spontaneously by external pressure or drainage. Furthermore, after obstruction to the bronchus, the portion distal to the occlusion not only dilates but also retains secretion which becomes a favorable medium for the growth of bacteria, so that it is not uncommon to see such complications as pneumonitis, lung abscess, bronchiectasis, or bronchiectatic cavitation. This is also true in tuberculosis, as we have seen in Chapter 8. See Chapter 15—Cohnheim's laws.)

Bronchial obstruction may be compared in a general way with obstructions elsewhere in the human body. When the obstruction is sudden and complete, there is usually atelectasis distal to the obstruction, and this may be permanent and may produce changes, as we have seen, due to the atelectasis. When it is incomplete, there may be dilatation distal with retention of secretions and a great amount of fibrosis and hypertrophy of muscular elements. When it is of an incomplete and ball valve nature, there will be great dilatation and formation of all types of cavities.

Foreign Bodies.—Foreign bodies are aspirated into the trachea and bronchi frequently. This is especially true in children. All sorts of objects have been recovered. Dr. Chevalier Jackson has catalogued these into food, hardware, jewelry, etc. Due to his efforts, bronchoscopy has

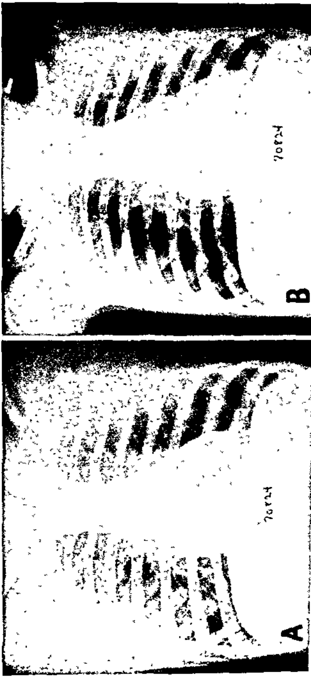

Fig. 233.—*A*. Nonopaque foreign body of the right mainstem bronchus. X-ray taken during *inspiration*. *B*, Same case. X-ray taken during expiration. There is an obstructive emphysema on the right, with partial collapse on the left. The right diaphragm is not elevated to the normal position. The heart is pushed over to the left, as is also the trachea.

been developed. The diagnosis is made from a history of aspiration of an object and a cough. In children any persistent cough must be investigated carefully by x-ray examination, which will easily reveal some foreign bodies, and, if the x-ray is negative, by bronchoscopic examination. A foreign body may cause a pulmonary abscess or erosions into a

large vessel; or rarely the object may be encapsulated or extruded into a bronchus or the pleural cavity.

Broncholiths.—Broncholiths (bronchial stones, bronchial calculi) are hard gritty fragments of calcium phosphate or calcium carbonate which are occasionally coughed up by patients who have bronchiectasis, lung abscess, anthrasilicosis, or other chronic inflammatory diseases. The source may be from (a) the lungs, (b) the bronchi, (c) the peribronchial lymph nodes. Calcifications occur in caseous tuberculous areas in the lungs or lymph nodes, old abscess cavities in the lung, chronic empyema, and histoplasmosis areas. Calcified areas erode through the bronchus and ultimately behave as a foreign body. While in the process of erosion, there may be persistent cough with some hemoptysis and much sputum.

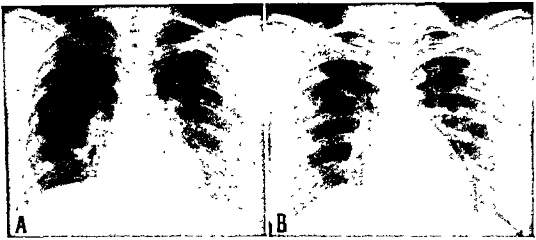

Fig. 234.—Broncholithiasis. Miss R. H., aged 26 years, complained of chronic productive cough with repeated hemoptysis. Patient had coughed up small broncholith on one occasion. Massive hemorrhage brought her to the hospital. After bleeding had ceased, bronchoscopy was done and a part of the broncholith was removed from the right middle lobe bronchus. Symptoms continued and atelectasis of the right middle lobe ensued. Thoracotomy and right middle lobectomy was done. The broncholith had eroded through the medial branch of the middle lobe bronchus and had engendered much fibrosis, occluding the lateral branch at its junction. The patient made a smooth recovery. Pathology report: Broncholithiasis, middle lobe showing complete ateleectasis, carnification with fibrosis, chronic pneumonitis. The term carnification is from *caro, carnis,* flesh, and *facere,* to make. Carnification is due to consolidation, and the term is used to describe the meaty appearance of the lung resembling muscle. *A.* Arrow points to broncholith. No atelectasis at this time. There are also calcified areas in the upper and lower lobes. *B.* Postoperative x-ray after middle lobectomy. (Case referred by Dr. R. Henry.)

Treatment.—The treatment consists of removal of the object by the use of the bronchoscope with long, specially designed forceps. Even lung tissue may be penetrated, and it is not unusual for the bronchoscopist to remove a pin from the main stem bronchus. Occasionally the surgeon will be guided by the bronchoscopist and will enter the lung through an intercostal incision to remove an extrabronchial foreign body. Complications such as lung abscess and bronchiectasis are treated as outlined elsewhere in this chapter.

Bronchiectasis

Bronchiectasis is a disease of the bronchi (in one or more lobes or segments) characterized by dilatation and infection. We have all been the victims of an acute bronchitis, with its fever, malaise, and persistent cough. Finally we are able to cough up the mucus and we feel better. In bronchiectasis this coughing-up process continues. The cause is unknown. However, the following is a list of possible contributory causes: sinusitis and disease of the accessory air passages, infections of the bronchi and lungs (recurrent bronchitis, acute and chronic, measles, whooping cough, scarlet fever, influenza, pneumonia, lung abscess, pleurisy, tuberculosis) cystic disease of the lungs, bronchial obstruction from any cause (foreign body, broncholithiasis, carcinoma or benign tumor of bronchi, etc.), the effects of bronchial obstruction (atelectasis or emphysema with infection), situs inversus with sinusitis "Kartegener's syndrome") has been a rare combination preceding bronchiectasis. In over 25 per cent no contributory cause is discovered. The pathological factors are also varied. Some observers say it is due to a chronic infection, with obstructing mucous plugs, persistent cough, and a subsequent dilatation or an obliterative bronchiolitis with fibrosis. Others believe the bronchi are pulled and held open by peribronchial fibrosis. Still others claim that it is due to a congenital weakness of the bronchial wall. The bronchi becomes destroyed and are replaced largely with fibrous tissue. This destructive process extends into the surrounding lung and the end result is a set of rigid tubes in a rigid cavity.

Behind the various causes and changes is the following over-all picture: The bronchi are dilated due to pulsion or traction, the former more than the latter. In pulsion types, bronchial obstruction is the usual cause. Cough alone does not do it, but cough with mucous or other plugs is probably at fault. If this is true we may infer that most bronchiectasis begins in childhood, and if this is true, more attention should be paid to whooping cough, measles, and bronchitis with the thought that postural drainage and breathing exercises may prevent the disease to some extent. Traction bronchiectasis is seen in chronic lung abscess, chronic empyema, and cavitary tuberculosis; almost invariably in lobectomy for chronic lung abscess there is extensive lung fibrosis and bronchiectasis. Here the bronchi are actually "held open" by fibrous tissue contraction. It is probably fair to say that in all cases both processes are at work. Even in the so-called congenital types this may be true because respiration does take place to a limited extent in utero, and also cystic disease due to congenital malformation may be present.

Gross changes are easily seen. The bronchi are dilated into various shapes and types: cylindrical, fusiform, saccular, and cavitary. There is thickening of the bronchial wall with vascular papillary projections of the mucosa. This may be due to proliferation or to uneven destruction as is present in chronic ulcerative colitis, for example. The lung parenchyma

is replaced to a great extent by fibrous tissue. Blood and pus are seen to exude from the infected bronchi. The process may involve any lobe of the lungs but is usually in the lower lobes and more in the basal than the apical segment. Abscess of the lung is more common in the apical segments. The left lower lobe and lingula account for about one-fourth of our cases. Both lower lobes may be involved and sometimes the disease involves both lungs.

Microscopic alterations include hyperemia, fibrous proliferation of fibrous tissue, destruction, and much granulation tissue. Glands, muscle, elastic tissue, and even cartilage may be largely destroyed and replaced by fibrous tissue. Thus normal bronchial contractility is lost, and under

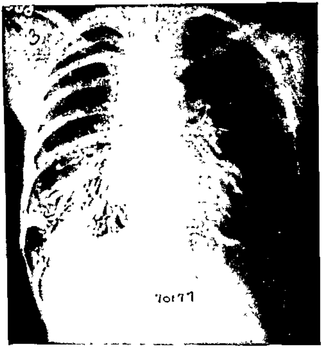

Fig 235.—Bronchiectasis. Lipiodol injection, showing dilatation, obstruction, and sacculation of the bronchi.

the influence of collecting secretions and cough, further dilation is inevitable, such as a hernia resulting after infections in an abdominal wound, which has healed by second intention. The epithelial lining is partially destroyed and perforations are seen. Blood vessels may rupture, giving rise to hemoptysis, or become thrombosed, causing embolism and brain abscess. Areas of atelectasis and compensatory emphysema may be observed about the primary zone. The disease remains static so far as the lobe or segment involved is concerned but is progressive within the segment. Bacteria of all types are found, including cocci, spirochetae, and fusiform bacilli.

Symptoms and Signs.—The principal symptom is a persistent productive cough with thick purulent malodorous sputum. Patients soon

learn that their breath is foul, not only to themselves but to others, and therefore the "inhibited personality type of patient in bronchiectasis" has been described. If the disease develops in early childhood, adult age is not ordinarily reached without treatment. It is true that there are all

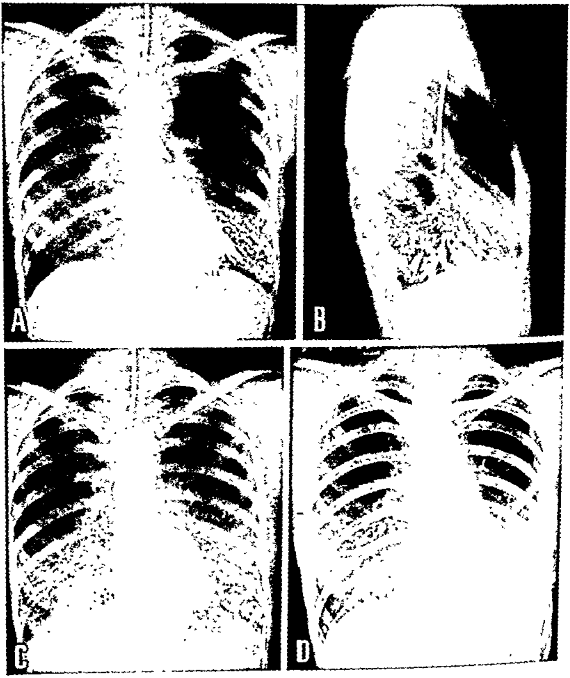

Fig. 236.—Bronchiectasis. Preoperative and postoperative x-ray pictures of F. G., a woman aged 26 years, with left lower lobe bronchiectasis and bronchiectasis of the lingula. The patient had a chronic, persistent cough with productive sputum which at times amounted to 10 ounces per day. *A*. Preoperative posteroanterior film showing extensive bronchiectasis of the left lower lobe and lingula following the introduction of Lipiodol by catheter (bronchogram). *B*. Lateral view. *C*. Bronchogram of right lower lobe. At operation a lower lobectomy and lingulectomy were performed by the individual hilar ligation technique. *D*. Postoperative film seven days after surgery. (Case referred by Dr. R. Henry.)

gradations in symptoms, from a productive cough only in the presence of an upper respiratory infection to coughing spells especially in the morning, of two to three hours, accompanied by hemoptysis, vomiting, and collapse. The slightest exertion produces dyspnea in advanced cases.

Physical signs are so varied that they may resemble any lung condition—usually there are dullness and moist râles and diminished breath sounds which may vary in intensity over different areas and vary from day to day. Later there is emaciation, anemia, general weakness, clubbing of the fingers (pulmonary osteoarthropathy). Bronchospirometric determinations reveal the pulmonary reserve in the good lung or in the better of the two and the extent of functional tissue in the affected side.

X-ray examination and fluoroscopic studies are essential to proper diagnosis. There will be areas of atelectasis, emphysema, dilated bronchi. The fluoroscope permits inspection in the posteroanterior, lateral, oblique, lateral decubitus, and Trendelenburg positions, so that every portion of the lung, including the posteromedial costovertebral area and medial diaphragmatic zones, will be seen and atelectasis found if present.

Bronchography is useful to determine the extent of the bronchiectasis and in some cases, especially postoperative (lobectomy cases, pneumonotomy) and congenital cystic disease, it may be necessary in the differential diagnosis of lung abscess, localized empyema with bronchopleural fistual, and congenital cystic disease of the lung and saccular bronchiectasis.

It is well to remember that Lipiodol is not innocuous and that after its use the oil may remain as a source of irritation if emphysema is present. Also after it passes a partially obstructed bronchus, it will not be coughed up from tension cavities, large abscess cavities, or saccular bronchi and must be removed with the lesion. It is conceivable that more lung tissue than is involved by the disease will have to be removed after its use.

Bronchoscopic examination is done routinely because it shows the main sources of exudate, areas of acute inflammation, tumors, or foreign bodies. Prior to operation the patient coughs up all of the sputum he can and then bronchoscopic aspiration is done to remove as much secretion and exudate as possible. Some surgeons prefer to operate in the afternoon because the patient will have emptied the bronchial tree of exudate by this time.

Treatment.—Treatment consists in general care—nutritious foods, fresh air, sunshine, and ample rest—and postural drainage, which must be prolonged. Above all, there must be tireless perseverance. In children a special iron frame covered with canvas is used. This is tilted at intervals, permitting easy expectoration. Bronchoscopic aspiration helps. Penicillin and streptomycin intramuscularly and by inhalation is of great value in early cases. If the bronchiectasis is symptomless (diagnosis by bronchography), medical management alone will give good results. In extensive cases, where all lobes are involved, or in those patients, usually

over 50 years, in whom the cardiorespiratory reserve is too poor to attempt surgery, medical treatment is indicated. In all others surgery should be done.

Surgical Treatment.—Preoperative preparation of a patient for lobectomy is designed to put the lungs in the most favorable condition possible and to improve general health. To accomplish the former, the lungs must be kept empty of their exudates by postural drainage and bronchoscopic aspiration if necessary, sinuses are treated if infected, pleural infections are drained, and bacterial flora are reduced by inhalation of penicillin, which is also given intramuscularly with streptomycin for three to four days. The general health of the patient is improved by attention to the focus, but, in addition, the anemia, which is usually present, must be combated by a nutritious diet and blood transfusion. Vitamins B and C are given and attention is paid to water and protein balance. Sulfadiazine is given by mouth in large doses (3 to 4 Gm. daily) to control bacteremia.

FIG. 237.—Pneumonectomy for extensive bronchiectasis and chronic empyema. K. K., a 7-year-old girl, had left lower bronchiectasis with productive cough since the age of 4. *A left lower lobectomy was done elsewhere, but the child continued to cough.* She had episodes of chills and fever and had lost much weight. Bronchoscopic and x-ray studies showed extensive saccular bronchiectasis of the remaining upper lobe. Upper lobe removed and parietal decortication done over the old empyema cavity. Portions of the fourth, fifth, and sixth ribs were removed and muscle flaps used to close the cavity. X-ray shows condition about one year after surgery. The child is well and has gained much weight. She is attending school and plays with other children without restriction. Note the position of the trachea and the stump of the left main stem bronchus. (Case referred by Dr. R. Henry and Dr. H. Call.)

The *operation* is conducted under ether-oxygen endotracheal anesthesia, or nitrous oxide-oxygen anesthesia supplemented with curare. Patients are placed in 20 to 30 degree Trendelenburg position with the operative site upward. *This favors drainage of mucopus into the*

pharynx where it may be aspirated by the anesthetist. A reverse position is used in bilateral bronchiectasis so that the secretions from the lung tissue being removed will gravitate to the dependent infected lobe of the other side instead of into the trachea, causing suffocation. We have been impressed with the prone position on the table with special upper chest and pelvis rests. This allows free breathing and all secretions find easy exit.

Posterolateral or anterolateral incisions are made, depending on the choice of the surgeon and the lobes involved. For lower lobes, the seventh rib is resected and subperiosteally and for upper lobes, the fifth. Incisions are made through the bed of the rib. Intercostal incisions may be used in thin persons or children but in our hands have given insufficient

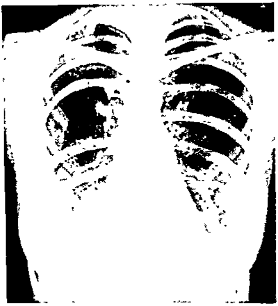

Fig. 238.—Although bronchiectasis is sometimes limited to pulmonary segments, permitting segmental resection of the lobe, very often it involves not only segments but lobes as well. Moreover, it may be bilateral, requiring bilateral resection. The above film illustrates the case of B. M., a girl 20 years of age, who has been an invalid since the age of 12. There was a persistent productive cough with great and extensive clubbing of the fingers, extreme weight loss, and chronic and persistent fever. She had been in and out of hospitals many times. Medical treatment, postural drainage, and all varieties of conservative management had been tried prior to the advent of pulmonary resections. These were unavailing. The patient was operated upon in two stages; the right lower lobe and middle lobe were removed first and then approximately six months later the left lower lobe and lingula were removed. The x-ray picture shows the present condition. This patient who had been incapacitated most of her life is now married and the mother of a child In addition, she is able to take care of her home and family. (Case referred by Dr. L. Levi.)

exposure in many cases. Segmental resections may be used in some cases but usually this will be restricted to the lingula. As our knowledge concerning pulmonary segments improves, more and more lung tissue may be spared. The individual ligation technique is used wherever feasible as is true in surgery of other organs.

During the operation, blood and fluids are given as required through an ankle vein. If necessary, an arm vein may also be cannulized so that

if a large amount of blood be needed, it may be given quickly. Before closing the chest, the lung is re-expanded and penicillin 500,000 units, is left in the chest cavity. Closed drainage is used posteriorly and anteriorly as well.

Postoperative Care.—*Postoperatively* the patient's requirements demand attention to the following: (1) Prevention of shock. Shock may occur from loss of blood and loss of plasma which is greater after thoracic operation than others, anoxemia, or cardiac embarrassment. To prevent shock, frequent blood and plasma transfusions are used. (2) Anoxemia is minimized by prevention of tension pneumothorax or pleural fluid and avoidance of bronchial obstruction by forced coughing, little use of opiates, and aspiration of the bronchi if necessary. Oxygen is used routinely. (3) Cardiac embarrassment is prevented by avoiding tension pneumothorax, large pleural effusions, mediastinal shift, and flutter. (4) Prevention of infection. Penicillin is given intramuscularly every three hours in 100,000 unit dosage and streptomycin, 0.25 Gm., every six hours. Sulfadiazine is given for three days postoperatively up to 4 Gm. a day with sodium bicarbonate. Empyema as a postoperative complication is seen less often since surgeons have paid special attention to the closure of the bronchial stump. This is accomplished by using one row of silk sutures and if possible inversion of the end by first removing a cartilaginous ring. Complete expansion of the remaining lung to avoid dead space and atelectasis which also may predispose to empyema (q.v.) is an invariable requirement.

Complications and Sequelae.—These include postoperative hemorrhage, reopening of bronchial stump with resultant tension pneumothorax or mediastinal flutter, or, later, bronchopleural fistula with empyema, empyema without bronchopleural fistula, acute or chronic, and extension of the bronchiectasis to other lobes. The latter is thought to be a failure to get all of the diseased lung at the time of operation rather than extension of the process. This seems logical because of the slow development of the disease. However, it is true that the basal segments of the lungs are most frequently involved. If the dependent position is a factor, then recurrence may take place in the dependent portion of the remaining expanded lung.

Prognosis.—The prognosis is excellent in children and young adults and is not so good in the older group or those with advanced lesions. Even here, symptoms are ameliorated, although some cough persists. Since most cases are seen in children and young adults, the prognosis is excellent in over 75 per cent of the cases. The mortality for all groups combined is about 5 to 8 per cent.

THE MEDIASTINUM

The mediastinum is the space in the thorax between the two lungs. *In front* is the sternum and behind, the vertebral column. The superior part of the mediastinum and behind, the vertebral column. The superior part of the mediastinum

contains the aortic arch, the innominate artery, the left common carotid and subclavian arteries, the innominate veins, part of the superior vena cava, the trachea, the esophagus, the thoracic and right lymphatic ducts, the phrenic, the vagi, the cardiac and recurrent laryngeal nerves; immediately behind the sternum lies the thymus gland. Fortunately, injuries are rare, due to the adequate bony protection. Infections occur infrequently, the most common cause being a perforation of the esophagus through accident or forceful instrumentation. This results in a spread ing infection known as mediastinitis, which is usually serious and often fatal.

Congenital Anomalies

Before birth the lungs are small and occupy only the dorsal portions of the thorax, whereas the mediastinum is very broad. With the onset of breathing, the lungs expand and compress the anterior mediastinum. The superior mediastinum lies above the upper level of the fibrous pericardium; the inferior mediastinum which lies below the level is divided into the following: (1) Anterior, which lies in front of the pericardium and is bounded in front by the sternum, laterally by the pleurae, and posteriorly by the pericardium. It contains loose areolar tissue, lymph vessels and nodes, and branches of the internal mammary arteries. (2) Middle, containing the heart and the eight great vessels passing to and from the heart. (3) posterior which lies behind the pericardium and also extends downward below its level. The lower eight thoracic vertebrae bound it behind, the pericardium and diaphragm bound it in front. Sometimes communications exist between the two pleural spaces. This is said to be due to overencroachment of the lungs on the yielding anterior mediastinum which becomes compressed and absorbs or is a thin septum as exists in the dog. Such communications cause no symptoms as long as the two pleural spaces are normal. If disease or malformation is present in either lung, herniation may occur with encroachment on the opposite side. The treatment for such anomalies is surgical repair, using the pericardium to make a septum.

Injuries to the Mediastinum

The mediastinum may be injured directly by a crushing force which drives the sternum inward or by penetrating wounds made by bullets or other foreign bodies. In Chapter 18 we considered the effects of injuries to the heart and blood vessels. Earlier in this chapter we reviewed the causes and effects of mediastinal shift and mediastinal flutter. Hemorrhage into the mediastinum, effusion, or actual flooding with retained fluid from traumatic perforation of the esophagus or emphysema increase the pressure within the mediastinum. When this rises to above zero, the large veins will collapse and all the symptoms and signs of cardiac tamponade will ensue, because blood cannot enter the heart, leading to early cardiac inadequacy with a precipitous fall in blood pressure which is sudden and dramatic. Any injury to the mediastinum may be serious because of the increase in mediastinal pressure. As in increased pressure elsewhere, the rapidity of its development is important. Thus in

brain injury a sudden increase in intracranial pressure causes alarming symptoms and signs, whereas the slow rise in pressure due to intracranial neoplasms allows local adaptations. The same is true of mediastinal pressures. Ultimately, however, in either case inestimable symptoms result.

The entrance of air into the mediastinum is more difficult to understand than the presence of blood, exudates, or transudates. Air may reach the mediastinum by the following routes: (1) along the fascial planes of the neck, following injuries to the neck, thyroidectomy, especially in substernal goiters, thymectomy, and other neck surgery; (2) through a perforation of the trachea, lung, bronchus, or esophagus, either traumatically or as an accident in bronchoscopy or esophagoscopy, rarely following pneumonectomy and lobectomy; (3) from the retroperitoneal space due to injuries through the back entering a hollow viscus, gas-producing bacterial infections; (4) from the interstitial tissues of the lung, the result of a rupture of the alveoli and the production of interstitial emphysema of the lung following injuries to the chest, thoracotomy, artificial pneumothorax; increase in intrapulmonary pressure from straining with the glottis closed or from occlusion of the trachea or bronchi with cough, rarely spontaneous rupture of the alveoli; (5) passage from the pleural cavity to the mediastinum following injuries or surgery on the lungs or mediastinum; (6) rarely, if ever, by dissecting its way between parietal pleura and the chest wall or beneath the visceral pleura. The most common is by way of the interstitial tissues of the lung (4).

Air escapes from the mediastinum (1) into the subcutaneous and deep tissues of the neck, (2) through the diaphragm about the aorta and the esophagus to the retroperitoneal tissues, and (3) into the pleural cavities, perhaps along the connective tissue surrounding the blood vessels. The reverse is not true; that is, air will go from the mediastinum into the pleura, causing a tension pneumothorax; the reverse is almost never true. Tension pneumothorax does not cause mediastinal emphysema unless there is a hole in the mediastinal pleura due to actual injury or there is associated interstitial emphysema of the lung.

The symptoms and signs may be mild on small accumulations; when large, there are pain, subcutaneous emphysema, obliteration of cardiac dullness, all the signs of increased intramediastinal pressure, pneumothorax, and x-ray evidence of air in the mediastinum, pleura, retroperitoneal space, and subcutaneous tissues.

The treatment for accumulations in the mediastinum is first to relieve pressure and then try to eliminate the cause. In hemorrhage this is done simultaneously. Foreign bodies may also be removed at this time or later. Fluid is drained. Air is evacuated through an incision in the jugulum and the introduction of a sterile catheter or tube. Rarely the sternum is split to get complete evacuation. Tension pneumothorax is treated as previously outlined; sometimes with small amounts of air, no treatment is necessary.

Inflammations of the Mediastinum (Mediastinitis)

Anatomy

The fascial spaces on the floor of the mouth, in the neck, and in the mediastinum are important because they are the passageways for exudates and transudates upward and downward, forming almost a clear channel from the mandible down to the diaphragm. (See Fig. 232.)

The floor of the mouth contains three paired and one unpaired space. The former consists of the submental, sublingual, and submaxillary and the latter is a variable space or spaces between the extrinsic muscles of the tongue. These spaces are in relation to each other and to the parotid spaces by way of the posterior facial vein. Without the pharynx, the peritonsillar space is in close relationship with the pharyngomaxillary (parapharyngeal) and retropharyngeal space which in turn may lead an exudate into the retrovisceral compartment of the mediastinum.

An infection may start from an injury to the lower lip and travel into the submental, then the submaxillary space, along the intra-oral prolongation of the submaxillary gland, and along Wharton's duct into the sublingual fossa; from here, across the midline through the space of the extrinsic muscles of the tongue to the opposite sublingual and submaxillary spaces. This leads to great swelling of the floor of the mouth as seen in Ludwig's angina. This may lead to further extension as follows: to the parotid space by way of the posterior facial vein, from the parotid space to the neighboring parapharyngeal and retropharyngeal spaces, from here to the subtemporal fossae, and then to the pterygoid spaces which contain the pterygoid plexus of veins. These may be involved by a thrombophlebitis and cause an infection to extend into the cavernous sinus, producing a meningitis. Extension may be downward into the mediastinum by way of the retrovisceral compartment.

The neck is enclosed in a collar of fascia (fascia colli) attached above to the mandible, zygoma, mastoid process, and superior curved line of the occipital bone and below to the sternum and clavicles. It is divided into three compartments by two fascial partitions which cross from one side of the neck to the other: a posterior or vertebral containing the muscles which support the cervical vertebrae; a visceral or middle compartment containing the great vessels of the neck, the pharynx, esophagus, and thyroid gland; and an anterior containing the sternohyoid, sternothyroid, and sternomastoid muscles. Within the vertebral compartment a cold abscess arising from caries of the vertebrae may pass upward to the base of the skull or downward to the posterior mediastinum, whereas in the visceral compartment, infections from the mouth and pharynx and perforations of the esophagus may cause deep cervical abscesses or spread down to the mediastinum. The carotid sheaths which are simply lateral enclosures by the cervical fascia and lymph channels may act as pathways of communication.

Mediastinal compartments (Pearse) may be divided into retrovisceral, viscerovascular, and previsceral.

The *retrovisceral compartment* lies in front of the prevertebral fascia. Therefore, it is a potential space which lies betwen the vertebral fascia posteriorly and the pharynx and the esophagus anteriorly and extends from the base of the skull to the diaphragm. However, at the bifurcation of the trachea it sometimes blends together, forming a platform which may act as a barrier to the descent of exudates into the retrovisceral compartment which lies below this level. Below the diaphragm the retrovisceral space continues as the retroperitoneal space.

The *viscerovascular compartment* is divided into three parts: (1) *Pretracheal space* which extends from the larynx above to the bifurcation of the trachea below, anterior to the trachea and behind the thyroid gland. This space is rarely involved by infections of the floor of the mouth. (2) *Vascular* space which is simply the lateral prolongation of the fascia of the visceral compartment. It is a sheath for the carotid artery, jugular vein, and vagus nerve. Many observers do not believe that this offers a direct connection with the mediastinum. Others aver that it may form a potential

avenue for infection to descend. It has been stated that if you wish to find pus deep in the neck, you must first locate the carotid artery. A curved incision from the angle of the jaw to the symphysis will expose the submaxillary gland lying between the two bellies of the digastric muscle, as a sling. The anterior border of the sternocleidomastoid muscle is a sure guide to the carotid artery below the level of the hyoid bone, and the posterior belly of the digastric is a guide to the artery higher up. Even though pus does not actually descend down the sheath, it is certainly true that the sheath acts as a pathway upon which exudate and transudate may find its way downward, although it is probably true that pus rarely forms in the sheath itself. (3) Previsceral compartment which is the potential space or compartment anterior to the thyroid gland and posterior to the ribbon muscles of the neck (sternohyoid and sternothyroid). It is closed below by fascial attachments to the manubrium. Every surgeon encounters this space as he does a thyroidectomy, and no doubt he has observed the loose areolar tissue with which it is filled. These spaces are important in the study of infections of the mediastinum and the neck because they form the roads which exudates will follow just as the fascial spaces of the hand, lower abdominal wall, and other fascial planes determinate the routes of exudates and transudates.

Causes of Mediastinitis.—(1) Perforation. This may be caused by foreign bodies, by accidental wounds penetrating into the thorax, or by instrumentation in doing esophagoscopy in an attempt to remove a foreign body or dilate a stenosed or strictured esophagus. (2) Intrathoracic inflammations such as lung abscess, pericarditis, suppuration of the tracheobronchial lymph nodes, mediastinal empyema, pneumonia, and among rarer conditions, the fungus infections such as actinomycosis. (3) Very rarely extension of infection below the diaphragm upward as in the subdiaphragmatic abscess. (4) Rarer still, complications of scarlet fever, or other exanthematous fevers, influenza, and septicemia. (5) In the posterior compartment vertebral caries due to tuberculosis or tuberculous lymph nodes breaking down and forming an infection which descends into the mediastinum. (6) Among the more rare, syphilis which may be a very disabling disease, forming a diffuse fibrotic mass of tissue and actually occluding the venous return through the mediastinum. (7) A postoperative infection following tracheotomy, and thyroidectomy, pneumonectomy, lobectomy, the removal of mediastinal tumors, esophagectomy, etc.; also, in operations on the pericardium and osteomyelitis of the spine, infection may occur in the mediastinum. (8) Infections secondary to inflammations of the neck and floor of the mouth which have already been discussed.

Signs and Symptoms.—Symptoms and signs of mediastinitis may be extremely mild with a low-grade fever and very little pain. The leucocyte count may also be within normal limits. The more severe types, however, are easily recognized because of pressure symptoms which give rise to nerve irritation and cause severe pain and tenderness in the chest and sternal pain radiating to both shoulders. In anterior mediastinitis the pain and tenderness are more localized in the sternal area. If there is an accumulation of fluid, whether it be transudate or exudate, there may be interference with venous return, and all the symptoms and signs of mediastinal pressure which have been discussed

under Injuries to Mediastinum and which will be discussed again under Mediastinal Tumors and Cysts may be present.

The x-ray offers considerable help in making the diagnosis because it may show a widening and a distortion of the mediastinal shadow. A lateral picture may fail to reveal the clear space which is ordinarily, but not invariably, demonstrated in the posterior mediastinum. Of course, if there has been a perforation of the esophagus, there will be air in the retrovisceral compartment which may be ascertained by x-ray examination. In addition there may be mediastinal emphysema of great magnitude. There may also be subcutaneous emphysema. Usually the diagnosis will not be difficult if a careful history is taken and if the lesion is suspected.

Treatment.—The treatment of mediastinitis requires immediate operation and will be considered in relation to the various causes of the disease. Before discussing this phase it should be stated that the mediastinum is indeed a closed space and, therefore, it would be unwise to wait for localization in the ordinary sense of the term because it is already localized anatomically. We have learned this principle in discussing infections of fascial spaces of the hand, the distal anterior closed spaces of the finger, and the ischiorectal space. This, then, is another example of an anatomical localization of infection which permits early drainage. Mediastinitis due to perforation of the esophagus may be prevented if the lesion is recognized and prompt suture of the esophagus is performed. A small perforation need not be sutured; that is perforations which are caused by a chicken bone or safety pin. However, large tears or injuries by the esophagoscope or penetrating wounds demand immediate suture. This is best accomplished by making an incision posteriorly, lateral to the vertebral column, and over the site of the perforation. An extrapleural approach is desirable. Sometimes, however, transpleural approach may be necessary. The esophagus is sutured and a soft drainage tube is placed into the mediastinum extrapleurally; then an intranasal tube is inserted so that feeding may be continued without using the esophagus.

Retropharyngeal abscess may be drained by an incision on the posterior wall of the pharynx. This is a common lesion and early drainage is indicated for two reasons: (1) so that perforation does not occur spontaneously, permitting aspiration of pus during sleep; this may be followed by a lung abscess or a disseminating pneumonitis (2) if the abscess is pulsating or if it has been present for some considerable time, a weakening of the wall of the carotid artery may result; this is important, as actually the pulsating abscess has caused a necrosis by pressure; then, when this pressure is suddenly released, severe or even fatal hemorrhage may result. Therefore, in such cases it has been our policy to isolate the common carotid artery first and place a ligature loosely around it. If bleeding does not occur, this need not be tied. It is left in place for twenty-four hours.

Mediastinitis due to infections in the neck or from many other causes in which the superior mediastinum is involved may be treated by an incision parallel and anterior to the sternomastoid muscle in the lower part of the neck. The great vessels are retracted posteriorly, the thyroid gland medially. It may be necessary to ligate the middle thyroid vein and inferior thyroid artery to mobilize the lateral lobe of the thyroid gland better. This is the same route that we use in removing esophageal diverticulum. This gives us a good approach and may be done bilaterally if necessary. Through this opening a foreign body may be removed or a perforation may be closed if it is large. If it is a small perforation with infection, drainage is instituted and a nasal feeding tube is passed so that the esophagus may be put at rest. This incision also permits drainage of the pretracheal space. However, the previsceral compartment is better drained through an ordinary thyroidectomy incision. Indeed, this area is sometimes infected following thyroidectomy and the incision is partially reopened.

A word should be said concerning drainage of the posterior mediastinum with abscess. If it is below the sixth dorsal vertebra, a posterior, extrapleural approach is best. The incision is made lateral to the vertebral column and the overlying ribs are removed subperiosteally for a distance of about two or three inches. The parietal pleura and endothoracic fascia are reflected anteriorly and thereby the pleura is not transgressed. Drainage tubes are placed down on each side of the infection.

The anterior mediastinum may be entered through a peristernal incision, very much like that which is made to enter the pericardium. Great care, however, is exercised not to violate either the pericardium or pleura. Usually this is not as difficult as it may sound, because the infection has thrown up barriers and the abscess cavity is entered rather easily. However, if either the pleura or the pericardium has been injured, it should be sutured immediately after irrigation has been done. Sometimes it is necessary to rongeur away a part of the sternum in order to reach this space.

In addition to the local treatment of mediastinitis, systemic treatment is always necessary. This consists of careful attention to water balance by intravenous route or by the Levine tube, blood transfusions where indicated, penicillin, and the sulfonamides, intravenously or through tubes. The high mortality of mediastinitis has been greatly reduced by early diagnosis and proper treatment.

Mediastinal Tumors and Cysts

Since the advent of modern chest surgery, hundreds of cases of mediastinal tumors have been reported. Heuer believes the origin of dermoids and teratomas to be due to ectodermal displacements or abnormal cells of branchiogenic origin drawn into the chest by the descent

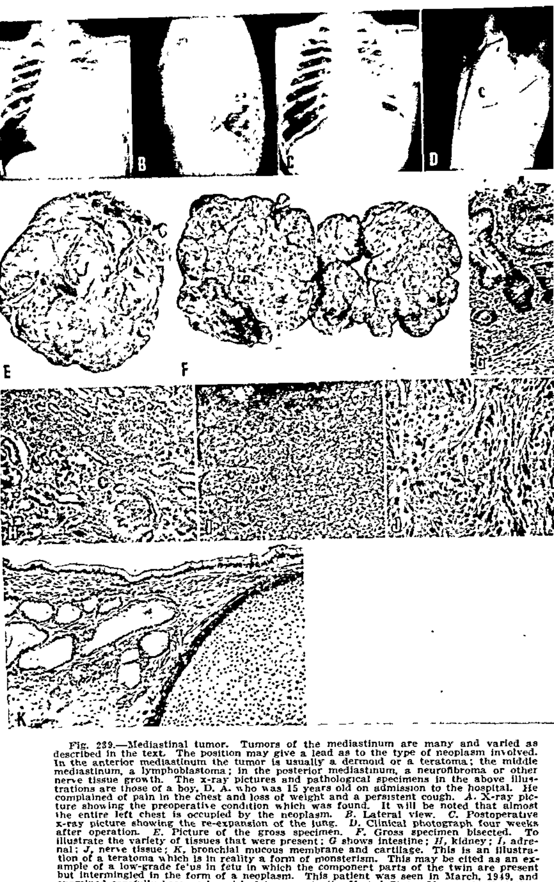

Fig. 239.—Mediastinal tumor. Tumors of the mediastinum are many and varied as described in the text. The position may give a lead as to the type of neoplasm involved. In the anterior mediastinum the tumor is usually a dermoid or a teratoma; the middle mediastinum, a lymphoblastoma; in the posterior mediastinum, a neurofibroma or other nerve tissue growth. The x-ray pictures and pathological specimens in the above illustrations are those of a boy, D. A. who was 15 years old on admission to the hospital. He complained of pain in the chest and loss of weight and a persistent cough. *A*. X-ray picture showing the preoperative condition which was found. It will be noted that almost the entire left chest is occupied by the neoplasm. *B*. Lateral view. *C*. Postoperative x-ray picture showing the re-expansion of the lung. *D*. Clinical photograph four weeks after operation. *E*. Picture of the gross specimen. *F*. Gross specimen bisected. To illustrate the variety of tissues that were present; *G* shows intestine; *H*, kidney; *I*, adrenal; *J*, nerve tissue; *K*, bronchial mucous membrane and cartilage. This is an illustration of a teratoma which is in reality a form of monsterism. This may be cited as an example of a low-grade fetus in fetu in which the component parts of the twin are present but intermingled in the form of a neoplasm. This patient was seen in March, 1949, and examined carefully because he wished to serve in the United States Navy. At that time his general condition was excellent and the x-ray film showed no return of the neoplasm. (From Berman, J. K., Powell, J. P., and Hennessey, P. C.: Am. J. Surg. 74: 205, 1947.

of the heart. Many other theories have been advanced to explain the presence of teratomas and dermoids which are perhaps the most common variety of mediastinal tumor.

Teratology is a subdivision of embryology that deals with abnormal development and its end products—anomalies. While it is certainly true that not all teratomas are examples of monsters, yet a great proportion probably are. Identical or duplicate twins are really an example of teratoma. They develop from a single egg, whereby each member acquires precisely the same chromosomal heritage and hence the same genetic constitution. If they are the same size and completely separate, they form two normal individuals. Identical twins may be a double monster when conjoined and this connection may take place anywhere in the body. If they are joined in the thorax, they are called thoracopagus, sternopagus, or xiphopagus. Sometimes they are not the same size and in such instances the larger is known as the autosite, the smaller the parasite. The latter may be almost a completely developed included twin, fetus in fetu, which grades down into the teratomas that contain disorderly assortments of tissues or organs.

Other theories include the idea that there is an arrest of certain blastomeres which subsequently undergo a partial fulfillment of their primitive developmental potentialities, Cohnheim's theory of cell rests which later for unknown reasons begin to grow, and, last, the unproved concept of parthenogenesis of ovarian eggs.

Types of Mediastinal Tumors.—The mediastinum is a fertile ground for tumors and cysts. This is due to the complexity of its development and its component tissues. The following is a useful, but by no means exhaustive, classification of these abnormalities:

A. Neoplasms and hyperplasias of the thyroid and parathyroid glands
B. Neoplasms and hyperplasias of the thymus
C. Neoplasms of nervous tissue
    1. Sympathicoblastoma
    2. Hour-glass tumors
    3. Neurofibroma, neurilemmoma, neuroma ganglionare
D. Connective tissue neoplasms
    1. Lipoma
    2. Fibroma
    3. Chondroma
    4. Myxoma
    5. Xanthoma
    6. Sarcoma
E. Tracheal and esophageal neoplasms
F. Tumors of lymph nodes
    1. Acute inflammations, tuberculosis (cold abscess)
    2. Lymphoblastomas
        (a) Hodgkin's disease
        (b) Leucemia
        (c) Lymphosarcoma
    3. Endothelioma
    4. Metastatic carcinoma

G. Cystic tumors
   1. Epidermoid
   2. Bronchiogenic
   3. Gastrogenic
   4. Lymphangiomatous
   5. Venous
   6. Pericardial
   7. Pleural
   8. Mixed (dermoid)
   9. Echinococcus
   10. Branchial
   11. Duplication of esophagus
   12. Undetermined

H. Vascular tumors
   1. Aneurysm of aorta
   2. Aneurysm of heart

I. Tumors of pericardium and heart, pericardial cysts, diverticula of pericardium

Symptoms and Signs.—The behavior of mediastinal tumors and cysts is erratic and variable. They may grow or remain quiescent for years. Most observers believe that they grow as the child grows and that they cease growing after maturity, barring complications which would increase their size, such as trauma, infection, or malignant change. Malignant degeneration is uncommon. Heuer states that the largest tumor reported was 15 × 11 × 9 cm. (Smith and Stone). Schneider's case was 45 cm. In sixty cases of dermoids and teratomas, only seven were the latter. Mediastinal tumors seem to grow as the child grows. We have reported one whose size is perhaps one of the largest on record, measuring 20¾ × 20½ × 9 cm. in a body 14 years of age. (See Fig. 239.)

Other types of neoplasms will cause symptoms, depending on the rapidity of their growth, their position, and type.

The symptoms and signs are due mainly to the increase in mediastinal pressure but also to displacements of organs. The former interferes with the return of blood through the superior vena cava and may cause cyanosis, orthopnea, dilation of the superficial veins of the thorax, pulmonary edema, and pleural and pericardial effusions. If the obstruction is above the azygos vein, the symptoms are less severe. If below and pressure is great, there may be subcutaneous edema of the head, neck, and upper part of the thorax, headache, vertigo, deafness, epistaxis, tinnitus, and even convulsions.

Posterior mediastinal tumors such as ganglioneuromas are apt to interfere with the function of the cervical sympathetics, producing Horner's syndrome.

By far the most common symptom of dermoids and teratomas is the persistent cough with or without hemoptysis and dyspnea, which is especially pronounced on the slightest exertion. There may also be dysphagia or regurgitation, hematemesis, and recurrent attacks of asthma or pneumonia. Occasionally a patient with a mediastinal dermoid will cough up hair. This symptom is diagnostic.

Fig. 240.—X-ray picture of a child, M. C., 4 years of age, with a mediastinal tumor involving the anterior mediastinum. This child was admitted to the hospital because she had swallowed a watch chain. Routine films disclosed the tumor mass. *A* and *B*. Preoperative film in the posteroanterior and lateral positions. *C*. Postoperative film taken nine days after surgery. The growth proved to be a teratoma. A checkup made in May, 1949, showed the child to be well and in good health two and one-half years after surgery.

Fig. 241.—X-ray films illustrating mediastinal tumor of the posterior mediastinum. The patient, a woman 31 years of age, complained of pain in the back which radiated anteriorly and into the epigastrium. *A.* Postteroanterior view of the neoplasm as it extends into the left thoracic cavity. *B.* Lateral view showing the tumor mass to be posterior and to lie over the vertebral column. *C.* Postoperative film after the removal of the growth which proved to be a neurofibroma of the hour-glass variety. Patient has remained well.

The size of the growth usually displaces the lung and heart so that there is absolute flatness on percussion, and heart sounds and breath sounds are absent or only faintly heard over the affected side. Sometimes there are no symptoms and the growth is discovered by routine *x-ray examination as in many of our cases.*

Diagnosis and Treatment.—The diagnosis of mediastinal growths *is made by the history, physical examination,* x-ray *films* made *in the* anteroposterior, lateral, and oblique positions, fluoroscopic studies, bronchography, partial pneumothorax, and thoracentesis. Roentgenographic studies are indispensable not only for diagnosis, but also for position and behavior fluoroscopically. In general, the roentgenologist will note the following characteristics:

1. Position. If in the anterior mediastinum the tumor is usually a dermoid or teratoma; the middle mediastinum, a lymphoblastoma; the posterior mediastinum, a neurofibroma or other nerve tissue growth. *Therefore, the position is a clue to diagnosis. Moreover, it is important* in determining the surgical approach. If it is cervical and retrosternal, presenting at the base of the neck, the cervical route or the cervical with division or resection of the superior portion of the sternum is the most direct avenue to the growth. If retrosternal, not extending beyond the mediastinum, access to the growth may be obtained through a trap door incision, transverse sternotomy, or median and vertical *sternotomy which may be superior or inferior or which may traverse the* entire length of the sternum. If the neoplasm is mediastinothoracic, extending into either thoracic cavity, or if it is in a lateral thoracic position, a transpleural approach is best. Posterior neoplasms may usually be removed extrapleurally by resecting the overlying ribs; sometimes laminectomy must be done in removing hourglass tumors.

2. The presence of shadows indicating teeth or bone leads to the diagnosis of dermoid or teratoma.

3. The spine may show evidence of compression. This, with the larger mediastinal shadow, is characteristic of an hourglass tumor.

4. The mass may pulsate. This is best observed fluoroscopically or by the roentgenokymograph and if present, together with a positive blood test for syphilis, or the presence of arteriosclerosis, an aneurysm is the most likely diagnosis.

5. The effect of x-ray treatment on *the size of the mass may help* distinguish between different types of lymph node involvement and may also locate the enlargement in the middle rather than in the anterior mediastinum—a distinction not always easy. Lymphoblastomas are sensitive to x-ray. Leucosarcomas in children regress after roentgen therapy and then later emerge with a full-blown *leucemia. Benign* tumors are not usually radiosensitive.

Bronchography will help in the detection of primary lung neoplasms with mediastinal metastasis and will indicate the site and degree of

bronchial compression from mediastinal growths. Partial artificial pneumothorax may help reveal the exact position of the mass, its fixation, density, and regularity, especially if studied fluoroscopically. Thoracentesis helps rule out encapsulated empyemas, particularly interlobar types. This is especially true now since the use of penicillin locally has become popular. A localized empyema may be sterilized and converted into an inflammatory cyst.

TRACHEOESOPHAGEAL FISTULA

Esophagotracheobronchial fistula may be congenital or acquired. Since most of these fistulae are primarily esophageal problems, they will be considered in Chapter 20 under the alimentary system. We are interested here in those anomalies and acquired defects of the esophagus which result in fistulae.

The *congenital defects* of the esophagus occur once in 2,500 births and may result in: (1) Its complete absence. (2) A blind upper and lower end. (3) Tracheoesophageal fistula, which may be present in three ways: (a) the upper end of the esophagus communicates with the esophagus, the lower segment is blind; this is a rare type; (b) the upper segment is blind and the lower segment communicates with the trachea; this is the most common type; (c) both the upper and lower segments communicate with the trachea; this is also a rare type. The diagnosis of congenital tracheoesophageal fistula is not difficult. In all types there is a large amount of mucus present at birth and all attempts at feeding result in strangling, coughing, and cyanosis. A catheter will not pass into the stomach and in type 3 (a) it goes into the trachea and Lipiodol swallowed goes immediately into the tracheobronchial tree and may be seen fluoroscopically. There is no gas in the stomach or intestines. Type 3 (b) presents the most common picture. A catheter will not pass. The stomach and intestines are greatly distended; Lipiodol is observed fluoroscopically to descend to the end of the upper segment and is then regurgitated and then aspirated, and from the trachea it may pass into the esophagus. Type 3 (c) may not permit the catheter to pass; gas will be present in the intestines and Lipiodol will go into the trachea and lower esophagus at the same time. Rarely an opening may be present at this juncture creating a tracheoesophageopleural fistula. Repair is accomplished through an extrapleural approach on the right side, posteriorly, with resection of one or more ribs. The fistula is ligated and divided and direct anastomosis is done. In type 3 (a) as well as in other types the distance between the two ends may be so great that anastomosis cannot be done without too much tension. In such cases the upper end is brought out through the neck and the lower end through the upper abdomen. Later a skin esophagus is made, uniting the two ends, or the stomach is mobilized by a transpleural approach and brought up to the neck.

Acquired fistulae between the esophagus and tracheobronchial tree may be due to: (1) malignant disease of the esophagus, (2) infections of the esophagus, trachea, or pleura due to tuberculosis, which may also be primary in the nodes, causing caseation, syphilis, fungus infections, suppurative esophagitis, and nontuberculous empyema, (3) traumatic injuries of the esophagus, (4) esophageal diverticula, (5) esophagomalacia seen as a terminal event in cerebral disease, as a result of digestion by gastric contents. The symptoms and signs are dysphagia and cough. Diagnosis is made by x-ray examination, bronchoscopy, and esophagoscopy. The treatment varies with the cause. Small fistulae may be treated by chemical cauterization through the bronchoscope; larger ones must be closed, usually by a transpleural approach, although traumatic types may be treated by an extrapleural operation. In empyema, primary closure or prolonged esophageal rest by nasal tube feeding and adequate drainage of the empyema is done. In carcinoma very little can be done because the lesion has already advanced too far, although a combined esophagectomy and pneumonectomy may be tried in some cases. Gastrostomy is done for feeding.

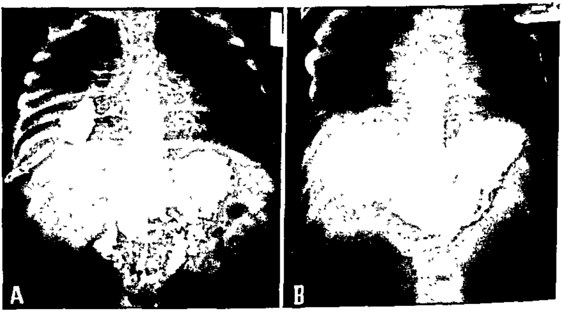

Fig. 242.—Sometimes pleural and mediastinal diseases are combined due to communications between the two compartments. *A*. X-ray picture showing a bronchoesophagopleural fistula. Iodized oil was injected through the thoracotomy wound. *B*. Roentgenogram showing the esophagus after a barium meal. Fistulae are closed and all wounds have healed.

D. A., a boy 23 months of age, was admitted to the hospital in 1941. His aunt, who gave the history, stated that the child had been desperately sick since birth and that everything he ate ran out through a tube which had been placed in the right chest. This had been done by the family physician because of an empyema. However, upon opening the chest cavity the physician noted that milk was present within the thorax. At the same time he noted that when milk was given by mouth, it was found to run *out of the* tube which had been placed within the thorax. The physician then did a gastrostomy for feeding. But when milk was injected into the gastrostomy tube, *it found* its way up and made the child cough. It was obvious that there was a connection between the esophagus and the bronchial tree and the pleural space.

The patient was operated upon in stages; the bronchoesophageal fistula was separated both openings were closed, and then the empyema cavity was obliterated by parietal decortication and muscle flap closure. The patient has remained well. (After Berman, J. K., and Walters, C. E.: Ann Surg. 117: 100, 1943.)

DIAPHRAGMATIC HERNIA

The subject of diaphragmatic hernia could be considered as a part of the discussion on the abdomen or on the thorax because it forms a floor of the latter and the roof of the former. However, it is perhaps best that we discuss it in connection with disease of the thorax since thoracic symptoms are prominent, and in most types of diaphragmatic hernia, the thoracic approach is desirable in the surgical correction of the defect. However, the abdominal route is favored by many and both may be used in a combined thoracic and abdominal incision.

Embryology

The diaphragm is a complex structure and is derived embryologically from several anlage. The first of these is the transverse septum and the fused dorsal mesentery. This gives rise to the anterior, lateral, and the central parts of the diaphragm, thereby forming the greater portion of this structure in the adult. The dorsal mesentery and the mesoderm which is derived from the receding wolffian body, together with the pleuro peritoneal membrane, which is derived from the pulmonary ridge, fuse to form the posterolateral portion of the diaphragm. The exact amount of muscle which is derived from each anlage is variable. The mesodermal cells from the receding wolffian body go to form the right and left crura of the diaphragm. It is probable that the dorsal mesentery gives rise to the posterior and central portions which contain the esophageal hiatus. The pleuroperitoneal membrane grows anteriorly, closing the remaining opening; namely, the pleuroperitoneal hiatus between the peritoneal and pleural cavities. This occurs by fusion with the transverse septum and forms the lateral portion of the diaphragm. Another classification as to the embryological derivation of the diaphragm is as follows: (1) its ventral pericardial portion from the septum trans versum, (2) its lateral portions from the pleuroperitoneal membranes, (3) its margins derivatives from the body wall, (4) a medial dorsal portion from the dorsal mesentery. An understanding of the embryological development will make clear the types of diaphragmatic hernia which may be encountered.

Hernia is seldom seen on the right side due to the broad attachment of the liver. On the left side the surgeon encounters the stomach, spleen, splenic flexure of the colon, and the left lobe of the liver.

Types of Diaphragmatic Hernia

(1) Subcostosternal diaphragmatic hernia. This variety goes through an area which should have been covered by a derivative of the septum transversum. It lies directly posterior to the sternum and has been called hernia through the foramen of Morgagni and through Larrey's fissure or space and substernal, retrosternal, parasternal, or anterior diaphragmatic hernia. The fissures or spaces occur on either side of the midline. This type is rare, and we have had one case. (2) Esophageal hernia through the esophageal hiatus. This type is most common in adults. (3) Dome hernia which is an opening which occurs at the highest point of the diaphragm which seemingly is due to lack of fusion between the septum transversum and the pleuroperitoneal membrane derivatives as well as the derivatives of the mesentery. (4) Pleuroperitoneal hiatus hernia. This is seen most commonly on the left side, although we have had two cases on the right side.

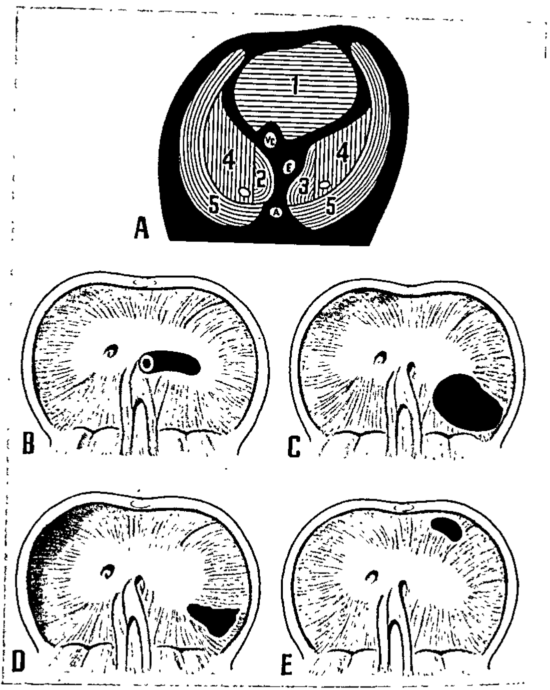

Fig. 243.—Congenital types of diaphragmatic hernia. *A*. Diagram which has been modified showing the origin of the diaphragm. (After Berman, J. K., and Ballenger, F.: Quart. Bull. Indiana Univ. M. Center 4: 36, 1942.) *1*, Septum transversum; *2* and *3*, derivatives of mesentery; *4*, derivatives of pleuroperitoneal membrane; *5*, parts derived from the body wall, *VC*, vena cava, *E*, esophagus; *A*, aorta. (From Prentiss, C. W.: Textbook of Embryology, Philadelphia, 1915, W. B. Saunders Co.)

The lower diagrams are modified from Harrington, S. W.: Western J. Surg., Obst., and Gynec. 44: 255, 1936.) *B*. Esophageal hiatus hernia. *C*. Congenital absence which may be due to the lack of development of derivatives of the mesentery, the pleuroperitoneal membrane, and body wall (transversalis and rectus muscles). More common on the left. *D*. Pleuroperitoneal hiatus hernia which is due to the absence of the derivatives of the pleuroperitoneal membrane. More common on the left perhaps because of the liver. *E*. Parasternal hernias are more common on the right than on the left, perhaps because of the larger attachment of the pericardium on the left. Since the septum transversum forms this part of the diaphragm, it is difficult to explain the hernia on a strict embryological fusion or absence basis. It may be due to a defect in the structure of the diaphragm or a faulty attachment of the right and middle leaflet of the diaphragm to the sternum and costal cartilages.

In addition to the foregoing classifications, there may be a congenital absence of half of the diaphragm. *Also a thoracic stomach, with* or without a short esophagus, may resemble hernia due to the development of the stomach above the diaphragm. Lastly, eventration, or a high diaphragm, may resemble a diaphragmatic hernia. In this case, the diaphragm is immobile and is fixed to a high point, permitting the stomach to lie at an extremely high level. Very rarely an inflammatory necrosis may occur. One other classification should be mentioned and this is congenital or acquired. Of the acquired types, trauma may play an important role. However, nontraumatic types of hernia are common, especially through the esophageal hiatus.

Symptoms and signs of diaphragmatic hernia will vary with the type or variety. Let us now discuss the symptoms and signs of each variety as given in our outline and then we may consider the methods of treatment.

One is the unusual congenital type of hernia known as the *subcostosternal diaphragmatic hernia.* It is also known as the substernal, retrosternal, parasternal, or anterior diaphragmatic hernia. Some authorities do not regard it as a congenital hernia and prefer to classify it as acquired. It is true that it would be difficult, on the basis of our embryological discussion, to account for the particular faulty fusion which may occur, since this part of the diaphragm is all formed by the septum transversum and no other structure. Therefore, there is an argument in favor of its acquired nature. However, the hernial opening is very constant and the hernial sac has a constant relation to the round and falciform ligaments of the liver. Also, the sac frequently protrudes in the right thoracic cavity at the same point as the cardiophrenic angle. Also in connection with this type of hernia, the abdominal cavity does close off from the peritoneal cavity as is evidenced by the presence of a peritoneal layer or sac.

Only two types of diaphragmatic hernia consistently have a sac, and this is important to the surgeon in effecting a cure. One is the hernia under discussion, namely, the subcostosternal hernia, and the other is the esophageal hiatus hernia which is clearly an acquired type, although in the latter, too, there must be a congenital defect or the hernia would not occur.

Symptoms and signs of the subcostosternal hernia will depend upon the abdominal viscera that have protruded and the impairment of respiration. In most types of diaphragmatic hernia there is an interference of respiration, producing dyspnea and cough, and there may be interference with intestinal functions producing symptoms and signs of intestinal obstruction. X-ray examination usually reveals the diagnosis very clearly. Fluoroscopic examination also helps to differentiate the particular variety of hernia which is being discussed. If there is *no protruding* bowel, but simply some omentum, diagnosis is more difficult and

sometimes cannot be made preoperatively. The omentum gives no abdominal symptoms, but there is interference with respiration. Sometimes this type of hernia may be mistaken for a mediastinal tumor.

Treatment for this type of hernia is surgical and the approach is perhaps easier through the abdomen because the opening is very accessible. Rarely there is also a congenital deformity of the thorax and a combined operation may be necessary; namely, both thoracic and abdominal incision. For this reason in all types of diaphragmatic hernia it is best to work under endotracheal anesthesia so that respiration may be continued when the chest is open. Usually the hernia sac is easily identified and may be tied off and the opening closed by overlapping edges of the diaphragm after the abdominal viscera have been replaced. If there is an associated anomaly of the chest, this may be taken care of in accordance with the principles laid down previously in this chapter.

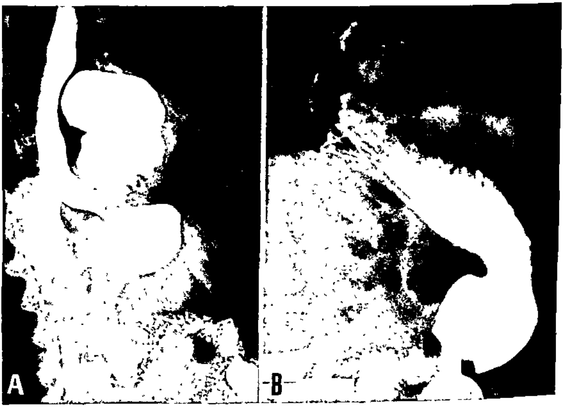

Fig. 244.—Esophageal hiatus hernia. Perhaps the most common of all acquired types of diaphragmatic hernia is illustrated by this case of a woman, M. H., who came to the hospital complaining of epigastric pain, regurgitation of food, and shortness of breath. *A*. Preoperative film in a slightly oblique view. This shows an esophageal hernia which has been popularly termed "upside-down stomach." It will be noted that the esophagus enters the stomach below the diaphragm, that the fundus of the stomach and most of the body of the stomach are within the pleural cavity, and that the pylorus is again below the diaphragm. *B*. Postoperative film showing the structures returned to their normal position. This operation was performed through the eighth intercostal space. The phrenic nerve was crushed and the hernial sac identified and opened. Careful exploration failed to reveal any ulcer or new growth or other abnormality at the site of the constriction. The sac was imbricated very much as in the method of treating a sliding hernia or a direct hernia by tiers of purse-string sutures. The diaphragm was then repaired, using interrupted silk sutures. A few of the sutures were passed through the serosa of the fundus of the stomach to prevent a re-ascent of the stomach into the pleural cavity. (Case referred by Dr. L. F. Bloemker.)

(2) *Esophageal hiatus hernia* is considered next because it is the only other variety of diaphragmatic hernia having a sac. The esophageal hiatus hernia, as its name implies, is a herniation through the esophageal opening. It is the most common type of diaphragmatic hernia occurring in adult life. Its symptoms and signs are so bizarre that it has been known as the masquerader of the upper abdomen, leading to erroneous diagnosis because it may simulate almost any disease in the upper abdomen. Furthermore, it is important because of some of its complications, such as intestinal obstruction, ulceration of the stomach, incarceration of the stomach, ulceration and fibrosis at the cardia, and severe secondary anemia. The cause of the latter is not known, although gastric bleeding is thought to be a factor, but it is an observed fact.

The symptoms and signs of esophageal hiatus hernia may vary from practically none at all to those of pain, abdominal distress, vomiting, gaseous eructation, dyspnea, hemorrhage, severe weakness with anemia, and the various symptoms and signs leading to the suspicion of heart disease. In fact, many cases have been diagnosed as angina pectoris before the true nature of the condition was discovered. The diagnosis is made, of course, by the use of the fluoroscope and x-ray films. Esophagoscopic examination may be used to rule out lesions within the esophagus.

Some patients require no treatment at all; others require weight reduction so that they may have more room in the abdomen and less pressure upon the diaphragm. A third group requires surgery because of a large opening or complications such as incarceration or ulcer of the stomach. Whenever a third or more of the stomach is involved, there will be abdominal or thoracic distress and surgery is definitely indicated. The types of hernia that are found at operation are as follows: (1) the esophagus maintains its attachment to the diaphragm and the cardiac end of the stomach herniates alongside the esophagus. This is called para-esophageal hernia and is present in 20 per cent of the cases. (2) The esophagus is shortened and retracted, but it is long enough to reach the diaphragm by traction. This type constitutes about 70 per cent of the cases. These are usually large hernias and they are very difficult to correct because an opening must be left after surgery and the stomach and lower part of the esophagus are pulled above the diaphragm by the shortened esophagus. Fixation of these structures is difficult. (3) Congenitally short esophagus with thoracic stomach. This may also include cicatricial contractions of the esophagus. Treatment may be instituted by abdominal or thoracic approach. Harrington prefers the former. We have used the thoracic approach with great satisfaction. The phrenic nerve is temporarily interrupted by the injection of Novacain and rarely is it necessary to interrupt the phrenic nerve permanently. The esophagus is mobilized for a short distance and in congenitally short esophagus it is mobilized throughout its lower two-thirds so that the stomach may be returned to the abdomen. Perhaps in the type in which there is congenitally short esophagus this may be necessary so that the dia-

phragm will come up high enough to lie above the stomach. Also in patients who cannot stand surgery, phrenicotomy done under local anesthesia is a satisfactory method of palliation. However, this is not a common procedure in the treatment of esophageal hiatus hernia. The repair must be carried out very much like herniorrhaphy elsewhere; namely, the sac must be identified and separated, the stomach returned to the abdomen, the sac imbricated and partially removed. The sac is usually attached to the serosa of the stomach very much like a sliding hernia and therefore we prefer separating and imbricating it. After the sac has been obliterated, the hiatus is closed tight around the esophagus. In order to avoid closing it too tight, a fairly large esophageal tube is introduced in the esophagus and closure is made around this tube.

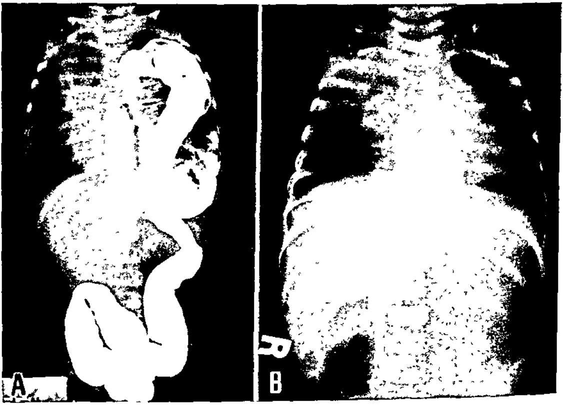

Fig 245—Pleuroperitoneal hiatus hernia. Congenital diaphragmatic hernia seen in a baby girl, S. F., 9 months old. *A*. Preoperative x-ray picture showing loops of bowel in the left half of the thoracic cage and dextrocardia due to the pressure of the intestines on the mediastinum, pushing the entire mediastinum to the right. *B*. Postoperative x-ray picture showing the lung to be expanded and the heart returned to the normal position. This case illustrates a left pleuroperitoneal hiatus hernia. The child has remained in good health. The congenital types of hernia are better repaired from below in general, particularly in the newborn. In older children and in adults the transthoracic route is by far superior in our experience.

Sutures are placed on both sides of the esophagus if the left crus is well developed at its muscular end. If not, it may be better to open the diaphragm anterolaterally and move the esophagus into a more anterior and lateral position before closing on each side. The esophageal hiatus should not be so tight that the forefinger cannot be inserted.

After imbrication of the sac and closure of the defect in the diaphragm, the mediastinal pleura is closed with interrupted silk sutures.

In some cases of very large hernias, a counter incision may be made in the diaphragm laterally, the herniated viscera delivered through this incision, and then the sac imbricated and the hiatus narrowed. Last, the incision in the diaphragm is closed. Fascia lata grafts may be used in extremely large defects. Recurrences are uncommon but do occur because the hiatus cannot be completely closed as in other types of diaphragmatic hernia.

Congenital types of hernia consist of *dome hernia, pleuroperitoneal hiatus hernia, congenital absence of half of the diaphragm* (which is usually within the posterior portion in the left side but may also be on the right), and those through the foramen of Morgagni or the subcostosternal type which we have already discussed.

Dome hernia is uncommon. Even its method of occurrence is not clearly understood. Since this occurs at the highest point on the diaphragm, it is not difficult to repair through the thorax. There is no sac; the commonness with which the abdominal viscera protrude is well known. It should be repaired through a thoracic incision in older children but not in infants because an abdominal approach at this high point would be extremely difficult. We have seen two of these and they have been repaired through the thorax with good results.

Pleuroperitoneal hernia is also a congenital type of hernia and may occur on either the left or right side. It is more common on the left, and on this side it is more conducive to the causation of symptoms. It does occur rarely on the right. We have seen three such cases. In two instances the liver had pushed up into the thoracic cavity to some extent. In one case, a loop of transverse colon had insinuated itself between the liver and the diaphragm and had pushed itself into the thorax, causing an obstruction. Since this type of hernia is a true structural deficiency, we find many associated anomalies, chiefly a failure of rotation of the right colon, but there may be many other anomalies. Protrusions through this type of hernia bring the abdominal viscera into direct contact with those of the thorax because there is no sac. Sometimes there is a little bit of loose areolar tissue which resembles peritoneum and this may be confusing, because it leads nowhere and it will be a waste of time to attempt to identify a sac in this particular type of hernia. Here, again, the phrenic nerve does not need to be crushed or divided, or permanently interrupted It may be temporarily paralyzed by using Novocain, but even this may not be necessary. We have used the thoracic approach in older children and an abdominal incision in the newborn or infant. The chief consideration in the care of such a hernia in an infant is the increase in the intra-abdominal pressure which occurs after it has been repaired. Very often when the contents of the hernia have been reduced there is not enough room in the abdomen to hold the returned viscera, and for

phragm will come up high enough to lie above the stomach. Also in patients who cannot stand surgery, phrenicotomy done under local anesthesia is a satisfactory method of palliation. However, this is not a common procedure in the treatment of esophageal hiatus hernia. The repair must be carried out very much like herniorrhaphy elsewhere; namely, the sac must be identified and separated, the stomach returned to the abdomen, the sac imbricated and partially removed. The sac is usually attached to the serosa of the stomach very much like a sliding hernia and therefore we prefer separating and imbricating it. After the sac has been obliterated, the hiatus is closed tight around the esophagus. In order to avoid closing it too tight, a fairly large esophageal tube is introduced in the esophagus and closure is made around this tube.

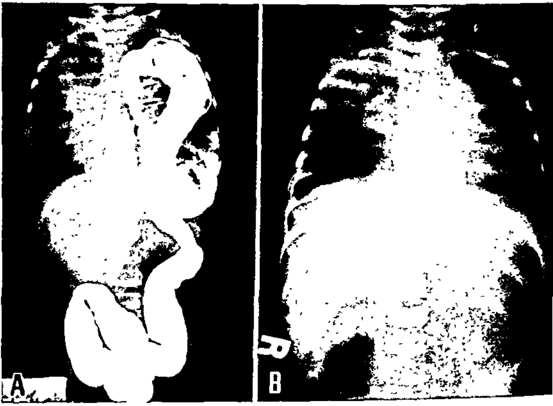

Fig. 245.—Pleuroperitoneal hiatus hernia. Congenital diaphragmatic hernia seen in a baby girl, S. F., 9 months old. *A*. Preoperative x-ray picture showing loops of bowel in the left half of the thoracic cage and dextrocardia due to the pressure of the intestines on the mediastinum, pushing the entire mediastinum to the right. *B*. Postoperative x-ray picture showing the lung to be expanded and the heart returned to the normal position. This case illustrates a left pleuroperitoneal hiatus hernia. The child has remained in good health. The congenital types of hernia are better repaired from below in general, particularly in the newborn. In older children and in adults the transthoracic route is by far superior in our experience.

Sutures are placed on both sides of the esophagus if the left crus is well developed at its muscular end. If not, it may be better to open the diaphragm anterolaterally and move the esophagus into a more anterior and lateral position before closing on each side. The esophageal hiatus should not be so tight that the forefinger cannot be inserted.

greatest causes for postoperative complications; namely, the great increase in intra-abdominal pressure which interferes with respirations, causing anoxemia. Usually in older children there will be enough room in the abdomen and thoracic operation is desirable.

Congenital absence of the posterior portion of the diaphragm usually occurs because the diaphragm simply does not form from the pleuroperitoneal membrane. The defect usually extends from the eighth rib posteriorly and medially to the esophageal hiatus. This type of hernia does not have a sac; however, the loose areolar tissue may simulate one. This type of hernia is really a greatly glorified pleuroperitoneal hiatus type of hernia. It is in this type of hernia that the intestines are apt to herniate to a high level. Sometimes the kidney or the spleen may be found in the thoracic cavity, and on the right side a great portion of the liver may ascend, although this is rare. The chief concern in the repair of large hernias is finding enough fascia or muscle to close the defect. Many ingenious devices have been suggested, and since there is no diaphragm to use, tissue must be borrowed. The posteroperitoneal fascia may be utilized in obtaining a closure by fixation to the thoracic wall; the phrenic nerve may have to be interrupted so that the diaphragm will not pull against the suture line and also so that the relaxed diaphragm will give a little more material with which to work. Sometimes rib resection is necessary so that this portion of the thoracic wall may be pulled in. Also, the transversalis fascia may be used by making an incision through the peritoneum and turning the transversalis fascia back over the defect. Last, a transplant may be made from the fascia lata as an inlay graft.

Congenitally short esophagus with a partial thoracic stomach is really not a hernia, but it is a stomach which lies high because it has never descended below the diaphragm, and this in turn is due to a congenitally short esophagus. This anomaly usually causes symptoms due to stricture. It may be corrected in many different fashions. If the esophagus is not too greatly shortened, the phrenic nerve may be interrupted and the esophagus mobilized from the arch of the aorta down in the hope that the diaphragm will rise sufficiently so that it can be sutured up around the cardiac end of the stomach, making this an abdominal rather than a thoracic stomach. By interruption of the phrenic nerve, the diaphragm can be elevated anywhere from 2 to 5 cm., and then by separation of the attachment of the esophagus from the hiatus and posterior thoracic wall some 5 to 8 cm. more of this organ can be drawn down into the abdomen. The elevation of the diaphragm and the pulling down of the esophagus is not without danger because it is apt to produce a great deal of tension and pull loose. It is perhaps just as well if there is no stricture or symptoms to let it alone. However, where symptoms are present and gastric retention is present, it may be desirable to attempt to correct the defect surgically. In one case we did an esophagogastrostomy in the manner of

this reason we have adopted the procedure of Ladd in the care of large hernias of this type. Here it is our custom to make an abdominal incision and repair the hernia, and if there is a great deal of intra-abdominal tension, the abdomen is closed incompletely; that is, a ventral hernia is established by leaving the peritoneum open and closing the rectus sheath and skin. The abdominal hernia is then repaired in two or three weeks. We believe it is proper to treat the congenital types of hernia, in infants, regardless of whether they are dome or pleuroperitoneal, by the abdominal approach, particularly if a large protrusion of the viscera is present in the thorax, for the reason that having to reduce them, the abdominal pressure may be so great that closure of the abdomen may be very risky. We have observed that this is one of the

Fig. 246.—Pleuroperitoneal hiatus hernia with partial obstruction. F. L. was a boy 8 weeks old who was brought to the hospital because of persistent vomiting. The x-ray photograph shows a diaphragmatic hernia with most of the alimentary tract in the left pleural cavity. There was great delay in the emptying time of the stomach and duodenum. At operation a large pleuroperitoneal hiatus hernia was found. The pyloric end of the stomach, duodenum, a small segment of jejunum, and the sigmoid flexure were all that remained in the abdomen. There was no hernial sac. A catheter was introduced through the opening in the diaphragm to relieve negative pressure and facilitate reduction. After reduction the defect was closed with interrupted silk sutures. In younger infants the abdominal incision would have been difficult to close. During the eight weeks of life, sufficient growth had taken place to permit primary layer closure of the incision. There were no postoperative complications. (Case referred by Dr. H. Stadler.)

diaphragm really does not belong in this discussion since it is not a true hernia. However, since it may give rise to respiratory symptoms due to embarrassment of respiration, operative intervention may be necessary, particularly in the extreme variety. We have only had two of these cases. In both instances they were corrected by a transthoracic approach and the high diaphragm was simply plicated by fine silk sutures. This procedure worked very well and we believe it is probably the best solution to the problem. However, it was found that in neither of our cases did the diaphragm resume its function, but the thoracic space was greatly increased, thereby relieving respiratory embarrassment. In children the respiratory reserve is not as great as in adults and therefore pulmonary symptoms and signs are more pronounced than the gastrointestinal complaints. These are dyspnea, palpitations, thoracic pain, attacks of cyanosis, sense of suffocation in older children, cough, asthmatic attacks, and, also in the older group, referred pain into the left or right shoulder. Sometimes there are gastrointestinal symptoms, and if the child is old enough, he will complain of pain in the upper abdomen, distention, and vomiting in some cases but not in all. The milder types may produce, as we have seen, very few complaints. On physical examination nothing abnormal is seen or palpated. However, bowel sounds may be heard if there are hollow viscera in the chest. A chest film may reveal the diagnosis. A barium enema and an x-ray examination usually give more information and if no obstruction exists in older children, a barium meal may be given. In the presence of obstruction in the newborn or the very young baby, one must consider a congenital diaphragmatic defect. Sometimes the signs and symptoms of esophageal atresia may resemble those of dome hernia. Therefore, in the newborn, when there is great distention and regurgitation with strangling and cyanosis, one must think of the two types of anomalies that have been mentioned. The associated anomalies in our cases of congenital diaphragmatic hernia have not been as common as in other types of congenital defects. We have found umbilical hernia and malrotation of the midgut with excessively long mesentery as associated defects in three of our cases. Dextrocardia is reported in two of our cases, but we believe that this was due to the collapse of the left lung from pressure in the left chest and mediastinal shift rather than to dextrocardia.

Summary

The only treatment that is curative is the surgical closure of the opening in the diaphragm. The approach should be through the abdomen in the newborn, and the muscle-splitting incision aids greatly in the closure of the incision and the prevention of the postoperative hernia. In older children and adults, the thoracic approach is best. A few practical points in the technique may be emphasized. (1) The child must be free from infections of the respiratory tract. (2) Intratracheal ether anesthesia is best. (3) Abdominal approach through muscle-splitting

a Finney pyloroplasty, and we left the stomach in the thorax, suturing the diaphragm around it after greatly enlarging the hiatus, very much like we do following esophagectomy. This man is perfectly well at this time, some years after the operation. The indications for surgery were partial obstruction of the esophagus with stricture and extreme dysphagia. In fact, there was a beginning megaesophagus formation.

Eventration or very high diaphragm. In this case the diaphragm is immobilized and fixed at a high point. This may interfere with respiration and may give rise to paradoxical respiration. Eventration of the

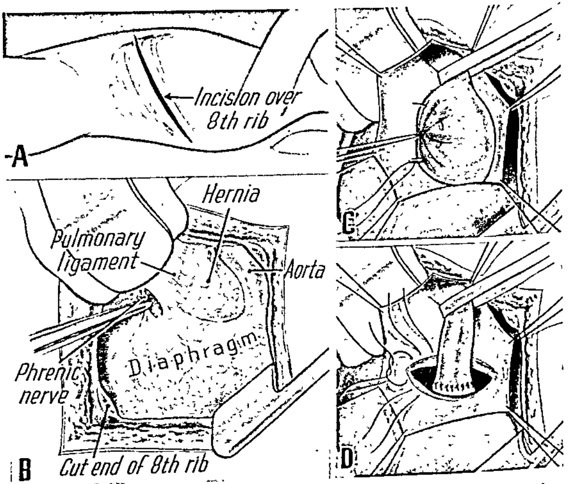

Fig. 247.—Diagrams illustrating transthoracic approach for the repair of esophageal hiatus hernia.

A. The usual incision over the eighth rib or in thin individuals in the eighth interspace without the resection of the rib. *B.* The hernia and contiguous structures. The lung has been retracted upward. The pulmonary ligament is divided and then the phrenic nerve is crushed temporarily paralyzing the diaphragm. The esophagus is freed and the vagi are carefully preserved. The sac is easily identified after incision of the mediastinal pleura. The sac is opened so that the cardiac end of the stomach and esophagus may be inspected for possible ulceration. The posterior wall of the sac is intimately attached to the anterior wall of the stomach so that the sac cannot be dissected free. In this way it resembles a sliding hernia which is described in Chapter 19. The redundant portion of the sac may be trimmed away and then closed and enfolded with a series of purse-string sutures or with interrupted inversion sutures of silk. *C.* Shows the method of purse-string sutures used to enfold the sac. The hiatus is then closed around the esophagus in a manner shown in *D.* Then the pulmonary ligament and mediastinal pleura are sutured with fine silk. It is desirable to make the hiatus large enough barely to admit the forefinger. A tube within the esophagus will guide the surgeon as to the snugness of the hiatus opening.

which was used to drain a perinephric abscess on the left side and the other followed an enormous subdiaphragmatic abscess. The hernia actually occurred many months after the patient had recovered. In both instances a thoracic approach was made and the hernia was closed from above. We believe that on the right side there can be no question about which approach is the more easily done. The liver is in the way and an attempt to close the hernia on the right side through the abdomen will be difficult. On the left side, either the abdominal or the thoracic route may be used. In most of these injuries, since there may be associated injury to the lung, the thoracic route is best. Furthermore, if there is injury to the spleen or the intestine, it can be taken care of through the tear or an incision in the diaphragm. Closure in all types of diaphragmatic injury or hernia may be effected by overlapping the diaphragm or by turning up the abdominal side of the diaphragm and turning in the pleural surfaces. Sometimes the diaphragm is so completely destroyed that a resection of the rib must be made in order to bring the chest wall in so that the ends may be brought together without tension. Usually not more than a few inches of the eighth, ninth, and tenth ribs and the angles need to be resected. It has been our policy not to employ fascia lata. Many authorities do believe that this form of suture is preferable. Where there is large defect, some type of graft, either pedicle or free, must be used. A pedicle flap from the transversalis fascia or the posterior layer of the perirenal fascia is preferable to a free graft from the fascia lata. The same is true of traumatic injuries to the diaphragm, particularly those following necrosis where large parts of the diaphragm may be absent. It is our feeling that using fascia lata as a suture has not great advantage over ordinary suture material and although it may take as a graft, usually if there is tension it will slough, just as slough will occur if there is any tension from any suture material. Where the diaphragmatic edges may be approximated, it has been our custom to evert the peritoneal portion first and then fold down the thoracic portion. In this way we have serosa to serosa on the peritoneal surface and serosa to serosa on the pleural surface. This leaves two raw ridges together and gives a very firm type of closure. In all types of hernia due to trauma, careful exploration of the abdomen is necessary. We recently had a condition of this kind in which there was a traumatic hernia with a rupture of the spleen and a tear in the jejunum. The man had signs of thoracic injury as well as signs of abdominal injury. In other words, this would come under the heading of thoracoabdominal wounds which we have previously discussed. In this case we opened the left thoracic cavity through the bed of the eighth rib. We found a large tear in the diaphragm, and a torn spleen, and also a rent in the jejunum. Splenectomy and repair were accomplished without any difficulty and the patient made an uneventful recovery. In a second case the diaphragm was torn on the right side and the left lobe of the liver protruded into the chest. This was easily repaired. This type of surgery has been well worked out during World War II and has proved effective.

incision is safer than the thoracic or combined approach in the newborn. (4) A semireclining posture facilitates the descent of the intestines from the thoracic cavity. (5) A catheter may be introduced through the hernia so that air may rush into the thoracic cavity. (6) Long guide sutures enable the surgeon to hold the diaphragm down so that a good repair may be obtained. (7) Preliminary phrenicotomy has not been necessary in children. (8) If replacement increases intraabdominal pressure too greatly, the skin of the abdomen may be closed and later the incisional hernia may be repaired as suggested by Ladd. (9) Postoperative care includes intravenous fluids, if necessary, because of vomiting or inability to take fluids and whole blood transfusions to replace blood loss (which is usually small) and to keep up the osmotic index and oxygen carrying power of the blood. Oxygen is routinely used to combat the anoxemia caused by collapse of the lung and temporary immobility of the sutured diaphragm. (10) Strict isolation is carried out to prevent respiratory infections, for pneumonia is the greatest hazard.

The time for the operation should be as soon as the anomaly has been discovered. In our experience, the newborn stands surgery very well if properly fortified with blood and if the fluid balance is controlled. Very often we think that we must improve the condition of these babies. This is not possible in the presence of a large hernia because oftentimes the child actually develops a complete obstruction from an incarceration during the waiting period. Babies are placed in the oxygen chamber and this has been a great help. Should we encounter the congenital types of hernia in the older child, we have invariably used the thoracic approach with great satisfaction.

TRAUMATIC HERNIA

Traumatic hernia really is a misnomer because it is not a true hernia according to our definition. We have defined hernia as "a protrusion of a viscus with a portion of the enveloping membrane through a normal or abnormal opening." It is true that in certain types of congenital hernia, there is a very primitive type of coverning for the hernial protrusion. However, in traumatic hernia there is nothing at all. In other words, this is simply an evisceration or a dehiscence of a suture line in which the abdominal viscera protrude into the thoracic cavity. This type of hernia is easy to diagnose because of the symptoms and signs and x-ray findings. Usually, however, it is thought to be an injury to thoracic organs, and sometimes open thoracotomy is necessary in order to make the diagnosis because there may be both lung and diaphragmatic injury. The diaphragmatic hernia which is the result of an inflammatory necrosis of the muscle caused by subphrenic abscess, or pressure from rubber tubes used in draining empyema cavities, is also a traumatic form of hernia but is very rare. We have seen two of these, one due to the pressure of a tube

was used to drain a perinephric abscess on the left side and the 'ollowed an enormous subdiaphragmatic abscess. The hernia actu- curred many months after the patient had recovered. In both in- s a thoracic approach was made and the hernia was closed from

incision is safer than the thoracic or combined approach in the newborn. (4) A semireclining posture facilitates the descent of the intestines from the thoracic cavity. (5) A catheter may be introduced through the hernia so that air may rush into the thoracic cavity. (6) Long guide sutures enable the surgeon to hold the diaphragm down so that a good repair may be obtained. (7) Preliminary phrenicotomy has not been necessary in children. (8) If replacement increases intraabdominal pressure too greatly, the skin of the abdomen may be closed and later the incisional hernia may be repaired as suggested by Ladd. (9) Postoperative care includes intravenous fluids, if necessary, because of vomiting or inability to take fluids and whole blood transfusions to replace blood loss (which is usually small) and to keep up the osmotic index and oxygen carrying power of the blood. Oxygen is routinely used to combat the anoxemia caused by collapse of the lung and temporary immobility of the sutured diaphragm. (10) Strict isolation is carried out to prevent respiratory infections, for pneumonia is the greatest hazard.

The time for the operation should be as soon as the anomaly has been discovered. In our experience, the newborn stands surgery very well if properly fortified with blood and if the fluid balance is controlled. Very often we think that we must improve the condition of these babies. This is not possible in the presence of a large hernia because oftentimes the child actually develops a complete obstruction from an incarceration during the waiting period. Babies are placed in the oxygen chamber and this has been a great help. Should we encounter the congenital types of hernia in the older child, we have invariably used the thoracic approach with great satisfaction.

TRAUMATIC HERNIA

Traumatic hernia really is a misnomer because it is not a true hernia according to our definition. We have defined hernia as "a protrusion of a viscus with a portion of the enveloping membrane through a normal or abnormal opening." It is true that in certain types of congenital hernia, there is a very primitive type of covering for the hernial protrusion. However, in traumatic hernia there is nothing at all. In other words, this is simply an evisceration or a dehiscence of a suture line in which the abdominal viscera protrude into the thoracic cavity. This type of hernia is easy to diagnose because of the symptoms and signs and x-ray findings. Usually, however, it is thought to be an injury to thoracic organs, and sometimes open thoracotomy is necessary in order to make the diagnosis because there may be both lung and diaphragmatic injury. The diaphragmatic hernia which is the result of an inflammatory necrosis of the muscle caused by subphrenic abscess, or pressure from rubber tubes used in draining empyema cavities, is also a traumatic form of hernia but is very rare. We have seen two of these, one due to the pressure of a tube

which was used to drain a perinephric abscess on the left side and the other followed an enormous subdiaphragmatic abscess. The hernia actually occurred many months after the patient had recovered. In both instances a thoracic approach was made and the hernia was closed from above. We believe that on the right side there can be no question about which approach is the more easily done. The liver is in the way and an attempt to close the hernia on the right side through the abdomen will be difficult. On the left side, either the abdominal or the thoracic route may be used. In most of these injuries, since there may be associated injury to the lung, the thoracic route is best. Furthermore, if there is injury to the spleen or the intestine, it can be taken care of through the tear or an incision in the diaphragm. Closure in all types of diaphragmatic injury or hernia may be effected by overlapping the diaphragm or by turning up the abdominal side of the diaphragm and turning in the pleural surfaces. Sometimes the diaphragm is so completely destroyed that a resection of the rib must be made in order to bring the chest wall in so that the ends may be brought together without tension. Usually not more than a few inches of the eighth, ninth, and tenth ribs and the angles need to be resected. It has been our policy not to employ fascia lata. Many authorities do believe that this form of suture is preferable. Where there is large defect, some type of graft, either pedicle or free, must be used. A pedicle flap from the transversalis fascia or the posterior layer of the perirenal fascia is preferable to a free graft from the fascia lata. The same is true of traumatic injuries to the diaphragm, particularly those following necrosis where large parts of the diaphragm may be absent. It is our feeling that using fascia lata as a suture has not great advantage over ordinary suture material and although it may take as a graft, usually if there is tension it will slough, just as slough will occur if there is any tension from any suture material. Where the diaphragmatic edges may be approximated, it has been our custom to evert the peritoneal portion first and then fold down the thoracic portion. In this way we have serosa to serosa on the peritoneal surface and serosa to serosa on the pleural surface. This leaves two raw ridges together and gives a very firm type of closure. In all types of hernia due to trauma, careful exploration of the abdomen is necessary. We recently had a condition of this kind in which there was a traumatic hernia with a rupture of the spleen and a tear in the jejunum. The man had signs of thoracic injury as well as signs of abdominal injury. In other words, this would come under the heading of thoracoabdominal wounds which we have previously discussed. In this case we opened the left thoracic cavity through the bed of the eighth rib. We found a large tear in the diaphragm, and a torn spleen, and also a rent in the jejunum. Splenectomy and repair were accomplished without any difficulty and the patient made an uneventful recovery. In a second case the diaphragm was torn on the right side and the left lobe of the liver protruded into the chest. This was easily repaired. This type of surgery has been well worked out during World War II and has proved effective.

hind gut. The anterior ectodermal cavity or stomodeum is separated from the pharyngeal cavity by the pharyngeal membrane. Portions of this membrane may persist at birth, but this anomaly is rare.

THE FACE, LIPS, AND PALATE

It is through the branchial clefts and arches (primitive gills) that the face, lips, palate, jaws, and neck develop (see Chapter 19). The complexity of this development may be understood by carefully studying the formation of the following chief processes:

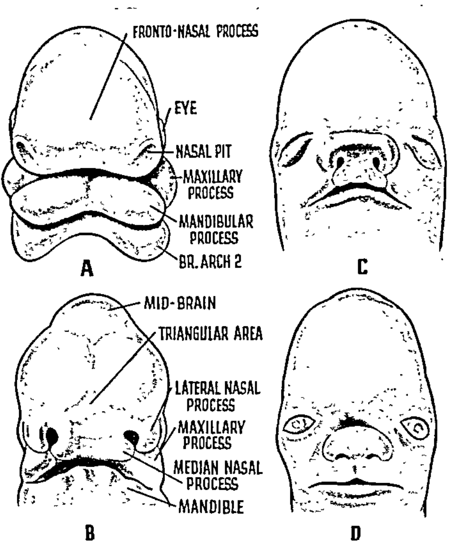

Fig. 248.—Diagram illustrating the development of the human face. (Adapted after Peter, from Arey L. B.: Developmental Anatomy, Philadelphia, 1942, W. B. Saunders Co.) *A*. At 6 mm. (×14). *B*. At 10 mm. (×11). *C*. At 15 mm. (×10). *D*. At 20 mm. (×7.5).

A median nasal process (which appears in the sixth week) in the center of the primitive head above the primitive mouth (which appears in the fourth week).

The medial and lateral nasal processes.

Chapter 20

THE ALIMENTARY SYSTEM

The alimentary tract extends from the mouth to the anus. Before food can be absorbed and used in nutrition, it must be acted upon chemically and mechanically. This action begins in the mouth and is carried on as far as the large intestine, where absorption of water and formation of vitamin K_2 takes place. The refuse is then eliminated through the rectum and anus. The alimentary canal is about thirty feet long.

This chapter will include discussions of the lips, mouth, pharynx, esophagus, stomach, small and large intestines, rectum, and anus. In addition, special organs found within the canal, such as teeth, gums, palate, tongue, and palatine tonsils, must be considered. The accessory glands placed external to the wall of the canal are considered in Chapter 22.

Since the face forms the outer covering of the oral cavity, it is intimately associated with its function and with many of its diseases. Therefore, it, too, should be described. In addition, it is necessary to consider the cavity which contains the gastrointestinal tract (the abdominal cavity) and its lining (the peritoneum), for they are intimately associated with the alimentary system in health and disease.

A description of the development of the alimentary tract is important in order to understand congenital anomalies as well as physiological functions. "An animal in its ontogeny recapitulates its philogeny." Indeed, in the successive stages of development of the human embryo we may trace the development of man from the pisces (fish), through the amphibia (frogs) and the reptilia (reptiles) and aves (birds), especially in the gastrointestinal tract, to the mammalia (mammals).

In the lower animals the digestive apparatus is a simple tube which passes through the center of the body from an anterior or mouth aperture to a posterior or anal aperture. In man this same arrangement exists, but there are certain modifications: (1) The tube is very long (seven to eight times the length of the trunk). (2) Certain portions of the tube have become modified to perform special functions. The mouth has teeth and tongue for mastication and deglutition. The stomach contains gastric glands, producing gastric juice; the small intestine has villi to facilitate absorption. (3) Certain special accumulations of glandular tissue outside the canal (salivary glands, liver, pancreas) are connected with it by ducts and pour secretions into it. These organs have been developed from the tube as outgrowths. They are considered under the glandular system. (4) Even the rectum is a late development in the phylogenetic scale and permits temporary storage of excreta.

In the early embryo the spherical vitelline sac has two entodermal tubes which develop cranially and caudally; these are the fore-gut and hind-gut, respectively. The region between these tubes opens anteriorly into the yolk sac and is known as the mid-gut. At each end the entoderm comes into contact with ectoderm ventrally, forming the pharyngeal membrane of the foregut, and dorsally, the cloacal membrane of the

hind gut. The anterior ectodermal cavity or stomodeum is separated from the pharyngeal cavity by the pharyngeal membrane. Portions of this membrane may persist at birth, but this anomaly is rare.

THE FACE, LIPS, AND PALATE

It is through the branchial clefts and arches (primitive gills) that the face, lips, palate, jaws, and neck develop (see Chapter 19). The complexity of this development may be understood by carefully studying the formation of the following chief processes:

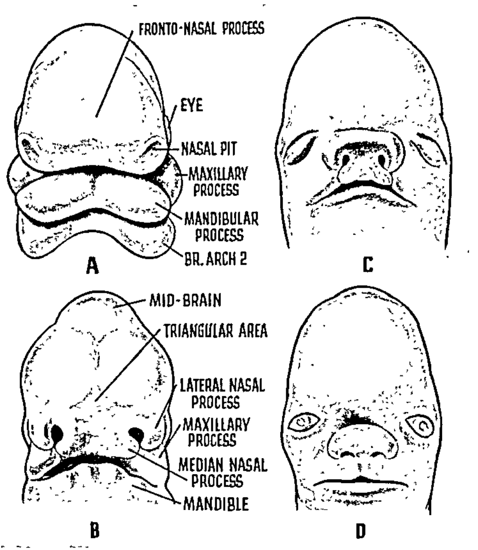

Fig. 248.—Diagram illustrating the development of the human face. (Adapted after Peter, from Arey L. B.: Developmental Anatomy, Philadelphia, 1942, W. B. Saunders Co.) *A*. At 6 mm. (×14). *B*. At 10 mm. (×11). *C*. At 15 mm. (×10). *D*. At 20 mm. (×7.5).

A median nasal process (which appears in the sixth week) in the center of the primitive head above the primitive mouth (which appears in the fourth week).

The medial and lateral nasal processes.

The maxillary processes, which will move toward the center and join the lateral nasal processes.

The mandible, which moves toward the center and fuses.

It is easily seen why most deformities are in the upper lip and palate. This is due to a failure of fusion between the medial and lateral nasal processes in the former case (harelip) and the maxillary processes in the latter (cleft palate), although other anomalies such as leontiasis ossea may result from irregular fusions.

The face is made up of skin and the muscles of expression and is lined by mucous membrane (the mouth). There is no deep fascia, so that the line of the face occurs due to muscular movements. These muscles are the continuation really of the platysma muscle (panniculus carnosus) in the neck, a well-developed structure in lower animals. There are great variations in the development of the various muscles of the face. The orbicularis oris muscle is of great interest in repairs of the upper or lower lip for congenital malformations and after the excision of new growth. This muscle is well developed at the corner of the mouth but quickly thins out as the alae of the nose are reached.

The nerve supply of the face is sensory and motor. The former function is carried chiefly by the fifth (trigeminal) nerve which has three divisions: the ophthalmic, supplying the area about the eyes; the maxillary, supplying the cheeks; and mandibular, supplying the lower jaw area. The chief motor nerve is the facial (seventh cranial nerve), which emerges from the skull through the stylomastoid foramen, just below and posterior to the ear, and is then distributed like a fan over the entire face. The surgeon is careful to avoid the facial nerve by making incisions parallel with it. The tongue is supplied by the hypoglossal nerve.

The arteries of the face come from below upward and are all branches of the external carotid. This is important because facial hemorrhage may be controlled by pressing this vessel against the carotid tubercle (anterior tubercle of the transverse process of the sixth cervical vertebra). The arteries are the external maxillary and the transverse facial; the latter is a branch of the superficial temporal. The chief vein is the facial, which empties into the internal jugular. The angular vein communicates, through the superior ophthalmic, with the cavernous sinus. The lymph flow is from above downward, except about the eyelids, from which the lymph drains laterally into the parotid nodes.

Congenital Malformations of the Lips and Palate

Harelip gets its name from the supposed resemblance to the rabbit lip. It may be single or double. The treatment is surgical repair and is done in the early weeks of life to prevent secondary facial deformities, speech defects, etc.

Cleft palate is a failure of the hard palate (palatine process of maxillary bone) to fuse. Fusion normally proceeds from before backward and therefore clefts may be partial or complete. The treatment is also surgical but is done at about 3 or 4 years of age because it is a much more serious operation and moreover the cleft later becomes narrower. The operation consists in trimming the edges and then suturing them carefully together. In cleft palate this is preceded by lateral incisions and elevation of the flaps. This is done to relieve tension and improve the blood supply.

Wound healing must be thoroughly understood by the surgeon who repairs harelip and cleft palate. Since the closure is made in a contaminated field, surgical trauma must be held to a minimum because it will predispose to infection. Tension on suture lines must be avoided; thus the

lip is mobilized together with the ala of the nose and the palate is pushed back by an anterior curved incision in congenitally short palates. Also in cleft palate repair flaps are elevated and sutured back; then after several weeks or months the flaps are lifted up and sutured. This permits them to form a better blood supply and also allows for more granulation tissue to form on the bed of the shifted flap. In addition, as the flaps are sutured, if tension is still present, only the anterior portion is sewed. Then after two or three weeks the posterior portion is closed. When a child is under anesthesia, the palatine muscles are stretched to get approximation of the palate. On awakening, the shortened muscle which has been drawn abnormally over into the midline becomes active and pulls on the suture

Fig. 249.—Double harelip. In the embryo the central portion of the mouth is formed by the nasofrontal process (median and lateral portions on each side), which unites with the maxillary process on each side to form the upper lip, maxilla, and nostrils. If union fails, an opening remains between the mouth and nasal chamber. If this failure occurs between the median and lateral nasal processes, as here shown, the premaxilla remains isolated, with its two central incisors.

line. To avoid this, the hamular process may be divided or the tensor palatine muscle may be severed. Obviously the palatine artery must not be injured or the blood supply to the flaps will be impaired. Last, some form of splint to obtain rest is used after harelip and cleft palate operations—in the former a special wire adhesive device and in the latter a cemented wire splint which is attached to the teeth. A failure will prevent perfect results by subsequent operations because of fibrous tissue replacement and lack of normal mucous membrane or skin (harelip). Thus the rules to secure repair of tissue by first intention must be observed meticulously so that the factors which delay healing will not occur; namely, in-

fection, poor blood supply, large space to fill in, lack of rest, foreign bodies, and poor general condition of the patient.

Prognathism or the protrusion of the lower jaw may require surgical correction for cosmetic as well as physiological reasons since it may interfere seriously with mastication. Varying with the degree and type of anomaly, the following procedures are available:

1. Resection of a portion of the body of the mandible in the retromolar area, either unilaterally or bilaterally through a submandibular approach. The alveolar nerve should be preserved. The bone ends are approximated with silver wire and the jaw is immobilized by interdental wiring for eight weeks.

2. Diagonal osteotomy and partial resection of the ramus or horizontal division of the ramus. In the latter method the incision is made behind and below the lobe of the ear and parallel with the ramus. The parotid gland is dissected forward. Sectioning should not be lower than one-half inch below the mandibular notch to avoid injury to the inferior alveolar nerve and vessels.

Infections of the Face

Infections of the face may be of the localized type, such as carbuncle, furuncle, and impetigo contagiosa, or of the spreading variety, such as erysipelas, or of the mixed type which in debilitated children starts in the mouth and may give rise to gangrenous stomatitis (noma, or cancrum oris). These and the rarer infections such as tuberculosis, syphilis, actinomycosis, and anthrax have been discussed in previous chapters. It is well to point out that many diseases behave differently on the face than elsewhere in the body. Examples are erysipelas, carbuncle, and lupus erythematosus. This is due to the anatomical and immunological peculiarities of the face as described in Chapter 5.

The lips may be inflamed due to actinic rays (actinic cheilitis), cosmetics (cheilitis venenata), virus (herpetic cheilitis), drugs, and avitaminosis (cheilosis).

Maxillofacial Injuries

Maxillofacial injuries are treated in the same way as injuries elsewhere on the body (see Chapters 5 and 16). However certain special problems peculiar to the face and mouth should be mentioned.

Because of the edema which usually results, an airway must be provided at once, either by nasal tube or tracheotomy.

Blast or tattoo injuries to the face require careful scrubbing with a stiff brush or curette to get out foreign bodies.

Injuries to the eyelids may cause great swelling, thereby obscuring severe injury to the eyeball which may be so severe as to require enucleation.

The external ear should be carefully sutured with nonabsorbable material and allowed to remain in place for two weeks since cartilage heals slowly.

The lips, tongue, and floor of the mouth should be cleaned and sutured; if injury to the latter is deep and cleansing is late, external drainage may be necessary.

The nose requires careful attention, and if a deformity results, cartilage and skin from the ear may be used as a graft. In fracture of the nasal bones a dental mold may be used after replacement of the fragments. Hematomas in the mucoperiosteum should be evacuated.

The accessory paranasal sinuses may be fractured and they may contain foreign bodies which should be removed even if a Caldwell-Luc operation is necessary.

Mandibular Fractures

Mandibular fractures, whether compound or simple, should be reduced promptly and retained by any of the following methods:

1. Interdental wire, using No. 22 or No. 23 gauge stainless steel wire.
2. Inside arch bar attached by interdental wire loops or by tooth bands; this is an excellent method, but a pressure gingivitis may occur.
3. Rubber ligature fixation is excellent but must be strong enough so that muscular action cannot displace the fragments. Wire loops are applied around the upper and lower teeth. Rubber bands hold the jaws together.
4. Instead of rubber bands, small wire may be used to hold the jaws in opposition.
5. In edentulous persons, alveolar wiring or wiring to a tray or splint may be used.
6. Intraosseous, intraoral, and extraoral wiring are indicated in fracture of the mandible and facial bones where it is impossible to maintain these fragments by other methods.
7. The cemented cast metal cap splint with adjustable screw or turnbuckle is useful in many types of fractures and allows for good oral hygiene.
8. Open types of splints made of acrylic or cast metal, locking in the interproximal spaces by projections from buccal and lingual flanges and hinged in the back, are useful in cases where some of the teeth are decayed or missing.
9. External pin fixation is useful only in very extensive fractures with much loss of bone. There inlay grafts are used.
10. Headcap or skullcap traction is used in 9, and sometimes in the edentulous type, maxilla fractures are reduced and maintained by labial arch bar or wiring of lower to upper jaw or by skullcap attachment and wiring to floating segments.

Zygomatic malar fractures should be reduced by the use of tenaculum forceps for grasping the bone through the skin or by the use of elevators

if a compound fracture is present. Direct wiring or external traction with a skullcap may be used. If there is an *associated fracture of the antrum*, this cavity may be packed with gauze through an antrotomy for additional support.

Injuries to the mastoid require curettement of its cells and packing.

New Growths of the Lips and Face

Benign neoplasms such as lymphangioma and hemangioma frequently cause enlargement of the lips (macrocheilia) and tongue (macroglossia). A more important group of benign growths include leucoplakia, white patches on the lining of the lip or palate due to irritation, uncleanliness, or syphilis; *keratosis senilis, small scalelike areas on the lips and face;* and fissures of the lower lip. These may be precancerous lesions and should be eradicated by surgery or radiotherapy.

Carcinoma of the face has been mentioned in Chapter 16. It is more common than any other skin cancer. Three types are seen: (1) basal cell *carcinoma,* (2) *squamous-cell carcinoma, and* (3) *mixed baso-squamous* carcinoma. Although the cause is unknown, many predisposing causes have been mentioned: contact with coal tar products and undue exposure to actinic rays or radioactive substances. Precancerous dermatoses, hyperkeratosis (senile or arsenical), and xeroderma pigmentosum may degenerate *into carcinoma unless protected from actinic rays;* uncleanliness is a factor. Facial cancer may occur anywhere on the face; however, basal-cell carcinoma is rarely observed below a line connecting the lobe of the ear with the mouth. Basal-cell carcinoma practically never metastasizes, whereas squamous-cell lesions of the face do so *only rarely.* The spread is by direct extension, and regional nodes are involved only in very late or traumatized (by inadequate x-ray or surgical or mechanical means) cases. In this regard squamous-cell cancer of the face differs from the same lesion of the ear or lip.

Diagnosis is made by biopsy since some other lesions resemble carcinoma: keratosis senilis, pigmented basal-cell carcinoma (may resemble malignant melanoma), fungus infection (actinomycosis, blastomycosis), mycosis fungoides, leprosy, leishmaniasis, syphilis, *and* tuberculosis.

Treatment is by radiation therapy, desiccation, or surgery. The former is indicated in very late cases or in those where operation is contraindicated because of the poor condition of the patient or inaccessibility of the growth. It should not be used where *cartilage or bone* is involved. Desiccation is useful in small superficial lesions followed by curettage and then more desiccation until all of the growth has been removed. This may be followed by the use of x-ray. Wide surgical excision is the treatment of choice. *Certain areas* require special care lest recurrence take place. First, the vasolabial fold close to the ala nasi; tumors here are apt to involve the superior maxillary bone and antrum (even bilaterally). *Cancers*

of the maxillary sinus may be primary and may extend to the face. Second, tumors of the nose involving the septum and ethmoid cells, which is almost impossible to extirpate.

Carcinoma of the ear is characterized by ear lymph node metastases and therefore requires extensive local excision, even lobation of the ear followed by preauricular and cervical node excision. Otherwise cancer of the face does not require dissection of the neck.

Recently, the old method of chemical destruction for squamous-cell carcinoma has been advocated. In carcinoma of the nose the area is treated with dichloracetic acid and as soon as it turns white, zinc chloride paste is applied. Biopsies taken from the margin show whether all of the growth has been removed.

Late cancer is treated by wide excision or destruction by electrocoagulation and by x-ray.

In all cases reconstruction should be attempted at the time of excision. Where destruction of the lesion has been effected by electrocoagulation, skin graft and plastic maneuvers may be advantageously delayed.

Carcinoma of the upper lip is very rare in our experience. Mixed tumors of the upper lip do occur as in the parotid gland. In the lower lip cancer spreads by lymphatic embolism to the cervical nodes—rarely beyond. Therefore, even in late cases with extensive local extension, excision of the carcinoma with dissection of the lower lip, mandible, and lymph nodes is indicated. Some authorities state that routine neck dissection is not necessary in early cases where no palpable nodes are found, if the patient is watched closely. Others aver that it should be done routinely. We have "sampled" nodes of the first echelon and if uninvolved we have not done a radical neck dissection.

THE MOUTH, TONGUE, AND JAWS

The epithelium of the mouth (buccal mucous membrane) is lined with mucous (apical) glands which lubricate it. However, the mouth is kept moist by the secretion of the salivary glands, which aids in the digestion of starch (ptyalin).

The teeth are set in the alveolar processes of the maxilla and mandible and are covered by gingiva (gums). The tooth is adermal structure, not bone, and is composed of dentine (mesodermal) which is covered by enamel (ectodermal) on its exposed surface and cementum (mesoderm) on its embedded part. In the center is the tooth cavity, or pulp, which contains a soft substance (pulpa dentis), through which nerves and vessels run. The tooth has a root (buried part), a neck (covered by gum), and a crown (the exposed part). There are twenty milk or deciduous teeth, which appear between the sixth and the twenty-fourth month of life. These fall out and are replaced by thirty-two permanent teeth, which begin to appear at about the seventh years and are complete by the twenty-third year. There are four kinds of teeth: incisors, cuspids, bicuspids (premolars), and molars.

The tongue is a muscular organ which is very rough, due to the papillae. On its pharyngeal surface are lymph follicles (lingual tonsils). Within the muscle of the undersurface of the tongue are the mixed serous and mucous glands—glandulae linguales

anteriores (Blandin or Nuhn). The blood supply is the lingual artery, and the nerve supply, the hypoglossal nerve. Sensation is carried by the glossopharyngeal nerve (which supplies the posterior part and carries afferent impulses by way of the sinus branch to the carotid sinus, see Chapter 14) and the inferior maxillary nerve (which supplies the anterior part), and taste by the glossopharyngeal and the chorda tympani branch of the seventh facial nerve which supplies the anterior two-thirds of the tongue.

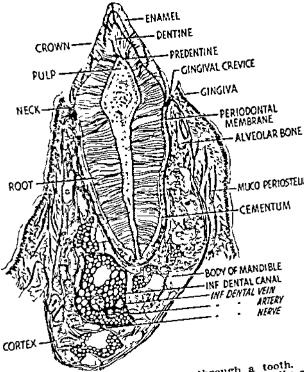

Fig. 250.—Diagram of a longitudinal section through a tooth. The gingival crevice is not normally as wide as indicated. Alveolar abscess is usually associated with caries of the tooth involved. It usually burrows between the periodontal membrane and the alveolar process, and ruptures, or is incised, at the gingival crevice. It may, however, loosen the tooth, invade the mandible or the maxillary antrum, or spread under the gingiva or buccal mucous membrane. Root abscess results from infections which follow down the devitalized pulp and are lodged at the root. These infections are usually not suppurative and do not produce symptoms because the reaction is mild and the area involved, deep. (See Fig. 25.)

Injuries to the Mouth and Tongue

Injuries to the mouth and tongue are usually lacerations which become secondarily infected. A clean incision may heal by first intention. If lacerated wounds are thoroughly cleansed and sutured loosely, they may do likewise. The lower jaw is frequently fractured by a blow or fall. The diagnosis is easy because the teeth do not align properly. X-rays reveal the exact location of the fracture. The treatment consists of proper alignment and then wiring the teeth in the region of the fracture; in addition, fixing the lower to the upper teeth as previously described. The patient must subsist on liquid nourishment. Scrupulous cleanliness in the mouth is advisable because the inevitable presence of bacteria predisposes this region to infection. Absorption of toxin from a mouth infection may lead to septicemia or aspiration pneumonia. Locally, osteomyelitis may and frequently does develop.

The salivary glands are occasionally injured (usually incised wounds). Extreme care in the handling of these tissues, together with rigid asepsis, will make the formation of a salivary fistula unlikely. Occasionally the salivary ducts are cut. These should be probed from within and through the wound and then sutured. Should a salivary fistula result, the law of fistula applies (Chapter 5). If the fistula persists, x-ray treatment over the gland will destroy its function, permitting the fistula to heal. Many occupations produce lesions of the mouth which may be classified as abrasions (holding nails in the mouth), decalcifications (explosive factories, acid dippers); caries (sugar dust); pigmentation (copper, silver, lead on the gingivae); inflammations (cheilitis from actinic rays, cosmetics, phossy jaw from phosphorus poisoning, mercury poisoning); circulatory disturbances (bleeding gums in benzene workers, lack of vitamin C); neoplasm and degeneration (from radium, actinic rays).

Infections of the Mouth (Stomatitis)

Acute catarrhal stomatitis is a nonspecific inflammation of the mucous membrane caused by irritants such as condiments, excessive smoking, and poisonous drugs where there is a low general resistance. The mouth becomes red, swollen, and painful. The treatment is rest, a bland diet, and occasional mouth wash of normal saline solution.

The mucous membranes of the body are supplied with lubricating mechanisms (glands). Their product is protective and antiseptic. It is therefore unwise to use mouthwashes to excess. Even though harmless ones be used, they wash away nature's protective barrier and may actually induce a stomatitis. The same may be said for vaginal douching and rectal irrigations.

Gangrenous stomatitis (noma) has been described previously (see Chapter 6).

Aphthous stomatitis (thrush, or canker sore) may be caused by a fungus, *Oidium albicans* or *Monilia* (*Candida*) *albicans*, and occurs in association with avitaminoses, bacterial infections, and irritations of the mouth, and manifests itself by small yellowish blisters or sores in the mouth, tongue, and lips (perlèche). Although it usually occurs in infants and children, it is also seen in adults, especially in those with pellagra and sprue and stomatitis nervosa. Boric acid mouth wash, or the application of 1 per cent silver nitrate solution to the lesions or 2 per cent aqueous gentian violet solution, shortens this self-limited disease. In resistant cases penicillin is useful.

Vincent's angina is also known as trench mouth. It was formerly thought to be due to the spirillum of Vincent and the fusiform bacillus growing in symbiosis. Although these organisms occur in the mouth normally, they are increased in the presence of the disease. However, it is doubtful if they are the specific cause; the condition is probably the result of a mixed infection. The buccal mucous membrane and gingiva become

ulcerated and are covered with granulation tissue which bleeds freely. The gums recede from the teeth. Zinc peroxide in weak solution as a mouthwash and sulfanilamide internally are excellent remedies. Penicillin is useful locally and intramuscularly. In addition, the excessive granulation tissue and tartar should be gently removed and systemic treatment instituted.

Infections of the Tongue

Infections of the tongue are known as glossitis and may occur (as a result of trauma) in the dangerous acute form or in the less fatal chronic form which may result from hypertrophied papillae and uncleanliness. The tongue may be cleansed by using one of the various digestant powders or liquids. These dissolve the food particles which have accumulated between the papillae.

Leucoplakia may be due to mechanical, chemical, or thermal irritation or to infection as has been described, or it may be carcinomatous. It is a "keratosis" of the mucous membrane which may correspond to a collus or hypertrophy seen in the skin. It may, however, be invasive, in which case it is carcinomatous. A biopsy should be done. If benign, escharotics or cauterization may be necessary after all possible causes have been eliminated. Carcinoma requires excision or radiation.

Simple ulcers occur on the tongue as a result of jagged teeth or improper denture. They are innocuous but should be treated with 5 per cent silver nitrate after their cause has been corrected. The danger is carcinoma. Tuberculosis, syphilis, and actinomycosis also occur in more or less typical form. Glossitis, associated with monilia, occurs in sprue, pellagra, and other avitaminoses.

Infections of the Jaws

Although dental caries is probably not due to an infection (but to hereditary causes, vitamin deficiency, mineral shortage, dietary indiscretions, etc.), it does open the way for infection to invade the dentine, pass into the pulp, and work its way outside the root under the periodontal membrane (the periosteum of the alveolar process). The first gives rise to toothache; the second, to alveolar abscess. The patient suffers severe pain, and the gum, buccal mucous membrane, and cheek become swollen. The abscess may burrow up into the antrum (when the abscess is in the upper jaw) or into the alveolar process, setting up an osteomyelitis of the jaw, which may in turn drain to the outside, causing a sinus (see Chapter 21). The treatment is that of an abscess anywhere: Wait for localization, which is aided by heat and the use of hypertonic salt solution as a mouthwash; avoid injury to the pyogenic membrane; therefore, do not perform an extraction, for this would spread the infection; incise and drain the abscess by cutting through the periodontal membrane close to the tooth. Root abscess follows the same path as the above but is said to be much less severe, due to the fact that it is caused by the less virulent *Streptococcus*

viridans. The evidences of such infection are the so-called granulomas at the root of the tooth. Under the microscope these look like fibrosed granulation tissue and are usually sterile. Formerly it was thought that these "tombstones" of previous infections were "silent and symptomless" foci of infection which caused a multitude of ailments. These teeth were ruthlessly, and sometimes unnecessarily, extracted. In Chapter 5 we have learned the symptoms and signs (local and general) of acute and chronic infections and we have studied the proper methods for their control. From these studies one may conclude that a focus of infection to be entirely silent and symptomless must have been completely controlled by nature (pyogenic membrane, local immunity). Examples may be found in the liver, spleen, and kidneys as infarcts, and as the roots of most teeth. They are probably innocuous. Should there be no evidence of tissue reaction to the presence of microorganisms, a contamination rather than infection is present.

Dirty mouths, full of tartar, food debris, and the ever-present bacteria, sometimes lead to pyorrhea alveolaris. This does not imply that "clean" mouths may not have the disease. As a matter of fact, the cause of this painless gum recession is unknown. The formation of tartar may be related to the precipitates elsewhere, such as kidney stones, salivary calculi, and gallstones and may be due to hereditary causes. Perhaps dogs rarely have it because they keep the tartar off by bone gnawing. Infection under a cover of tartar causes a gingivitis which may be serious. Slow, painstaking cleaning up must be carried out to secure a recovery. Any quick, traumatizing methods may cause a diffuse infection. This clean-up should not be done immediately before an operation. Local and systemic use of penicillin before and after this treatment, especially if extractions are done, may minimize the transient bacteremias which may follow such treatment.

Tumors and Cysts of the Mouth, Tongue, and Jaws

The mouth is one of the most frequent sites of *cancer.* It manifests itself as a chronic ulcer or a raised tumor on the buccal mucous membrane, gingiva, or floor of the mouth. It is more common in men, particularly in smokers and chewers of tobacco. All jagged teeth and sources of irritation should be removed, for here chronic irritations are to be feared. Metastasis is by way of the submental and submaxillary lymph nodes. Early and complete removal of the growth and lymph nodes followed by x-ray gives good results. Usually this is not feasible because of the advanced stage and therefore radium is preferable in many cases. However, every effort should be made to remove even advanced growths surgically because of their tendency to remain in the locale in which they start. Intraoral carcinoma may be multiple due to its lateral spread. Occasionally it is multicentric in origin. Rarely adenocarcinoma may arise in the parotid (Stensen's) or the submaxillary (Wharton's) gland ducts.

Benign mucous cysts occur in the apical glands of the mouth and mucous glands of the tongue and should be excised.

The *tongue* is also a frequent site of *carcinoma*, especially on its lateral and anterior edges. Carcinoma is frequently associated with syphilis of the tongue. Any chronic ulcer, fissure, tumor, or chronic leucoplakic area warrants removal by the cautery for microscopic study. Symptoms are pain and interference with speech. Later, a large infected ulcer forms, with excruciating pain, involvement of the cervical lymph nodes, and death from cachexia. The disease may be prevented in a few instances by avoiding chronic irritations by proper dental care. Cure can be produced by removal of the growth, with a wide margin, and the cervical nodes. Radium needles, implanted, give good results. Speech is impaired, but not badly, after resection of half or more of the tongue.

Fig 251.—Carcinoma (squamous-cell) of the tongue.

Tumors and cysts of the jaws are closely related to the teeth. Epulis is any tumor of the gingiva but is usually a fibrous type of benign, giant-cell tumor. Odontomas correspond to teratomas. A composite odontoma is composed of enamel (ectoderm) and dentine (mesoderm); a radicular odontoma is composed of root elements only. The tumor is made up of pieces of malformed teeth in a fibrous capsule. Root cysts, or dental cysts, are small epithelial-lined cavities containing a yellow fluid. They correspond to epidermal cysts in the skin. Dentigerous (follicular) cysts contain bits of teeth in a fibrous wall and are analogous to dermoid cysts. Inflammatory cysts are not uncommon. Their mode of formation has been discussed in Chapters 4 and 15. They are lined with connective tissue which is thick and must be excised if repair is to follow by healthy granulation tissue. Epithelial-lined cysts require complete extirpation. If small bits of epithelium remain, the cysts may recur. Other benign mandibular tumors which may be single or multiple are benign giant-cell, osteitis fibrosa cystica (hyperparathyroidism), fibroma, ossifying fibroma,

fibrous osteoma, fibrous displasia of bone, and cementoma (which is due to reaction of the periodontal membrane). Malignant growths include fibrosarcoma, osteogenic sarcoma, metastatic carcinoma (breast and thyroid), and ameloblastoma (adamantinoma). The latter arise from the dental follicle or the gum. They are epithelial and may result in adamantine carcinoma. Diagnosis of mandibular tumors is by x-ray and biopsy because there is great variation in x-ray pictures of these growths and there is no characteristic finding. Tumors of the upper jaw correspond to those of the mandible. This includes practically all of the tumors that involve bony tissue and, in addition, many cystic and calcified tumors of the odontoma group. Last, tumors of the accessory nasal sinuses, the nose, and oral cavity may invade the superior maxilla.

Fig. 252.—Epulis. This was not a giant-cell tumor. There was hyperplasia of the gingival epithelium on a fibrous base, with chronic inflammation. Excision was curative.

The *neck* has not been discussed as an anatomical entity but rather its various structures have been included in their proper place. Fascial planes and infections of the neck are discussed in Chapter 19. Since about 85 per cent of the cases of Ludwig's angina follow the extraction of the lower molars or the posterior bicuspids, it is well to mention here that the extraction of teeth may have serious potentialities.

Lymph nodes in the neck are discussed in Chapter 17. Very often a posterior pharyngeal or intraoral carcinoma is overlooked and the first evidence of the growth is in the cervical nodes. Not too rarely cervical node metastases are the first evidence of carcinoma of the thyroid and salivary glands and of structures below the clavicle (breast, lung, esophagus, pancreas, kidney, and adrenal).

Neoplasms in the neck which are primary may be related to the salivary glands, thymus, thyroid, and parathyroid glands (Chapter 22). Some of the rarer neoplasms should be mentioned: primary carcinoma of the eustachian tube; primary growths of the salivary gland (papillary cystadenoma lymphomatosum, pseudoadenomatous epithelioma which is benign, Hashimoto's massive lymphocytic salivary adenitis); branchial

Benign mucous cysts occur in the apical glands of the mouth and mucous glands of the tongue and should be excised.

The *tongue* is also a frequent site of *carcinoma*, especially on its lateral and anterior edges. Carcinoma is frequently associated with syphilis of the tongue. Any chronic ulcer, fissure, tumor, or chronic leucoplakic area warrants removal by the cautery for microscopic study. Symptoms are pain and interference with speech. Later, a large infected ulcer forms, with excruciating pain, involvement of the cervical lymph nodes, and death from cachexia. The disease may be prevented in a few instances by avoiding chronic irritations by proper dental care. Cure can be produced by removal of the growth, with a wide margin, and the cervical nodes. Radium needles, implanted, give good results. Speech is impaired, but not badly, after resection of half or more of the tongue.

Tumors and cysts of the jaws are closely related to the teeth. Epulis is any tumor of the gingiva but is usually a fibrous type of benign, giant-cell tumor. Odontomas correspond to teratomas. A composite odontoma is composed of enamel (ectoderm) and dentine (mesoderm); a radicular odontoma is composed of root elements only. The tumor is made up of pieces of malformed teeth in a fibrous capsule. Root cysts, or dental cysts, are small epithelial-lined cavities containing a yellow fluid. They correspond to epidermal cysts in the skin. Dentigerous (follicular) cysts contain bits of teeth in a fibrous wall and are analogous to dermoid cysts. Inflammatory cysts are not uncommon. Their mode of formation has been discussed in Chapters 4 and 15. They are lined with connective tissue which is thick and must be excised if repair is to follow by healthy granulation tissue. Epithelial-lined cysts require complete extirpation. If small bits of epithelium remain, the cysts may recur. Other benign mandibular tumors which may be single or multiple are benign giant-cell, osteitis fibrosa cystica (hyperparathyroidism), fibroma, ossifying fibroma,

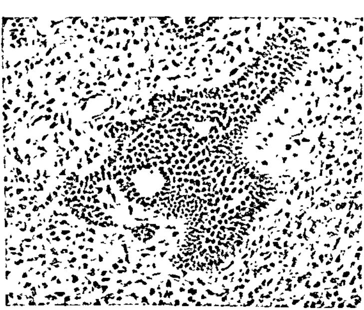

Fig. 255.—Adamantinoma The columnar cells around the periphery are the enameloblasts. The center is filled with these cells which have degenerated.

cleft tumors (pseudoadenomatous epithelioma, benign, branchiogenic carcinoma); thymus (*malignant thymoma, hygroma*); thyroid and parathyroid (Riedel's struma, Hashimoto's disease, aberrant thyroid, Hürthle-cell carcinoma, adenoma of the parathyroid, *adenocarcinoma of parathyroid*, liposarcoma); and tumor of the carotid body, ganglioneuroma, Schwannoma (Chapter 18) liposarcoma, and rhabdomyosarcoma. The *diagnosis in some cases is made by the presence of the growth and biopsy*; in others, by secondary effects such as osteitis fibrosa cystica from parathyroid *adenoma or carotid sinus syndrome from a tumor of the carotid* body. Excision of the growth in every instance is the treatment of choice wherever feasible.

Fig. 253.—Dentigerous cyst. The undeveloped tooth is surrounded by a fibrous sac.

Sarcoma of the jaw occurs either as osteogenic or fibrosarcoma. *Carcinoma of* the jaw is secondary to carcinoma of the mouth or antrum. The treatment of the benign tumors and cysts is local excision, including removal of the epithelial lining about the cysts. The malignant types *may* be *treated* by radium implantation rather than radical resection. However, the latter are preferable *if feasible, including* hemiresection of the mandible. Jaw function may be restored by proper appliances and bone and *soft* tissue grafts.

The veins form a plexus on the exterior of the esophagus from which branches pass in the lower part to the coronary vein of the stomach and higher up to the azygos and thyroid veins. The plexus in the lower part of the esophagus, as in the rectum, forms a free communication between the portal and systemic venous systems. In obstructions of the portal or coronary veins, esophageal varices may form and may bleed profusely (see Chapter 18). The same is true of the hemorrhoidal plexus in the rectum when obstructions to the inferior mesenteric or portal vein are present.

The lymph vessels pass to the deep cervical nodes in the neck, the posterior mediastinal in the thorax.

The nerve supply is derived from the recurrent laryngeal and cervical sympathetic in the neck and the vagus and sympathetic in the thorax.

The act of swallowing is divided into three stages. The first is under voluntary control and is brought about by the action of the tongue and lingual muscles. A pressure of 20 cm. of water is developed in the posterior part of the mouth (a negative pressure is normal in the anterior part of the mouth and in the closed mouth). The second stage is brief and consists of involuntary or reflex contraction of constrictor muscles (see first part of chapter). A negative pressure amounting to 35 cm. of water is created in the pharynx and esophagus, thus aiding the descent of the bolus. In the early days of esophagectomy, when the upper end of the esophagus was exteriorized for further extrathoracic anastamosis, the force of the swallowing reflex was easily demonstrated. In an adult, liquids could be forced for twelve to fourteen inches outside the neck.

The third stage is also involuntary. Food is carried by peristalsis to the cardiac sphincter which is closed except when the peristaltic wave approaches.

The embryology of the fore-gut has been described in Chapter 19. Congenital anomalies have also been mentioned. They consist of atresias, duplications, and enlargements.

Congenital Atresias

We have, in the 2 mm. stage embryo, an entodermal tube, blind at both ends, known as the head and tail folds, respectively. In the former there is a membrane that separates the fore-gut from the stomodeum which goes to form the mouth. This is known as the pharyngeal membrane. The same thing is true in the hind-gut where the blind end is separated from the proctodeum. The latter is known as the anal membrane. Therefore, in the 2 mm. embryo this pharyngeal membrane separates the ventral ectodermal cavity or stomodeum from the pharyngeal cavity of the fore-gut. However, by the 3 mm. stage the membrane is perforated and the stomodeum and the fore-gut becomes a continuous channel. The fore-gut extends from the oral cavity, then to the duodenal papilla, and gives rise to or is differentiated into the pharynx, trachea, lungs, esophagus and stomach, first portion of the duodenum, and the pancreas and liver. The gut is suspended from the dorsal body wall by the dorsal mesentery. In the diagram we have indicated the development of the respiratory organs as well as the esophagus. It will be noted that at first in the 2½ mm. embryo, the respiratory anlage is simply a pouch which has been formed by a groove in the floor of the entodermal tube, just caudal to the pharyngeal pouch. This groove produces an external ridge on the anterior wall of the tube, a ridge which becomes larger and rounded at its caudal end and which is known as the lung bud. The laryngeal or the laryngotracheal groove, as it is called, and the ridge are the forerunners of the larynx and the trachea. The rounded end which we mentioned is the unpaired forerunner of the lung. Externally two lateral longitudinal grooves form, which are the dividing line between the esophagus posteriorly and the trachea anteriorly. By the time that the embryo has reached the 5 mm. stage, the lung bud has divided. These lateral grooves become deeper, and finally a septum is formed which grows superiorly, separating first the lung anlages and then the tracheal tube from the esophagus. The trachea is not developed from the branchial pouches but may correspond with the air bladder of

THE ESOPHAGUS

The esophagus is the part of the alimentary canal which connects the pharynx with the cardiac end of the stomach, passing through the esophageal hiatus in the diaphragm. It lies behind the trachea and the left bronchus. At about the level of the cricoid cartilage pharyngeal and esophageal muscles merge (cricopharyngeus muscle) and form a constrictor mechanism. Just above this point, on the posterior side, esophageal diverticula form (of the pulsion type), if the constrictor does not relax properly in the act of deglutition. Another sphincteric mechanism is present at the cardiac end of the stomach, although a definite cardiac sphincter is not demonstrable.

The gullet extends from the inferior border of the cricoid cartilage and opposite the sixth cervical vertebra to the cardiac orifice of the stomach opposite the eleventh thoracic vertebra, below the diaphragm. It is in the median plane except high in the neck where it lies slightly to the left and continues in this line of the arch of the aorta at the level of the fourth thoracic. Lower down, posterior to the pericardium, it again passes to the left and at the same time forward in order to reach the esophageal opening in the diaphragm which is placed anterior to and to the left of the aortic opening, maintaining this direction until the stomach is reached. In addition to its lateral deviations, it is curved anteroposteriorly to follow the curves in the vertebral column in its upper two-thirds. The esophagus is about ten inches (25 cm.) long and varies from one-half inch (13 mm.) to one inch or more (25 mm.) in the fully distended state. There are three constrictions reducing the lumen to about 23 mm., one at its beginning, another where it is crossed by the left bronchus, and a third where it passes through the diaphragm.

The length of the esophagus varies from 8 to 14 inches (20 to 35 cm.). The distance from the upper incisors to the beginning of the gullet averages about 6 inches (15 cm.). In its course the important relations are as follows: (1) In the neck, anteriorly the trachea to which the esophagus is loosely attached, laterally in the groove between the pharynx and trachea lies the recurrent laryngeal nerves (see Chapter 22), the carotid sheath and its vessels, the corresponding lobe of the thyroid gland, and the inferior thyroid artery. Since the esophagus deviates to the left here, the relations are more intimate on this side. (2) In the thorax, the trachea is anterior to its bifurcation (level of fifth thoracic vertebra); immediately below this it is crossed by the left bronchus, then the pericardium. Posteriorly are the vena azygos, the thoracic duct (which in its upper portion is on the left and may cross it anteriorly and thereby be injured in surgery), the upper five aortic intercostal arteries on the right side, and, in its lower part, the thoracic aorta. The vagus nerves form a plexus which finally forms a left trunk which winds anteriorly, and a right which is posterior. These trunks are severed just above the diaphragm in the operation of supradiaphragmatic vagotomy.

The esophageal wall is composed of the following: (1) Tunica mucularis (longitudinal outer and circular inner layer); the outer layer of longitudinal muscle is covered by adventitia and not serosa. Slips of muscle pervade this layer, attaching the esophagus loosely to the left pleura, left bronchus, pericardium, aorta, and other structures. The absence of a serous coat is important in surgery because of the possibility of leakage. The mediastinal pleura covers the esophagus. (2) Submucous coat which is made of areolar tissue and contains racemose mucous glands. (3) The mucosa which is stratified squamous epithelium thrown into folds.

The blood supply of the esophagus consists of small branches derived from (1) the inferior thyroid artery in the neck, (2) the bronchial arteries and the thoracic aorta in the thorax, and (3) the left gastric and inferior phrenic in the abdomen. The weak area so far as blood supply is concerned is the middle third of the esophagus and therefore anastamoses are usually planned so that the inferior thyroid or gastric-phrenic branches will ensure a good blood supply. However, even the middle third will heal if suture lines are carefully made.

bony fishes. In the 4 mm. embryo the lung bud is present and in 5 mm. embryos the primary bronchus has formed. However, it should be said that before the trachea bifurcates to form the primary bronchus, there appears on the right side the tracheal bud of the upper lobe of the right lung. This bronchial bud is developed only on the right side and appears in the embryos of the 8 and 9 mm. stage. Therefore, we may state that the right bronchus is a direct development of the originally bifurcated lung bud and is really to be considered as a continuation of the trachea, the left side being an offshoot of the former. Within the esophagus the development is of such a nature that the anomalies may occur.

This is due to the fact that the esophagus is originally a vacuolated tube. It really looks like two or more tubes as one sees it from above. In the early embryo it is said to be due to the fact that like the rest of the alimentary canal, the mucosa is laid down first. However, in the esophagus, mucosa is of a stratified squamous type. In its development this becomes ciliated and low columnar, but this changes before birth. The glands of the esophagus are purely mucous. We call attention to this intrinsic development because of the possibilities of obstructions due to persistence of membrane or vacuoles as we have termed them, and in this regard they resemble the same type of stenosis or atresia which may occur in the duodenum or in other portions of the small bowel. Also it is perhaps correct to assume that this peculiar method of development may be the cause of esophageal cysts or duplications which sometimes occur and which are important clinically because they may resemble congenital atresias with various types of tracheal-esophageal fistula.

It is easy to understand from the foregoing review how various types of anomalies may form in the esophagus and trachea. We are interested here only in the former. The anomalies which may be seen, and we are sure this by no means represents all of them, are illustrated in Fig. 256. Types as originally described by Vogt in 1929 are as follows:

Type 1. Complete absence of the esophagus. This is extremely rare and of course is incompatible with life. However, even here attempts may be made to create an artificial opening in the stomach and in the small esophageal bud if there is any which is long enough to bring to the outside.

Type 2. There is a blind end at both the upper and lower segments, but there is no communication with the trachea.

Type 3. Divided into four subgroups:

- 3 (a) The upper segment communicates with the trachea and the lower segment is blind. This is rare.
- 3 (b) The upper segment is blind and the lower segment communicates with the trachea at or about the level of the bifurcation. This is by far the commonest type.
- 3 (c) Both the upper and lower segments have a communication with the trachea. This is rare.
- 3 (d) The esophagus communicates with the trachea but is open throughout its course. Communication is present as a separate tube.

These subdivisions may be *extended, depending* upon the distance between the two ends and the various types of communication. Further-

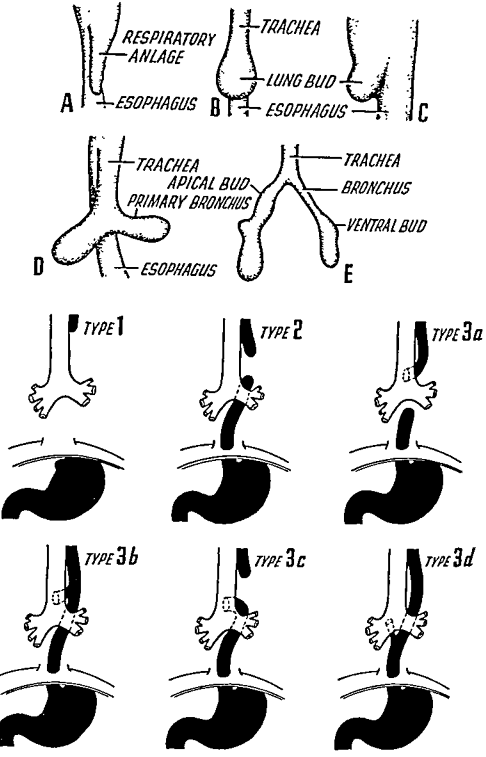

Fig. 256.—Diagrams illustrating the embryology of the development of the esophagus and trachea. (Adapted from Prentiss, C. W.: Laboratory Manual and Textbook of Embryology, Philadelphia, 1915, W. B. Saunders Co.) *A*. At 2½ mm. *B*. At 4 mm. *C*. At 4 mm. in side view. *D* At 5 mm. *E*. At 7 mm. The illustrations below are the various types of congenital anomalies of the esophagus as originally described by Vogt (Vogt, E. C.: Am. J. Roentgenol. 22: 463, 1929). *Type 1*. The esophagus ends blindly and there is no distal end of the esophagus, and the cardiac end of the stomach is also atretic. *Type 2*. The upper and lower ends of the esophagus are present; however, they are both blind, and there is a short distance between them. *Type 3a*. The upper end of the esophagus communicates with the trachea. The lower end of the esophagus is blind. *Type 3b*. The upper and lower ends of the esophagus are in continuity, however, there is a tracheoesophageal fistula. *Type 3c*. The upper end of the esophagus is blind; the lower end communicates with the trachea close to its bifurcation. This is by far the more common variety. *Type 3d*. A variation of *Type 3b* which we have encountered showing the esophagus to be continuous, but there is a tracheoesophageal fistula low down in the esophagus.

catheter will slip down into the stomach, and yet as it is pulled out and the small amount of Lipiodol is injected, some of the oil will find its way into the trachea. Esophagoscopy helps in the diagnosis of this type. Type 3 (c) will give rise to the symptoms of both 3 (a) and 3 (b). Type 2 will show the catheter in the blind upper segment and there will be no gas in the stomach or intestines. In such cases a preliminary gastrostomy is safe and will permit the injection of Lipiodal to determine the distance between upper and lower blind segments so that the subsequent operations may be properly planned.

It may be seen that when the nurse reports difficulty in swallowing, with choking spells, that this anomaly must be considered, and that really a scout film of the thorax and the abdomen immediately gives one the right clue, which may be definitely proved by the methods which have been described.

Treatment requires immediate operation. This consists of a direct anastamosis between the two ends of the esophagus, and this must be preceded by a ligation of the tracheoesophageal fistula if this exists. It is possible to mobilize the esophagus over a distance of approximately 2 to 3 cm. Wider gaps than this are difficult and in such instances the upper end of the esophagus must be brought out through the neck and a gastrostomy must be established; then an external subcutaneous tube must be fashioned or the stomach mobilized and brought up into the neck. This outside tube or stomach mobilization may be made when the child is older. The artificial esophagus may be made by a loop of jejunum transplanted under the skin or of skin entirely. However, reports of the former have not been numerous in American literature, particularly following esophageal anomalies, but they have been reported in connection with strictures and other defects of the esophagus in adults. It is to be desired that a direct connection be established. At best, the artificial subcutaneous esophagus is subject to many complications, and it requires constant attention, although recently Ladd has reported several such cases which have been successfully completed. The classical operation as originally outlined by Richter and first successfully done by Haight is as follows:

An incision is made in the right paravertebral area, extending from the level of the second to the level of the seventh rib. The incision is curved slightly outward, the muscles retracted, and the second, third, fourth and fifth ribs partially resected, subperiosteally. The seventh may be divided, not necessarily resected. Intercostal bundles are tied and the pleura is pushed forward, being careful not to tear it and thereby produce a pneumothorax. Sometimes the azygos vein is in the way, and it must be ligated and divided. The mediastinal pleura is opened and the upper end of the esophagus is easily identified by having the anesthetist or an assistant place a catheter in the blind upper end. The vagus nerve is a good guide. The fistula is doubly ligated with silk and divided, the

more, it may also be subdivided according to whether or not the communication is with the right main stem bronchus or the posterior trachea. The incidence of these anomalies varies with different groups of statistics. After a careful review of the literature it would appear that one may expect to see one of the types of esophageal anomalies in about twenty-five hundred births. This is an equivocal statement and various statistics give it as common as one in three hundred. It is probably true that the former figure is more in accordance with the actual incidence of these anomalies. Of all the types, however, type 3 (b) is by far the more common, accounting for approximately 90 to 95 per cent of all esophageal anomalies. We have observed and treated all types except 3 (a).

Symptoms and signs of the anomaly: Any infant who has more than a minimum amount of mucus should be carefully watched after birth. If, in addition, the child strangles when water or milk is given, one should become suspicious of this anomaly. The most important symptom is this attack of choking and cyanosis, which is aggravated when fluid is given by mouth. There is immediate regurgitation, choking, coughing, cyanosis, and evidence of aspiration of the material. As the infant lies in his crib, mucus drools out of his mouth, and this is excoriating because it contains gastric juice which has found its way into the bronchial and tracheal channel. In addition, there is great distention due to the fact that there is a communication between the trachea or bronchus and the stomach. The diagnosis is easily established without the use of Lipiodol. The following rules should be noted in making the diagnosis:

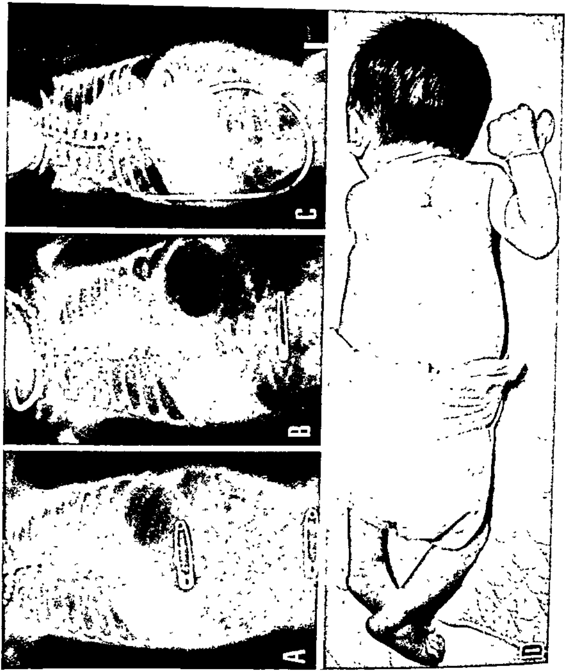
1. When the lesion has been suspected, all nourishment should be stopped by mouth.

2. Barium is absolutely contraindicated and should not be given under any circumstances because it will cause a severe pneumonitis which is apt to be fatal.

3. If it is decided that Lipiodol is necessary, a very small amount is needed; namely, approximately ¼ of 1 c.c. If a large amount is given, it will be aspirated and the child may lose his life by suffocation. Furthermore, Lipiodol is irritating to the bronchial and pulmonary tree. In fact, all that is needed is a No. 8 or 10 rubber catheter which may be inserted to show the blind pouch in the x-ray. This, in addition to enormous distention where no food has been given and where mucus and saliva and irritating juice drools from the mouth, gives clear evidence of a blind upper end and a communication of the lower end with the bronchial tree. Should the anomaly be a type 3 (a), every effort at swallowing will produce violent coughing and cyanosis and there will be no gas whatever in the gastrointestinal canal as detected by x-ray. A catheter may find its way into the trachea, giving rise to a coughing episode. The other types which have been mentioned may give rise to some difficulty in diagnosis. Here again, if type 3 (d) is present, the

Fig. 257.—Congenital atresia of the esophagus, type 3c. *A.* X-ray photograph showing the blind esophagus with an opaque catheter introduced within its lumen. The stomach and intestines are filled with gas, indicating a tracheoesophageal fistula. This is really all the information that is necessary in order to make the diagnosis of type 3c. *B.* However, a small amount of Lipiodol was introduced in the blind esophagus and immediately the child regurgitated this and aspirated it into the trachea. In this way a bronchogram of both lungs was made. *C.* X-ray photograph showing the condition of the patient eight days after surgery. The esophagus is patent, as demonstrated by the catheter introduced from above. The lower catheter is introduced in the stomach through a gastrostomy opening which was made on the day following surgery. *D.* Clinical photograph showing the child after two weeks ready to be released from the hospital.

This infant was operated upon twenty-four hours after birth. A variation of this sequence may be practiced in infants that are not in good condition. The gastrostomy may be done first and continuous suction applied, thereby preventing regurgitation into the lungs. After the child has improved somewhat, then the operation may be done as follows: An incision is made medial to the right scapula, and the fourth rib is resected throughout a distance of about two inches or more. The pleura is carefully stripped and the ribs are spread apart. The azygos vein should be ligated and divided. The upper end of the esophagus is easily identified due to the fact that the anesthetist may introduce a catheter, thereby showing it very clearly. The lower end is easily found by tracing the trachea, downward, and the fistula is encountered usually just above, the bifurcation on the posterior side. The fistula is divided and the proximal end doubly ligated. The distal end is then sutured to the proximal end of the esophagus in an oblique manner, thereby increasing the diameter of the suture line. Two small Penrose drains are introduced in the retropleural space. At no time is the pleural cavity opened. The muscles and skin are then closed with interrupted sutures. This patient was last seen in September, 1949, and is in good condition. He is now 2 years of age and has not required any dilations. (*Case referred by Dr. M. Salzman.*)



A
B
C
D

above factors, fibrosis may occur as a result of ulcer or of chronic esophagitis with resultant strictures. Esophagogastrostomy or partial esophagectomy may be necessary in advanced cases. In early lesions dilations with bougies or pneumatic bag may be done. The treatment of the associated diaphragmatic hernia has been described in Chapter 19.

Duplications of the esophagus are usually blind cystlike cavities which have been described in Chapter 19 and which behave as other mediastinal cysts or tumors. Excision should be done and if a connection exists with the esophagus, this must be closed.

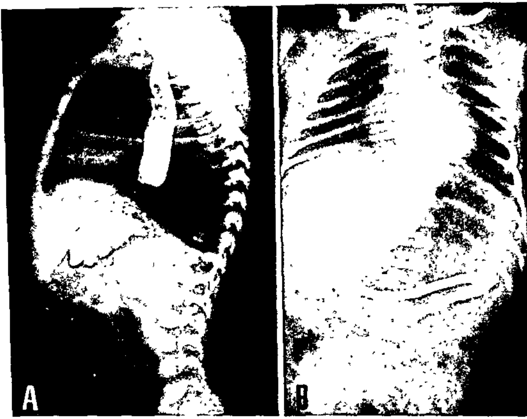


Fig. 258.—This infant was brought to the attention of the surgical department when he was 2 days old because of regurgitation of all fluids. *A*. Barium study showed a stenosis of the esophagus just above the diaphragm. This was dilated and a catheter introduced as shown in *B*. Feedings were administered by this catheter for several days until the baby's condition improved, and then the esophagus was dilated further. This illustrates a very rare type of congenital stenosis of the esophagus due to a small membrane which is amenable to treatment by dilation. The child recovered and has remained well. No further dilations were required after approximately 3 months of age.

Megaesophagus has been reported in infants. It is thought to be due to some form of obstruction near the cardiac end. However, this stenosis cannot always be demonstrated. In this way "congenital megaesophagus" resembles the true Hirschsprung's disease of the colon. Esophagogastrostomy is the treatment, or if the muscles of the cardia are greatly hypertrophied, simple incision down to the mucous membrane is curative as in the Ramstedt operation for pyloric stenosis.

catheter is then introduced into the stomach, and an anastomosis is made between the upper and lower esophageal segments, not by a transverse suture line, but by a diagonal suture line. This is a very important point and is probably responsible for the fact that no stenoses have occurred to date in our cases where this has been done. The entire suture line is made with fine silk. Penicillin is introduced into the operative field, one small Penrose drain is inserted, and the muscles of the back are closed with interrupted silk sutures and the skin is closed with the same material. Postoperatively the child is placed in oxygen for from twenty-four to forty-eight hours. After the second day a gastrostomy is made under local anesthesia for feeding. This, in our opinion, is preferable to intravenous feeding. The entire operation is done under ½ of 1 per cent Novocain anesthesia. Oxygen is administered during the procedure. On about the ninth or tenth day, water may be given by mouth, and if no leakage occurs, the Penrose drain may be removed. It is wise to keep the gastrostomy open four to six weeks to be sure that a stenosis does not occur, because if this does occur it may be necessary to grasp a swallowed thread so that further dilatation may be accomplished.

Many modifications have been advocated since the first successful operation by Haight. The most important of these is that only one rib is resected. This is the fourth rib, and a liberal piece is removed subperiosteally from the posterior angle well around toward the posterior axillary line. The pleura is then stripped from the posterior thoracic wall and the ribs are spread apart with a small mastoid self-retaining retractor. This prevents paradoxical respiration which in some of our cases has been the cause of a great amount of anoxemia.

A second modification is the preliminary performance of gastrostomy as originally suggested by Bigger. This is not done to feed the child but is done to keep the stomach empty by suction so that regurgitation will not occur and, more important, so that a desperately sick infant can be put into better shape for surgery.

Congenital Stenosis

Congenital stenoses due to webs or membranes are usually transient or may be "broken" with a soft rubber catheter. We have seen two of these.

Congenitally Short Esophagus

Congenitally short esophagus has been described in Chapter 19 in connection with diaphragmatic hernia. Sometimes an associated stricture is present. Various theories have been advanced to explain this. When the cardia sphincter is released from control, gastric juice regurgitates into the esophagus; this in turn causes irregular spasmodic contraction due to esophagitis; in addition, heterotopia of gastric mucous membrane may be present, increasing the acid in the lower esophagus. As a result of the

masticated food, chicken bones, etc.), or infection (sectioning the vagus does reduce esophageal motility, but in the experimental animal the results are conflicting); spasm of the diaphragmatic crura (phrenospasm); scleroderma and acrosclerosis (scleroderma with Raynaud's disease) which produce fibrosis in various tissues (vascular, skeletal, and gastrointestinal); severe anemia.

This concept would put cardiospasm in the same category of other psychosomatic problems, Raynaud's disease, segmental ileitis or colitis, essential hypertension, and peptic ulcer.

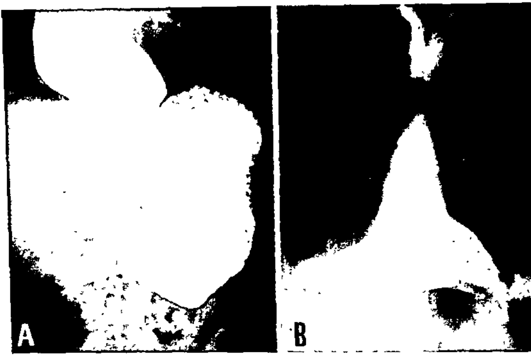

Fig. 259.—Megaesophagus due to cardiospasm and achalasia. *A*, X-ray photograph showing an enormously dilated esophagus which is tortuous. W. N., a man 30 years of age, had complained of dysphagia for many years. Recently he stated that anything he ate, whether liquid or solid, seemed to move no further than the chest and then he was able to regurgitate part of it undigested. In fact, unless he emptied the esophagus, he was unable to move about due to severe chest pain.

The condition is that of cardiospasm or achalasia (meaning without relaxation). The enlargement of the esophagus has been called megaesophagus when it is straight and dolechoesophagus when it is tortuous. The x-ray photograph clearly demonstrates the tortuosity and enlargement of this esophagus Esophagogastrostomy was performed by the transthoracic approach. *B*. X-ray photograph showing the result after surgery. This patient has remained well since operation three years ago. (Case referred by Dr. H. Carpentier.)

Regardless of the cause, whether due to cardiospasm or achalasia at the cardiac end of the esophagus, usually there is little if any thickening, although the wall may be slightly fibrosed in some cases. Above this point there is great dilatation and the esophagus resembles a funnel (megaesophagus) or it becomes dilated and tortuous, resting as a large pouch on the diaphragm (dolichoesophagus). The wall becomes extremely thin and may be pierced by instruments or sharp particles of food. In fact, minute leaks may occur without apparent cause resulting in mediastinitis.

Functional Disturbances of the Esophagus

True reverse peristalsis probably does not exist in the esophagus without obstruction. Reverse wavelets or ripples do occur and are probably responsible for such symptoms as coating on the back of the tongue and regurgitation of fluids. "Heart burn" may be due to the stimulation of the mucosa of the upper part of the esophagus due to regurgitation of acid fluid. Distention by pneumatic bags will produce the symptoms as will the introduction of acid or cold water or excessive smoking. Spasm will also give the burning symptom. In two cases of pernicious anemia with achlorhydria that we saw, heart burn was a prominent symptom. Therefore, acid per se is not the cause and the sensation does not originate in the stomach. Belching is due to reverse waves originating in the cardiac end of the stomach which were thought to relieve the large "magenblasse" or air bubble in the upper end of the stomach after a meal. This is only partially true because some of the air is held in the lower end of the esophagus. Practically all of this gas is swallowed or sucked in. This may be annoying in those who habitually swallow air (aerophagy). Intragastric pressure is not increased as a result of the air swallowing nor is it decreased after belching. Air sucking as opposed to swallowing is seen after operations done under general anesthesia and may be one cause of postoperative abdominal distention.

Cardiospasm is the term used to describe the condition in which the sphincter does not relax properly during deglution, causing dysphagia. Since there is also an incoordination between the muscle of the esophageal wall and the sphincter, the term achalasia has been applied. The cause of cardiospasm is not definitely known. It may be neurogenic in origin and related to a similar condition known as globus esophagitis which has been suggested as a cause. This, in turn, is thought to be due to minute puncture wounds through the esophageal walls, made by sharp particles in ingested food. Ultimately an organic stricture may occur, although fibrosis is not demonstrated. Sometimes it is reflex in nature due to irritation of afferent fibers from the stomach, gall bladder, or other viscera. It may be initiated by intrinsic factors such as irritation of the mucous membrane as previously described. Then, in some, it appears when there is nervous excitation or worry. The sequence in this group may be hurried gulping of food, temporary contraction, and irritation of the mucous membrane which in turn favors spasm. Indeed, an old aphorism concerning the "lump in the chest" which many people complain of after eating while worried avers that "it is not the food, but the mood." "Globus hystericus" represents a nervous contraction of the cricopharyngeus muscle and also produces the "lump in the throat." Other theories as to the cause of cardiospasm are degenerative changes in the cells of Auerbach's plexus at the lower end of the esophagus, possibly due to a vitamin B deficiency; reflex irritability of the vagus nerve which is primary or secondary due to disease or abnormalities in the abdominal viscera, or injury (hard, poorly

observe the esophagus carefully in all positions, including the Trendelenberg. Last, esophagoscopy with a biopsy should be done when indicated.

The treatment includes attention to the general condition of the patient from a neuropsychiatric standpoint and local measures. Attention to the diet (avoidances of rough or hard foods), antispasmodics (atropine), and sedatives (phenobarbital) help. As the disease progresses, dilation with mercury-filled bougies or dilators inserted through the esophagoscope or the pneumatic bag should be tried. If this is not feasible, a gastrostomy is done and retrograde dilations may be started with the fingers and bougies, then followed with the pneumatic bag which is the best and safest of all dilating instruments.

In late cases or in those which do not repond to conservative measures, surgery is necessary. Many procedures have been advocated; namely, (1) extramucous cardiomyomotomy, anterior and posterior. This corresponds to the Ramstedt-Fredet pylorotomy. (2) Cardioplasty with longitudinal incision and transverse suture, like a Heineke-Mikulicz pyloroplasty. (3) Cardiectomy which seems irrational. (4) Phrenotomy (incision in the diaphragm) which creates a hiatus hernia but does not help. (5) Vagectomy and sympathectomy which offer only transient relief. (6) Esophagogastrostomy.

The side-tracking operation is best. It may be done through the abdominal or thoracic approach. We have preferred the latter. The fundus of the stomach is sutured to the esophagus and a horseshoe incision is made very much like a Finney pyloroplasty. The stomach is then anastomosed to the esophagus. In extreme cases of dolichoesophagus the lowermost pouch may not be straightened by this procedure. In this event the dependent pouch is anastomosed to the lesser curvature.

Esophageal Varices

Esophageal varices have been discussed in Chapter 19. They usually occur as a result of cirrhosis of the liver, Banti's syndrome, or thrombosis of the portal vein or splenic vein if the coronary enters it distal to the occlusion. Sometimes there is no apparent cause. The symptoms and signs are those of the primary disease with splenomegaly and ascites and hematemesis. Only rarely is there any other symptom. Often the only symptom or sign is hemorrhage. Diagnosis is made by the history, symptoms and signs, and fluoroscopic examination using barium. With the Valsalva experiment the veins empty; with the reverse Valsalva, they fill. Esophagoscopy establishes the diagnosis.

The treatment is designed to eliminate the cause if possible. Usually this is only partly possible. Less blood enters the portal vein after splenectomy (see Chapter 22). Shunts between the splenic and left renal vein and between the portal vein and inferior vena cava (Eck fistula) offer the best chance of cure. The varices may be removed surgically or injected with sclerosing solutions (5 per cent sodium morrhuate) through the esophago-

The vague methods by which the disease evolves and the more or less characteristic changes which it induces has led to a variety of descriptive terms such as cardiospasm, achalasia, phrenospasm, idiopathic dilatation of the esophagus, esophagectasia, hiatal esophagismus, megaesophagus, simple ectasia of the esophagus, preventriculosis, dilatio fusiformis, and dolichoesophagus. Some observers believe that cardiospasm is a different entity than achalasia.

Symptoms and signs: The disease is usually seen in the third and fourth decades. Dysphagia is present, but it varies from time to time and with the progress of the lesion. Early, it occurs spasmodically and is sudden in onset and may be induced by solid food (usually), but also by liquids. However, it is "all or none" so far as difficulty in swallowing goes. Later there is dysphagia at all times and regurgitation of small, then large quantities of food which at first occurs only once a day, but later, after every meal. Finally, only liquids go through and a large amount of undigested and fermented food is regurgitated after every meal. The entire course of the disease is insidious and the appearance of the patient belies the nature of the process.

Plummer-Vinson syndrome is also called hysterical dysphagia. It occurs usually in women with an unstable nervous system and with associated abnormalities; namely, hypochromic anemia, glossitis, and splenomegaly. The obstruction is usually in the upper end of the esophagus. Treatment consists of repeated dilations with sounds and attention to the anemia and nervous instability. Recurrences are common but once the esophagus is open, other symptoms disappear.

Painful swallowing (odynophagia) is not observed unless there is already a large amount of material in the esophagus which then becomes enormously overdistended. Pain in the chest is different from angina pectoris. Esophageal pain is not related to muscular exercise, but to swallowing, especially highly seasoned foods. There is some loss of weight and no hematemesis. Hoarseness, dyspnea, or cough are not observed, although dyspnea from overdistention and cough from overflow secretion at times do occur.

From symptoms alone the nature of the disease may be suspected. The dysphagia in the early phase may be entirely present or entirely absent. At least it varies greatly from time to time. In organic disease it is progressive, with difficulty in swallowing solid food, first, then soft foods, then liquids. The absence of pain, loss of weight, hoarseness, dyspnea, cough, or bleeding tends to rule out organic disease, although a positive diagnosis cannot be made without fluoroscopic and esophagoscopic study.

In esophageal disease, then, the history, complete physical examination (including mouth, nose, throat, pharynx, larynx, pyriform sinuses and neck, serology), fluoroscopic study of the chest, and fluoroscopic study of the esophagus with barium mixtures are necessary to establish a diagnosis. The roentgenologist should be apprised of the possibilities so that he will

peptic ulcer of the esophagus; fourth, the more specific types of infection, including tuberculosis and syphilis, as well as nonspecific types of infection may produce an esophagitis. Since dysphagia is the chief symptom in all types, a careful examination as outlined previously should be made. This is true in all cases of dysphagia.

Inflammations due to mechanical, thermal, or chemical causes clear up quickly when the causative agent is removed unless there has been destruction of the mucous membrane where fibrosis and stricture result. Bismuth subnitrate in 0.5 to 1.0 Gm. doses is helpful. Ethylaminobenzoate (Anesthesin) in 0.1 Gm. doses is helpful in relieving pain. Penicillin intramuscularly and by insufflation is useful.

Tuberculous esophagitis is treated as tuberculosis elsewhere (see Chapter 7) unless stricture occurs. If the stenosis is in the lower part of the esophagus, esophagectomy and esophagogastrostomy may be done should conservative measures fail.

Syphilis is treated by antisyphilitic therapy and the stenosis which may result is dilatable as a rule.

In all forms of severe esophagitis gastrostomy is indicated to put the esophagus at rest.

Peptic ulcer of the esophagus is probably more common than was formerly thought. The disorder which predisposes to ulceration is hernia of the stomach through to esophageal hiatus into the posterior mediastinum. The hernia may be congenital or acquired and may be reducible or irreducible. The latter may be caused by ulceration, fibrosis, and shortening of the esophagus. Other theories as to its cause are mentioned in the discussion of congenitally short esophagus.

The pathological changes include a recurrent acute esophagitis, then chronic esophagitis with recurrent acute ulceration, then chronic ulceration. The ulcer produces stenosis due to the surrounding induration, and above this is intense inflammation. Sometimes there is perforation or bleeding. Finally there is fibrosis with permanent stenosis.

The symptoms of the acute ulcer are epigastric pain relieved by food and alkalis, heartburn, and regurgitation, especially in the recumbent position or on bending forward. The chief symptom of a chronic ulcer is dysphagia. Often ulcers of the stomach or duodenum are present. Diagnosis is made by careful history, symptoms and signs, fluoroscopy, and esophagoscopic examination.

Treatment should be conservative with ulcer diets, sedatives, antispasmodics, and bed rest. If a hiatal hernia is present, it should be repaired. If stenosis exists, jejunostomy may be necessary for feeding until the ulcer has healed. It should not be done for a fibrous stenosis, which may be dilated by bougies, or, if this fails, esophagogastrostomy should be done. When the hernia is repaired, vagotomy should be done and the splanchnics are infiltrated with novocaine or removed and the phrenic is crushed.

scope, or injection of fibroblastic agents such as dicetyl phosphate may be injected around the esophagus. Resection of the lower esophagus and greater portion of the upper part of the stomach or even total gastrectomy with esophagogastrostomy or esophagoenterostomy will stop esophageal bleeding.

Injuries to the Esophagus

Injuries to the esophagus have been discussed in Chapter 19. Spontaneous rupture does occur in the lower end of the esophagus. Esophagitis or ulcer may be present sometimes. No predisposing cause is found except a bout of drinking, then severe vomiting. The vomiting precedes the pain. In all stomach ailments which may resemble esophageal perforation, the reverse is true. If small, the perforation may heal spontaneously. If large, it must be sutured. (See Chapter 19.) Injuries by strong acids or alkalies are all too common, especially in children, and, when not fatal, leave large raw areas which heal by dense cicatrization. The result is a stricture of the esophagus. These may be treated by repeated dilatations with bougies or dilators and sometimes cured. More often the stricture does not respond and gastrostomy is necessary for feeding. If the stricture is limited to the lower end of the esophagus, esophagogastrostomy will cure the patient. This is not usually the case; the stricture involves a large area and for this reason treatment by any method other than extirpation is useless. Yudin reported eighty cases treated by the "Roux-Herzen" type of esophagoplasty consisting of the construction of a subcutaneous esophagus made from a loop of jejunum. This is done in three stages: gastrostomy, exteriorization of the loop of intestine onto the neck, and its direct anastomosis with the cervical portion of the esophagus. The cicatrized esophagus remains in situ. Sweet has recently applied a much simpler and more practical operation; namely, esophagectomy with mobilization of the stomach high in the thorax and esophagogastrostomy. He believes it necessary to sever the esophagus at the cardia so that complete mobilization of the stomach is possible. Esophagectomy is done so that an end-to-side anastomosis may be accomplished.

Foreign bodies which enter the esophagus usually go through into the stomach. Even open safety pins may do this. However, early x-ray and esophagoscopic examination will reveal the foreign body and permit its removal. Meat impaction may be digested with papain or removed. Sometimes esophagoscopic or manual manipulation through a gastrostomy is necessary.

Inflammations of the Esophagus

Esophagitis may follow mechanical, thermal, chemical, or bacterial trauma. In the first group may be included instrumentation and the presence of a Levine or Miller-Abbott tube for long periods; in the second, hot and cold liquids or solids; in the third, the ingestion of acid or alkalis not sufficiently strong to cause ulceration and cicatricial stenosis; in addition, the acid gastric juice may be a factor in the production of

in the pharyngo-esophageal type) or traction (usually in the large sacs where traction began the process which was continued by pulsion). In the neck, the mechanism of production is like an inguinal hernia. There is a weakness or separation between the fibers of the inferior constrictor muscle of the pharynx and those of the cricopharyngeal muscle, and during swallowing the cricopharyngeal muscle is slow to relax, resulting in a strong pulsion force on the weak area of the posterior pharyngeal wall or the esophageal wall and ultimate bulging of the esophageal wall. Some observers state that the cricopharyngeal muscle does not exist as a separate entity from the inferior constrictor and that the weakness is not congenital but acquired since it rarely occurs before 15 years of age. Since the diverticulum is on the posterior wall, it may point to the left or right side of the neck, but usually it is the former because of the lesser resistance at this point due to the distance of the large vessels of the neck.

Fig. 261.—Traction diverticulum of the esophagus visualized by barium meal. These are not uncommon lesions due to local adhesion and tugging during swallowing. They may occur anywhere along the esophagus but are usually encountered near the hilus where many lymph nodes are present. If they give symptoms, they should be removed or imbricated because they increase in size due to the fact that they are converted into a pulsion type as they enlarge. Then there is danger of spontaneous perforation.

Symptoms and signs of pharyngo-esophageal diverticulum: Food enters this pouch and creates a gurgling sound, or the patient may regurgitate food eaten two or even three days previously. Dysphagia is the chief symptom. Diagnosis is made by the fluoroscopic and esophagoscopic examinations, although the latter must be done carefully lest the thin sac be perforated. The treatment consists of surgically excising the sac. This is done through a longitudinal incision in the neck, with the aid of the esophagoscope, which illuminates the concealed sac. The sac may be easily

In severe cases which remain active in spite of all measures, *esophagectomy* may be done. Since the ulcer originally occurred as a result of hiatal hernia, the operation may be questioned because part of the stomach will be mobilized into the chest. To overcome this criticism, Allison and others have suggested jejunal transplants. However, these too may develop ulcers and therefore resection in addition to careful medical management may be used in the extreme cases. Such treatment should not be required except on rare occasions. Some observers believe that a *radical gastric resection* (four-fifths) of the lower portion of the stomach and pylorus is the treatment of choice.

Diverticula of the Esophagus

Diverticula of the esophagus may be present in the neck (pharyngoesophageal) or in the thoracic esophagus (supradiaphragmatic; epiphrenic). These pouches are said to occur as a result of pulsion (usually

Fig. 260.—Pulsion diverticulum of the esophagus, also known as pharyngoesophageal diverticulum. J. W., a man 45 years of age, complained of increasing pain and discomfort following a meal. Recently he had been forced to make pressure on the right side of the neck, and he was able in this way to regurgitate some of the food which he had eaten and which was not digested. *A* and *B*. Photographs show a fairly large pharyngoesophageal diverticulum. This was removed by a one-stage procedure. The incision was made anterior to the sternomastoid muscle on the right side. The inferior *thyroid artery* and vein and middle thyroid vein were divided, and the right lobe of the thyroid gland was turned medially. The esophagus was identified and the diverticulum was illuminated by the introduction of an esophagoscope by an associate. This made identification of the esophagus very simple, and with the esophagoscope in place the diverticulum was removed and then the edges sutured transversely with two tiers of sutures, using a chromic double zero catgut on the inner tier and silk on the outer. The introduction of an esophagoscope prevents *the complication of taking off too much, and* thereby producing a stricture, or, what is equally serious, leaving too long a pedicle, permitting a recurrence of the diverticulum If possible, the suture line should be made in the transverse diameter. The reason for this is to prevent a narrowing of the lumen, and also the second tier of sutures is more easily introduced in the inferior constrictor muscles since the fibers go transversely. (Case referred by Dr. D. Paris.)

herniation of the mucous membrane through the muscle wall. Its wall is made of mucosa, submucosa, and adventitia. The various layers may be greatly thickened. The cause of this latter type is not known, but it is probably due to a combination of factors such as congenital weakness, cardiospasm, local injuries, or ulcerations. The epiphrenic type of pulsion diverticulum may be the beginning of dolichoesophagus.

Symptoms are dysphagia, odynophagia, regurgitation, anorexia, and loss of weight. The symptoms are episodic. Diagnosis is made by the history and barium examination with the fluoroscope.

Treatment is not necessary for those diverticula discovered by x-ray and without symptoms. When there are symptoms, the pouch may enlarge and should be removed. This is accomplished through an incision in the seventh or eighth left interspace. The mediastinal pleura is incised, the diverticulum exposed and removed, and the opening closed. The mediastinal pleura is left partially open or sutured behind the esophagus so that if infection occurs it may drain into the pleural cavity which is drained by a water-sealed intercostal drain.

Stenosis of the Esophagus

Stenosis of the esophagus may be congenital or acquired and may be caused by external, intramural, and intraluminal factors. Among the external causes are: anomalous vessels (dysphagia lusoria, Chapter 18), mediastinal tumors and cysts, hiatus hernia (Chapter 19), aneurysm. Intramural causes include cardiospasm, scleroderma, neoplasms (benign or malignant), whereas intraluminal abnormalities are due to congenital anomalies, trauma (chemical, such as lye, mechanical, thermal), peptic ulcer, foreign body, spontaneous rupture and fibrosis, feeding tube erosion and stenosis, syphilis, tuberculosis, neoplasms (benign or malignant).

The symptoms common to all are dysphagia, odynophagia, and regurgitation. The diagnosis is made by the history, symptoms and signs, fluoroscopic examination with the barium meal, and esophagoscopy.

The treatment depends upon the cause. (1) General treatment is given for syphilis, tuberculosis, peptic ulcer; in addition, attention is given to water balance, acid-base balance, blood volume, and shock in cases of lye burns and other trauma. (2) Local treatment consists of dilations by bougies or bags. Provision for feeding is made by doing a gastrostomy. This also facilitates dilation. The gastrostomy should be of the Stamm variety so that instruments may be easily introduced. Foreign bodies should be removed. (3) Short circuitive procedures—esophagogastrostomy may be used in short low strictures which are not due to neoplasms. (4) Benign neoplasms are removed. (5) Extensive strictures due to lye are best treated by esophagectomy and esophagogastric anastomosis, or, if limited, by resection and end-to-end anastomosis of the esophagus. (6) Malignant growths require esophagectomy and esophagogastrectomy with esophagogastric anastomosis. (7) Congenital atresias are treated by direct

identified if large. If small, the esophagoscope may be used to identify it. Local anesthesia is preferred if an endoscopist is not available because swallowing distends the sac, making it easy to see. Some surgeons prefer to do the operation in two stages so that in the event of leakage after removal of the sac, adhesions will prevent a mediastinitis (see Chapter 19). At the first stage the sac is freed and turned upward so that it cannot fill and is anchored to the skin. Two weeks later it is removed. We have used the one-stage technique routinely with excellent results.

Fig. 262.—Traction-pulsion diverticulum of the esophagus. X-ray photograph indicating a traction-pulsion type of diverticulum. The diverticulum is of the right lateral wall of the middle third of the esophagus which is a very common position. Although small traction diverticula and traction-pulsion diverticula of the esophagus may be symptomless and may not require surgery, it is probably wise to remove them if they cause symptoms or are known to be increasing in size. A third variety of diverticulum is sometimes encountered above the diaphragm. It has been referred to as epiphrenic or supradiaphragmatic diverticulum It is classed as a pulsion type. These are rare and the symptoms which they produce are very similar to those of cardiospasm. If they are increasing in size they should be attacked surgically. The cause of supradiaphragmatic diverticula is said to be linked with cardiospasm, and it is thought by some that it is the first sign of dilation following cardiospasm taking place in an abnormal way due to a weakness in one portion of the esophageal wall.

Thoracic esophageal diverticula are rare. They are of the traction or pulsion variety or both. The traction types are conical and result from adhesions to tuberculous lymph nodes as a rule. The mouth of the diverticulum is wide open so that food entering may leave, and therefore they do not produce symptoms except from perforations. As they enlarge, pulsion forces become active also. The pulsion type is said to result from

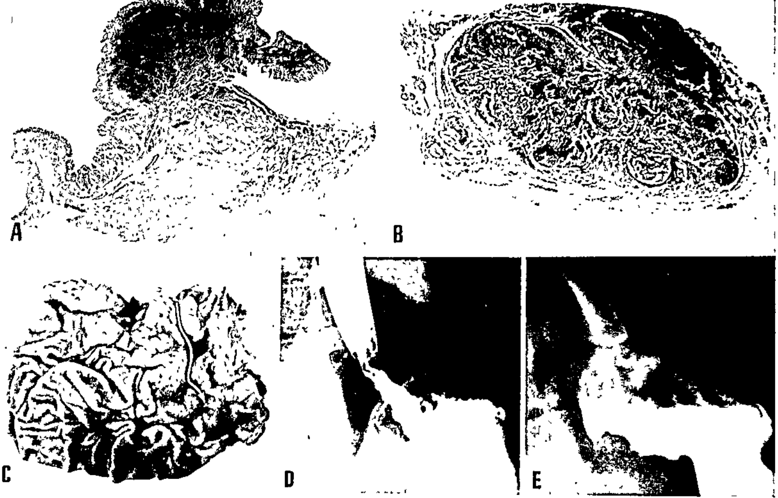

Fig. 264.—Carcinoma of the lower third of the esophagus. A. A. was a woman 46 years of age who complained of difficulty in swallowing solid foods and an oppressive feeling in the lower thorax. She had been sick for over a year and the dysphagia increased, until just before her admission into the hospital it was difficult for her to swallow liquids. She was operated upon through the bed of the seventh rib, and the lower end of the esophagus and upper end of the stomach were removed and an esophagogastrostomy was performed. *D*, X-ray photograph showing the neoplastic filling defect in the lower esophagus and the cardiac end of the stomach. *C*. Photograph of the gross specimen, with arrow pointing to the lesion in the esophagus.

anastomosis when feasible. If the defect is too extensive, the proximal end of the esophagus is brought out through an incision in the neck and gastrostomy is done. Later a subcutaneous esophagus is made by (1) a skin tube, (2) a segment of jejunum within the skin tube or the proximal end of the esophagus is later anastomosed in the neck as follows: (a) the stomach is brought up into the chest and anastomosed to the esophagus in the neck, and (b) a segment of jejunum is brought up into the chest after a Roux Y anastomosis to establish intestinal continuity.

Fig. 263.—Esophageal stricture with perforation. Patient was a woman aged 20 years with a congenital stricture. She had received repeated dilatations. Note the dilatation of the esophagus above the lesion. The arrow points to a perforation which was accidentally produced at the time of esophagoscopy.

Neoplasms of the Esophagus

Neoplasms of the esophagus may be benign or malignant, primary or secondary. The former include intramural fibroma, lipoma, fibrolipoma and fibromyxoma, leiomyoma, adenoma, and papilloma. They cannot be diagnosed by the history because dysphagia is common to all esophageal diseases. Pedunculated types may be regurgitated into the mouth. Fluoroscopy with barium meal and esophagoscopy reveal the true nature of the

For extirpation, the esophagus may be divided into four groups:

1. The upper fourth presents at present many technical difficulties. The extreme upper end may be removed in connection with carcinoma of the larynx and a permanent tracheotomy and esophagotomy done, or pedicle tube grafts may be fashioned and an external esophagus made connecting the hypopharynx with the cervical esophagus. A few cases have been reported. Below this, in the upper fourth resections may be done and the stomach or jejunum brought up into the neck for anastomosis.

2. The middle half of the thoracic portion of the esophagus when involved should be removed down to the cardia and then a high esophagogastric anastomosis done above and anterior to the aortic arch.

3. The lower fourth of the esophagus or fundus of the stomach may be removed for lesions in this area with esophagogastric anastomosis.

4. Lesions which involve most of the stomach and the extreme lower end of the esophagus require total gastrectomy and an esophagojejunostomy (or rarely esophagoduodenostomy) if the duodenum can be mobilized.

The approach for the extreme upper portion is through the neck. A collar incision which extends down as the perpendicular part of a T may be projected into the superior mediastinum.

For midthoracic resections the left eighth rib is resected (sometimes the seventh), and in addition the fifth and sixth ribs may be divided posteriorly. The incision may be carried down into the abdomen as far as necessary. The chest is opened and the resectability determined. Next, the mediastinal pleura is incised and the esophagus freed down to the hiatus. The phrenic nerve is crushed. The diaphragm is divided anterolaterally and the stomach mobilized, care being taken to leave the right gastric and right gastroepiloic arteries to preserve the blood supply to the mobilized stomach which is brought high into the chest for anastomosis. The esophagus through its lower portion, including the growth and a safe margin above it, is removed, the cardiac end of the stomach closed, and esophagogastric anastomosis done.

For the lower portion of the esophagus and for extensive stomach resections, a combined abdominothoracic incision is excellent. We have used an oblique one up through the bed of the eighth rib (or the eighth and ninth costal cartilages may be cut and an intercostal incision made). The abdominal incision is made first to determine operability. We have supplemented this with a feeding jejunostomy.

Other methods of anastomosis include the Torek operation. This consists of removing the esophagus, bringing out the upper end through an incision in the neck, and doing a gastrostomy. The two ends are joined by making a subcutaneous skin-lined esophagus at a second stage. An exteriorized loop of jejunum with one primary branch of the mesenteric artery and vein may be implanted under the skin. Later its blood supply may be divided and at a third stage the two ends joined to the distal end of the esophagus in the neck and the proximal end of the stomach below.

lesion. Treatment: Some intraluminal pedunculated polyps may be removed through the esophagoscope. Most will require local excision by transthoracic operation. If the entire circumference is involved, resection of the esophagus is necessary, with end-to-end anastomosis or, if extensive, with esophagogastrostomy.

Malignant growths include carcinoma and rarely sarcoma. Primary carcinoma of the esophagus is usually of the squamous-cell variety but may be an adenocarcinoma which has extended up from the stomach. The tumors often spread in the submucous and muscular coats for a distance of several centimeters, detectable only on microscopic examination. Metastases to regional nodes and even those below the diaphragm and neck are frequent. Metastases to the liver are late, whereas the lung may be involved because venous return from the high gastric and esophageal areas enters the systemic circulation directly without passing through the portal system. Secondary carcinoma of the esophagus may originate in the trachea, bronchus, stomach, larynx, breast, pancreas, testes, and other organs which cannot be identified from microscopic section and therefore are termed undifferentiated.

Primary carcinoma is by far the more common. It is squamous in 75 to 80 per cent, adenocarcinoma in 10 to 15 per cent, and undifferentiated in about 3 to 5 per cent. Grossly the tumors are scirrhous, medullary, or papillary types.

Symptoms and Signs: The disease is more common in males and usually in middle life, but may occur at any age from 20 to 85 years. The onset is so insidious that in most cases the growth is fairly well advanced when suddenly there is some difficulty in swallowing hard food. Later there is pain, weight loss, regurgitation with some blood; the dysphagia now is present with soft foods, then liquids. Finally there is complete obstruction with overflow, causing cough and, very late, hoarseness due to recurrent laryngeal nerve involvement.

The diagnosis is made conclusively by barium meal fluoroscopy and a biopsy taken through the esophagoscope. Operability may be predicted by the result of these examinations. If barium is seen to extend outside the esophagus, there is already perforation which has been temporarily sealed. The extent of the lesion and fixation of the esophagus is a clue. A constant boring pain in the interscapular region of the back, persistent fever, masses in the rectal shelf, nodular liver, enlarged nodes in the neck (which may be biopsied) all indicate, but do not prove, inoperability.

Treatment consists of radical extirpation of the involved portion of the esophagus for cure. In late cases not suited for radical resection palliation may be obtained by careful dilation or gastrostomy (Ssabanejew-Frank's technique) which is permanent and will not leak. X-ray treatment affords relief from pain and will occasionally arrest the disease in lesions of the upper fourth of the esophagus. Jejunostomy as a preliminary measure to resection has been of no help in our cases.

and splanchnic layers of mesoderm. Later the mesocardium attaching the heart to the anterior body wall disappears and the right and left limbs of the U-shaped cavity become confluent anterior to the heart, forming a large pericardial chamber.

The primitive coelom is divided into separate cavities as has been described in Chapter 10 by the formation of three membranes; the septum transversum which separates the pericardial and pleural cavities from the peritoneal cavity incompletely, the pleuropericardial membrane which completes the division between the pericardium and pleural cavity, and the pleuroperitoneal membrane which closes the pleuroperitoneal hiatus on each side of the diaphragm, separating the pleural cavities from the peritoneal cavity. This has been discussed in connection with diaphragmatic hernia. Thus the abdominal wall evolves into a structure composed of an internal layer of mesothelium, an outer layer of epithelium, and between mesodermal derivatives, muscle and fat.

THE ABDOMINAL WALL

The abdominal wall is made of fibrous and muscular layers. These are attached above to the thorax; below, to the pelvis; and behind, to the erector spinae muscles and the vertebral column. In front, the layers join in the midline, forming the linea alba. The outside of this wall is, of course, covered by skin; the inside is lined by the parietal peritoneum. In between these layers are (from without inward) the superficial fascia (Camper's and Scarpa's in the groin), the external oblique muscle, the internal oblique, and the transversalis muscle. The aponeuroses of these muscles unite on each side (linea semilunaris) to form a sheath for the large rectus abdominis muscle. The right and left rectus muscles, in their upper three-fourths (above the linea semicircularis, which lies at the level of the iliac crests) have separate sheaths including a posterior layer (formed by the split internal oblique fascia and the transversalis), but in their lower fourth have only the transversalis fascia forming the posterior layer. The rectus muscles contain lineae transversae, transverse fibrous bands, which are also produced by transverse incisions at the lower level, and anterior to the recti are the pyramidales, and at the upper, the muscle is inserted into the xyphoid and superficial surface of the seventh, sixth, and fifth costal cartilages. On its anterior surface and adherent to the sheath are three or four transverse tendinous intersections (inscriptiones tendineae), the lowest opposite the umbilicus. The posterior abdominal wall is made up of muscles and fasciae. The muscles include the psoas major and minor, the quadratus lumborum, and, in the pelvis major, the iliacus. The transversalis muscle and aponeurosis are extremely important for they give the abdominal wall great strength and must be dealt with carefully during abdominal operations. In addition, the direction of their fibers vary in different constitutional types (in the lateral type, the fibers run transversely in the upper abdomen; in the linear type, obliquely); then too, is fascia, which covers its deep surface, is continuous with the fasciae of the quadratus lumborum, psoas, and diaphragm, and (below the inguinal ligament) with the fascia iliaca, with which it forms the femoral sheath, enclosing the femoral vessels and canal in their passage behind the inguinal ligament. It is penetrated by the spermatic cord or round ligament, forming the internal spermatic or infundibuliform fascia (q.v.). It is lined internally by the peritoneum and aids in forming various supporting structures about the pelvis.

The blood supply comes from the internal mammary (off the subclavian) and through the superior epigastric (off the external iliac). These two anastomose, thereby connecting upper and lower limbs. In addition, the lower two intercostals, the lumbar, iliolumbar, and circumflex iliac arteries help supply the abdominal wall. Superficial branches in the inguinal region (superficial epigastric, superficial circumflex iliac, and superficial external pudendal) come from the femoral. Venous return above the umbilicus is by companion veins which ultimately enter into the superior vena cava and below the umbilicus through the inferior vena cava. Thus, venous return flows in two directions; that is, from the superior epigastric into the internal mammary vein into the subclavian and from the inferior epigastric into the external iliac. The superficial veins

A right thoracic approach has been employed by some surgeons who make an upper, left paramedian abdominal incision. The stomach is mobilized and a jejunostomy done. At a second stage, the right sixth rib is removed and the operation carried out through the right thorax.

Prognosis without surgery is obviously 100 per cent fatal. The operation mortality for lesions in the lower portion of the esophagus is about 15 per cent, for the mid-thoracic esophagus, about 20 to 25 per cent at present. These figures will be improved as techniques are developed.

The rate of curability is still low and the time interval in most cases is too recent to draw conclusions. As the technique of these operations are improved and the diagnosis is made earlier, more cures will be obtained. The patients are comfortable after resection and eat anything they wish. The large stomach in the chest does present complications such as dyspnea after eating, regurgitation on reclining, and cardiac irregularities. However, they are inconsequential as compared to complete esophageal obstruction with gastrostomy feeding. We have had one case of sprue following the operation which was controlled by high protein diet, vitamin B complex, liver, and iron therapy.

DEVELOPMENT OF BODY CAVITIES

In the earliest embryo, segmentation takes place with the formation of the blastula and the early bastodermic vesicle. During this stage there is no differentiation into layers. Such differentiation takes place later, and the three primary germ layers, ectoderm, entoderm, and mesoderm, are formed. From these layers all of the body tissues and organs are derived. The germ layers consist of an outer ectoderm, inner entoderm, and a cavity known as the archenteron. Between the ectoderm and the entoderm lies the single sheath of mesoderm which soon splits into two, the cavity between being the coelom or body cavity. (See Fig. 17, Chapter 3.) After the mesoderm splits, the outer layer, which is known as the somatic layer, with the ectoderm forms the somatopleurae or body wall. The inner splanchnic layer with the entoderm forms the intestinal wall or the splanchnopleure.

In embryos of 1½ mm. the coelom consists of a U-shaped pericardial cavity, the right and left limbs of which are continued below into the paired pleuroperitoneal cavities, which in turn extend out into the extraembryonic coelom. Later the splanchnic mesoderm and the somatic mesoderm are united at the level where the vitelloumbilical trunk courses to the heart, forming the septum transversum. This separates the ventral mesenteries which have been formed into an upper, or thoracic portion, and a lower, or abdominal portion. Above the septum the heart is suspended into the ventral mesentery which forms the dorsal and ventral mesocardia. In the ventral mesentery below the septum grows the liver. This portion of the ventral mesentery gives rise posteriorly to the lesser omentum of the stomach and with the septum transversum forms the ligaments of the liver. Anteriorly the ventral mesentery persists as the falciform ligament. Posterior to the gut, the splanchnic mesoderm on each side is folded together in the median saggital plane and constitutes the posterior mesentery which extends to the caudal end of the digestive canal. This mesentery suspends the stomach and intestines from the dorsal body wall and it is divided into the dorsal mesogastrium or greater omentum of the stomach, mesoduodenum, the mesentery proper of the small intestine, the mesocolon, and the mesorectum. The covering layers of the viscera of the mesenteries and of the body wall are continuous with each other and consist of mesothelium lying on connective tissue. They are derived from the somatic

The abdominal cavity has entrances and exits: the esophageal, vena caval, and aortic openings in the diaphragm; the umbilicus, which permitted the temporary exodus of the intestines during intrauterine life; the inguinal canal for the spermatic cord in the male and for the round ligament in the female; the femoral canal medial to the femoral vein, artery, and nerve; and the obturator and sciatic openings in the pelvic basin. These constitute congenital points of "least resistance" to intra-abdominal pressure, which may give rise to a protrusion called hernia.

Congenital Anomalies Involving the Abdominal Wall and the Umbilicus

Congenital anomalies which are more commonly encountered in the abdominal wall are the following: (1) cyst of the umbilical cord, (2) omphalocele, (3) patent urachus and urachal cyst, (4) peristsent vitelline or omphalomesenteric duct, (5) umbilical hernia, and (6) ventral hernia.

Cyst of the Umbilical Cord.—Cyst of the umbilical cord is in reality a collection of Wharton's jelly close to the abdominal wall. The obstetrician is loath to tie the cord, thinking that this cystlike protrusion may contain abdominal viscera. He usually ties distal to the cyst, which is proper. Sometimes the cyst is large and may interfere with delivery. As soon as the child has been delivered and after careful inspection, the cyst is removed. The condition is extremely rare.

Omphalocele.—Omphalocele has many symptoms. The malformation has been called funicular hernia of the umbilicus, hernia into the umbilical cord, umbilical eventration, amniotic hernia, exomphalos, and omphalocele, (3) patent urachus and urachal cyst, (4) persistent vitelline skin. It is in reality a herniation of abdominal viscera into the base of the umbilical cord. The covering of this protrusion is a thin translucent membrane which consists of peritoneum internally and portions of amniotic membrane externally. From previous discussions we have seen that between the sixth and tenth week of fetal life, a portion of the abdominal viscera is extruded from the coelomic cavity proper into the external coelom through the base of the umbilical cord. We have also seen that this probably occurs so that the space necessary for the great enlargement of the liver may be available. After the tenth week, the size of the abdomen is increased to such a degree that the organs begin to return and the abdominal cavity can accommodate them. However, if there should be any disparity in size between the abdomen and the size of the viscera, the intestines or the liver, or both, may continue to remain outside the coelomic cavity proper. It is our impression from the cases that we have seen that it is not the size of the liver or the intestines but rather the retarded development of the abdominal cavity that is at fault.

Pathological Findings.—The sac is thin and the intestines and the liver may be seen through it. Usually it varies in thickness in different portions, indicating that some parts of the sac are covered with amnion and other parts are covered only by peritoneum. The size varies. Sometimes the entire abdominal wall is deficient. The average size is about 6 cm.,

also follow this course. Last, from the umbilicus blood is carried into the portal circulation by the veins of the round ligament of the liver and in this way the abdominal wall circulation may be connected with the mesenteric.

The superficial lymphatics of the upper anterior abdominal wall drain into the axillary and those below the umbilicus into the superficial inguinals (Chapter 23). The deep lymphatics in the upper anterior abdominal wall drain into the deep axillary, and those below the level of the umbilicus into the deep femoral (via inferior epigastric and deep circumflex iliac trunks) and into the periaortic nodes by way of the trunks which follow the lumbar vessels.

The superficial lymphatics of the umbilicus empty into the axillary (upper half, and inguinal (lower half) nodes. The deep lymphatics drain into the deep axillary, anterior mediastinal (via internal mammary), deep femoral (via inferior epigastrics), and the periortic (via lymphatics which accompany lumbar vessels) nodes. From the deep femoral, lymph channels go to the iliac lymph nodes. Lymph channels are also found along the ligamentum teres (obliterated umbilical vein) which run in the porta hepatis to the liver; in the obliterated urachus to the bladder; and in the vitelline duct *if present to reach the intestines.*

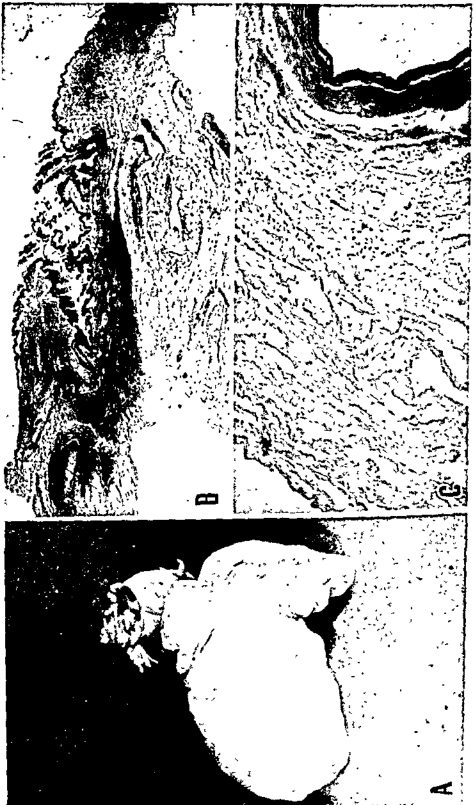
Small isolated nodes are found in the deeper fascial planes, recti muscles, and periumbilical extraperitoneal tissues. The latter are often felt in extensive intra-abdominal cancer. The linea alba has no lymphatics crossing it so that this median rape really divides the superficial (but not the preperitoneal) lymphatics into right and left halves; this is not true in the immediate vicinity of the umbilicus.

Rigidity of the abdominal muscles is a useful sign in diagnosing intra-abdominal and often intrathoracic lesions. It is also termed muscle spasm, defense, or splinting. The recti muscles have a bilateral cortical innervation and ordinarily one cannot be contracted without the other voluntarily. Localized abdominal rigidity as ordinarily elicited with one hand over an inflamed appendix is not really localized because if both hands are used, both recti are contracted as are the obliques. This is a voluntary protection on the part of the patient. If the unaffected side is palpated first, no rigidity is found; therefore the practice of using one hand and feeling the unaffected side first is good examining technique. If there is a peritonitis, a "one hand" examination reveals equal rigidity in both sides. Another illusion occurs when unanalogous parts of the abdominal wall are palpated because the recti have more tone than the lateral group of muscles. Last, a tumor mas may be at first thought to be rigid. Involuntary rigidity may arise from parietal peritoneum or parietal pleural irritation; also from thoracic or abdominal viscera disease without irritation of the overlying pleura or peritoneum. Since embryologically the enteron is a midline organ, rigidity caused by "visceromotor" reflexes is supposed to be bilaterally symmetrical. Distention of the hollow abdominal viscera or stimulation of the central end of the superior mesenteric nerve will cause contractions of the anterior abdominal muscles in decapitated animals. The objection to this hypothesis is not the existence of a visceromotor pathway, but rather the observation that the peritoneum or pleura responds to any stimulus as a whole rather than in segments, even in certain instances of acute myocardial infarction.

Since the nerve supply comes from the lower intercostal nerves on each side, incisions are made close to the midline, or in an oblique direction, in order to avoid injuring them, since injury to the nerves causes muscular paralysis and abdominal weakness. Even more important is the use of muscle-splitting or anatomic incisions, thereby avoiding the division of these structures. The abdominal wall is not only an enclosure for the abdominal contents but is also important for their protection, and, by the variations in intra-abdominal pressure which it may produce, helps the function of the abdominal organs as well as the function of respiration. The umbilicus is an important structure because it represents a landmark of important embryological events. It is of interest to the surgeon because of its relation to the portal circulation, liver, peritoneal cavity (umbilical hernia), urinary bladder (patent vitelline duct), the anterior mediastinum (by way of the lymphatics), and umbilical ligaments (obliterated umbilical vessels).

Fig. 265.—Omphalocele. *A.* Photograph of the gross specimen of an omphalocele removed from an infant 18 hours of age. This was small enough so that the mass could be removed and the layers of the abdominal wall closed in layers. *B.* Photomicrograph showing the transition zone between the skin and the omphalocele. *C.* High-power photomicrograph through the wall of the omphalocele which, as can be seen, is composed of peritoneum and amnion. In larger defects it may be hazardous to replace the contents of the sac because the intraabdominal pressure would be increased to such a magnitude that the diaphragm would be elevated and respirations could not take place fully. Also the venous return to the heart would be impeded. Therefore, Ladd has suggested that in such cases the contents be replaced and only the skin closed; then at a later date, when the abdominal cavity increases in size, the abdominal wall may be closed in layers. We have employed this method in several cases.

In very large omphaloceles it is, perhaps, best not to attempt to remove the sac but simply to close the skin over it if possible, leaving the omphalocele sac in situ. We have had success with this method. The operation should be done as early as possible because the sac is thin and soon becomes hard and friable and cracks and may cause peritonitis if delay is too long. It is best, wherever possible, to open the sac and examine the abdominal contents if this is consistent with the possibility of closure. If, however, the sac is so large that it cannot be removed, then wide undermining of the skin and closure of the skin over the sac is the desired method of treatment. The reason for exploring in the smaller sacs is that associated anomalies are frequently present, and, although the sac may be closed perfectly, atresias may be present within the abdomen which may result fatally.



B
C
A

not only because it permits better closure, but also because it enables the surgeon to discover other anomalies which may be incompatible with life. We have recently had two cases of this type with congenital atresias of the small bowel. The atresias were removed, lateral anastomosis done, and the abdominal defect closed.

Patent Urachus and Urachal Cysts.—In early embryos the bladder normally extends up to the umbilical region. The bladder subsequently descends along the anterior abdominal wall. During this descent, the upper part forms a tubelike structure, the urachus, which subsequently becomes obliterated. The urachus is derived from the superior part of the alantois.

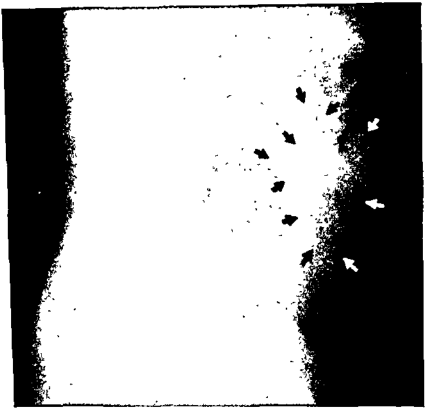


Fig. 266.—Urachal cyst. A persistent urachus is apt to manifest itself in one of four ways. It may be open at the umbilicus, permitting urine to flow from the bladder to the outside. This would be a urachal fistula. It may be closed at the bladder side but open at the umbilicus and become repeatedly infected. This would be a urachal sinus. It may be closed at both ends and this would constitute a urachal cyst. The danger of this cyst is that it may become infected and cause fever and all the symptoms and signs of inflammation. The fourth possibility is that the umbilical end may be closed and the bladder end open, in which case there may be a discharge of pus from an infected cyst giving rise to repeated attacks of cystitis. The lateral x-ray photograph shows a child 2 years of age (R. S.) with an infected urachal cyst. (Arrows point to the cyst.) This did not communicate with the bladder nor did it have an outside opening at the umbilicus. The patient was operated upon and the cyst was removed extraperitoneally, without complications. (Referred by Dr. H. Call.)

The symptoms and signs of a patent urachus vary with the degree of patency. If the entire urachal channel is open, there will be intermittent escape of urine through the umbilicus. If the cutaneous opening is patent

and the fascial opening is usually about 4 or 5 cm. in diameter. The skin of the abdominal wall may end abruptly or may grow irregularly over the top of the sac. This latter finding is important because it may mislead one into believing that the sac will be covered by epithelium. However, the blood supply of the sac is poor and soon it dies and shrivels and breaks and peritonitis sets in from leakage. Evisceration may occur and such cases are usually fatal. The symptoms and signs of this condition are also misleading because during the first day or two of life, the infant seems to be doing very well. The sac is so large that obstruction is rarely encountered. Like all congenital anomalies, the lesion rarely occurs singly and there are usually associated anomalies, such as imperforate anus, harelip, and even hydrocephalus.

Treatment.—The treatment of this condition is *immediate surgery*. The very large sacs are difficult to handle because there is not enough room within the abdominal cavity for the viscera and not enough skin to cover them over. If one waits until the abdominal cavity grows, the membrane will surely rupture and a fatal peritonitis will ensue. The best time to operate upon the baby is within the first 12 hours of life. If the sac is extremely large, the plan of procedure should be as follows:

The replacement of viscera should not be attempted in large omphaloceles. In our experience this procedure in itself will cause death on the table by pressure on the vena cava which prevents the proper return of blood to the right heart. The membrane is left in situ and the skin of the abdominal wall closed very loosely over it, leaving a gap of as much as is necessary in order to avoid too much tension. If the gap is inordinate extensive undermining of the skin of the abdomen and chest may permit closure or a split-thickness graft is taken from the mother, placed over the plicated opening, and held in place by the sutures in the skin margin. Later the graft dies, but valuable time will have been gained. We are aware that this is at best an incomplete procedure. However, it permits the tension on the sac to be released, thereby preserving this membrane for another few days. With this brief respite of time, the skin may be closed and the fascia is left open, thereby leaving a permanent hernia which is covered only by skin and peritoneum. Later, when the child is older, this large hernia may be closed. In the smaller types of omphalocele the procedure is that of the closure of any hernia; replacement of viscera, excision of the sac, and closure of the abdominal wall. The two umbilical arteries and umbilical vein are tied. This is not always necessary because there may be a blood clot in them, but it is our practice to do so. It is not always possible to dissect free the muscle and fascial layers, but if this is possible a better closure results. The peritoneum and posterior rectus sheath are closed; the rectus muscles are then mobilized so that they may be loosely approximated, and then the anterior fascia is dissected out and closed with interrupted stitches placed so the fascia will be overlapped if possible. Wherever possible, it is desirable that the sac be removed

can be done extraperitoneally, if it is done with care. Sometimes, however, the adhesions between the posterior wall of the cyst or fistula or sinus and the peritoneum are extremely thin. Every effort should be made not to violate the peritoneum. Should this occur however, the peritoneal membrane should be closed promptly. The fistulous tract is traced down to the bladder, it is divided and the bladder wall is turned in. The results are uniformly good and the mortality is extremely low.

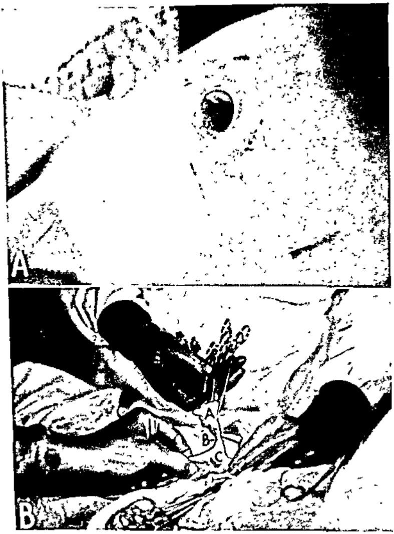

Fig. 267.—Meckel's diverticulum with patent omphalomesenteric duct. *A.* Photograph showing protruding and excoriated umbilicus of a 5-month-old boy. The child had had repeated hemorrhage from the bowel. The umbilicus was covered with a thin membrane, beneath which was clotted blood. *B.* Photograph at operation. (a) Umbilicus; (b) Omphalomesenteric duct; (c) Meckel's diverticulum. The tissue from the diverticulum contained gastric mucosa which was ulcerated. The operation resulted in complete recovery. (After Berman, J. K.: Internat. Clin. 4: 240, 1937.)

Persistent Vitelline or Omphalomesenteric Duct.—In our discussion of the embryology of the midgut, we shall see that the vitelline duct is an embryological structure which extends between the ileum and the yolk

and the epithelial lining ends blindly, there will be more or less mucoid secretion at the naval, and should this channel become secondarily infected as it usually does, there will be a recurrent episode of omphalitis with abscess formation. The patient usually refers to his "recurrent boils of the navel." Should there be no communication with the outside and no communication with the bladder, a cyst results which will be extraperitoneal. This cyst manifests itself as a swelling below the navel and it has a *definite broad attachment to the internal part of the abdominal wall.*

Urachal cysts are seen in infants and in adults. Sometimes the cyst suddenly increases in size. This is thought to be the result of an incomplete membrane separating the urachus from the bladder and this membrane suddenly ruptures. The history in most of our cases has been as follows: The child was perfectly normal until 5 years of age when a swelling occurred below the umbilicus. This caused the child to become very sick with chills and a high fever. Subsequently, a diagnosis of pyelitis was made because the *family doctor found a great amount of pus in the urine.* The child's symptoms quickly subsided, only to recur within several months. At operation a large urachal cyst with connection in the bladder was found. This, then, was a closed external opening and a patent internal opening forming a sinus which communicated not only with the skin but with the bladder. Urachal cysts frequently become infected because even though they have no internal or external communication; the endogenous bacteria multiply due to mild trauma or hemorrhage and cause an infection. In fact, frequently the diagnosis is that of a boil of the abdominal wall which is opened, and sometimes a cure results due to the fact that the infection has destroyed the wall of the cyst.

The diagnosis of urachal cyst is difficult to make if there are no openings. Lateral x-ray films sometimes help because no intestines will be found in the mass. A cystogram may show the distortion of the bladder. This may aid in diagnosis. If the urachus is patent to the outside, differential diagnosis must be made between a granulating umbilicus, which is nothing more than a small amount of granulation tissue left over after the cord has sloughed, and granulation tissue secondary to an omphalitis or a persistent vitelline duct. We shall discuss the latter in the next paragraph. The discharge from a persistent vitelline duct or omphalomesenteric duct is that of fecal matter rather than urine, or if the channel is lined with gastric epithelium, which it sometimes is, there may be hemorrhage due to peptic ulcer. Injection of Lipiodol into the fistula or sinus may help make the differential diagnosis. A cystogram helps in making the diagnosis using an iodized solution for visualization.

The treatment is comparatively simple. If an infection is present, this should be drained, and as soon as immunity has been established, the child should be given penicillin and streptomycin and the cyst or fistula or sinus should be removed. If the connection includes the umbilicus, it must be excised with the fistula or with the cyst. The entire operation

ment are uniformly good. As in other anomalies, the lesion does not occur singly and there may be other defects present.

Meckel's Diverticulum.—It is generally believed that in 2 per cent of normal adults some remains of Meckel's diverticulum are present. The literature is full of various reports concerning changes which may occur in the diverticulum or as a result of its presence. Heterotopias of the mucous membrane and associated glands, superficial and deep, may occur and become implanted in various portions of the alimentary canal. The esophagus, stomach, pancreas, common bile duct, and lung all are a part of the original entodermal canal and its derivatives in the 5 mm. embryo. This explains the possibility of heterotopia.

The various complications which may result from Meckel's diverticulum may be listed as follows:

1. Peptic group in which gastric mucosa is present with ulcer, hemorrhage, or even perforations. In this connection it is surprising how little gastric tissue is necessary to produce an ulcer.

2. Obstructive group which may give rise to intussusception, volvulus, bands and adhesions, contents of inguinal or femoral hernia.

3. Diverticulitis group which may be simple, acute, acute with perforations, and gangrenous or chronic.

4. Umbilical group which may give rise to fecal fistula, umbilical adenoma, or prolapse of intestine through umbilical fistula.

5. The tumor group which may be benign, malignant, or heterotopic tissue such as pancreatic tissue or embryonal rests.

6. Incidental group which contains normal intestinal structure.

Pathologic changes occur in one-third of the cases.

Intussusception of Meckel's diverticulum is a cause of about 6 per cent of the intestinal obstructions.

Associated anomalies in this group are said to be present in about 15 per cent. In our study of congenital anomalies of the rectum and anus, we found 56 per cent associated anomalies.

The prevalence of this congenital abnormality warrants inspection of the terminal ileum for possible Meckel's diverticulum in abdominal exploration.

Umbilical Hernia.—Umbilical hernia is discussed in connection with congenital anomalies of the abdominal wall because it is said to result from a muscular and fascial defect where the wall has been pierced by the blood vessels of the umbilical cord. The hernia is covered by peritoneum, subcutaneous fat, superficial fascia, and skin. The hernial ring usually has a firm connective tissue edge which is made up of the posterior rectus and anterior rectus sheaths and the transversalis fascia. The rectus muscle bellies are separated in the periumbilical region. However, they may be separated up to the ensiform, producing more or less of a protrusion due to the diastasis of the recti muscles. This is not uncommon in women who have borne children. Umbilical hernias are more common in girls than in boys.

sac, at the base of the umbilical cord. During early embryonic life the ileum communicates with the yolk sac. This opening gradually narrows down as the ileum pulls away. The yolk sac remains within the cord and the vitello-intestinal duct loses its connection with the intestine at about the 7 mm. stage. At the base of the omphalomesenteric duct a small diverticulum may persist. This is known as Meckel's diverticulum and is said to be present in from 2 to 3 per cent of normal persons. Usually this small pouch is not connected with the umbilicus. However, occasionally a cord of tissue which is a remnant of the primitive vitelline duct, connecting the ileum to the umbilicus, may remain. If this duct remains open, a fistula may result, running from the ileum at about eighteen inches from the ileocecal valve to the umbilicus. This opening will permit the egress of fecal matter from time to time. As in the case of the urachus, if the external opening should be closed, there may be a communication with the inside, in which case there would be a large diverticulum known as Meckel's diverticulum which would persist. If both ends are closed a cyst of the omphalomesenteric duct will result. This cyst forms an attachment to the intestine and also to the inner aspect of the abdominal wall. In fact, such a cyst is not far removed from a duplication of the intestine, and some observers have thought that many duplications arise in a manner similar to the mode of origin just described. Usually the sinus or cyst or diverticulum is uncomplicated. However, repeated infections may occur and inflammations result. The complications of this condition will be discussed later but should be mentioned here; namely, that sometimes there is an heterotopia of other tissues within the persistent vitelline duct. This tissue may consist of gastric mucous membrane or pancreas or other types of tissue. If gastric mucous membrane is found, it will secrete gastric juice and cause considerable digestion of tissue around the umbilicus, producing an ulceration with bleeding. If the tissue is present within the Meckel's diverticulum, hemorrhage may ensue just as in the case of bleeding peptic ulcer.

The diagnosis of a persistent vitelline duct can be made by the symptoms and signs which are usually very simple to detect in the true fistula because of the intermittent discharge of fecal matter. If there is great ulceration or digestion of tissue around the navel, again the diagnosis is more or less obvious. The cysts are more difficult to diagnose and the small fistulae are also hard to diagnose, particularly from an urachus, as has just been described. A small amount of Lipiodol may be injected into the tract, and if it finds its way into the intestine, the diagnosis is made.

Treatment consists of excision of the umbilicus together with the fistulous tract or with the cyst. The tract should be traced down to the ileum and the surgeon should make sure that a Meckel's diverticulum does not remain behind. The preoperative preparation of these children is important. We have been using Sulfasuxidine, 1/4 Gm. per pound of body weight. Sulfathaladine may also be used. The results of this treat-

dividuals are apt to keep on gaining and then a real problem arises. If the hernia is incarcerated and weight reduction may be pursued, this should be done. If the hernia is strangulated and if the bowel is viable at operation and the patient a poor risk, a herniotomy is the treatment of choice. This is done to increase the size of the umbilical orifice so that threats of gangrene are removed. At a later date, after weight reduction and symptoms have subsided and obstruction relieved, the hernia may be repaired. If strangulation has been present long enough so that the bowel is already gangrenous, exteriorized portions of the bowel should be drained by an enterostomy and a Miller-Abbott tube should be anchored. Then, at a later date, with adequate preparation with Sulfasuxidine, introduced through the tube and through the fistulous opening, the bowel should be trimmed away and lateral anastomosis should be done. The hernia defect may be closed at this time or at another stage if the patient's condition does not warrant a continuation of the operation. Therefore, we may see that umbilical hernia in a child is usually not difficult to care for, but in an adult, particularly in an obese adult, umbilical hernia may constitute a real problem.

Ventral Hernia.—Any protrusion through the anterior abdominal wall has been called ventral hernia. In this sense, umbilical hernia is also a ventral hernia. We have not chosen to include umbilical hernia within this term nor do we include the incisional hernias or postoperative hernias in this group. This leaves three types of ventral hernia which should be considered with the defects of the anterior abdominal wall.

1. The epigastric hernias. These are protrusions of the properitoneal fat which occur in the midline of the abdomen. Most of them occur above the umbilicus and are small. Many of them, however, assume importance and may have complications such as incarceration or strangulation. Epigastric hernias are more common in men than in women and may be easily recognized because they are above the umbilicus as a rule and therefore are not truly umbilical hernias. We have recently seen two cases of epigastric hernia with incarceration. Another name of the epigastric type of hernia is hernia of the linea alba.

2. The second of this group of ventral hernias include the ventral lateral hernias or the hernias of the linea semilunaris (Spiegel's) which arise at the outer edge of the rectus muscle. They are due to a developmental defect, or according to some of the observers, the point of least resistance may occur as a result of abnormal banding of the abdominal muscles. It is important that the surgeon be aware that immediately above and medial to the ordinary direct and indirect inguinal hernia, the hernia of the linea semilunaris may occur. Hernias of this variety usually occur as a result of a defect in the internal oblique. The external oblique and the transversalis are not likely to have the defects described. The hernia of the linea semilunaris, then, is a protrusion of fat with or

The size of the hernia, of course, depends upon the size of the defect. Some of them reach very large proportions. Sometimes the umbilical hernia will contain omentum, a knuckle of bowel, or a large amount of the intestines. In the child, this is rarely true. However, in the adult, particularly in the obese adult, the hernia may reach huge proportions and as the intra-abdominal pressure increases due to the obesity, loops of bowel may become firmly attached in the sac, and intestinal obstruction may ensue in spite of the large abdominal defect.

The treatment of umbilical hernia in the infant is adhesive strapping which will help many of the children. Approximately half of these children have a narrowing of the opening so that strapping is directly responsible for a spontaneous cure; not that strapping causes the cure, but as the individual grows and the rectus muscles constrict, the hernial sac is fused by the two layers of peritoneum growing together. Sometimes the same result occurs whether the umbilicus is strapped or not. However, if the two edges are held together, the chances for a spontaneous cure are better. Also, the strapping prevents bowel or omentum from getting into the sac and may prevent complications. Umbilical hernias which persist to the age of 4 years of age usually will not be cured spontaneously, particularly if they are more than 1½ cm. in diameter. These should be closed by operation. Also surgery is indicated in those in which repeated incarcerations occur or in which strangulation is present. Umbilical herniorrhaphy should be done by a transverse incision, transverse closure, or a vertical incision and a vertical closure depending upon which direction has the greatest diameter; that is, if the transverse direction has the longer diameter, the hernia should be closed in a transverse manner, whereas the reverse is true when the transverse diameter is short and the vertical diameter is long. Many surgeons believe in preserving the umbilicus by undercutting and lifting it up. This may be done with either type of incision. If the umbilicus is preserved, it is their contention that it saves the child embarrassment, and, of course, the cosmetic result is better. Since this does not in any way complicate the procedure, it is probably a point well taken. In the uncomplicated types of hernia, the flaps are dissected loose from the underlying muscle, the peritoneum, and fascia. The redundant peritoneum is imbricated or excised if it is large and closed with interrupted silk sutures. The fascial surfaces are then closed by overlapping in a transverse direction or a vertical direction as indicated by the diameters of the defect. The skin is then closed with interrupted silk sutures. The operation is simple and the results are excellent.

In complicated umbilical hernias many problems arise, particularly in adults and especially in obese individuals. If there are no reasons for surgery due to the immediate complications, the patients should be urged to lose weight so that the "right domicile" is re-established and so that the contents of the sac may be returned to the abdominal cavity. Where a small defect exists in obese people, this should be closed because such in-

taneously by the end of the first or second year unless the cord is too short. Should descent fail to occur, operation, with replacement of the testicle, should be done before the age of puberty. To stretch the cord, after all adhesions have been cut, a suture is introduced through the gubernaculum and tied to a rubber band anchored to the thigh.

Anterior pituitary hormone has been used to aid in testicular descent. Some cures have been reported. Since it is not a reliable method, and since a hernia may be present, surgery is preferable. The hernia which usually accompanies the cryptorchidism may be abnormal in that the sac will be placed between the oblique muscles, since the processus vaginalis does not protrude beyond the external abdominal ring (interstitial hernia). In ectopic testes the sac may be in the perineum. Often an undesirable premature maturity is induced with this hormone. Experience has shown that if the testicle is going to descend, it will do so spontaneously before adolescence. If this does not occur, surgery should be done. Intra-abdominal testes should be removed because of the incidence of malignancy.

The incidence of malignancy in the abdominal type of undescended testes is greater than in the normally placed organs. Various theories have been advanced to explain this. One of them is that the temperature in the abdomen is entirely too high for the functioning of the spermatogenic cells and that due to the lack of function, atrophy and degeneration results. The nonfunctioning organ is more "susceptible" to malignancy in this case than in other organs of the body (Chapter 15). This tendency is of sufficient importance to warrant removal of an abdominal testis.

Ectopic testis is really not a nondescended testis. The organ usually follows the attachment of the gubernaculum, and this may be abnormally placed outside the external ring over the pubic bone or the upper thigh or even within the perineum. Here, there is clearly no lack of descent but an ectopic placement. The term retracted testes means that the cord and its structures are long enough, but due to the normal strong cremasteric reflex, it may lie in a very high position. The testes should be replaced within the scrotum. The reasons for surgery are (1) cosmetic, (2) the psychological effect in a child who is apt to find that he is different from other children, (3) to avoid trauma and injury if the organ lies beneath the skin and is exposed, (4) to avoid predisposition to malignant degeneration, since the abnormally placed organs have a diminished spermatogenic function leading to atrophy and degeneration.

Two rare conditions within the testes should be mentioned here. First, *torsion of the testis* which occurs occasionally as a result of a sharp blow and sometimes without any apparent cause. Torsion produces great pain and tenderness, nausea and vomiting, and swelling within the organ. The clinical symptoms and signs resemble those of an epididymitis which is gonorrheal in origin. However, it may be dis-

without intra-abdominal contents, coverings of which are peritoneum and the herniated fat and the external oblique fascia, which may also be thinned out, and the skin.

3. Lumbar hernias are included in the group known as ventral hernias. These occur between the crest of the ilium and the costal margin. Usually they are seen on the left side. The reason for the occurrence of lumbar hernias is difficult to explain except that above the middle of the crest of the ilium there is a small triangular space which is formed by the edge of the external oblique in front, the latissimus dorsi behind, and the crest of the ilium below. The floor of this triangle is formed by the internal oblique. The older anatomists called this the triangle of Petit or the trigonum lumbale. It forms a weak point in this region in which collections of pus pool or more rarely ventral hernia may occur. Above and a little posterior to the Petit triangle is another triangular space known as the fascial triangle. Its base is the twelfth rib. Anteriorly its wall is the posterior edge of the internal oblique and posteriorly the outer edge of the quadratus-lumborum forms its boundary. The lower portion of the kidney lies immediately beneath it, and the latissimus dorsi is pushed backward. The external oblique must be pushed forward in order to uncover this triangle. Two important nerves cross it; namely, the iliohypogastric and the ilioinguinal. Through these anatomical weak spots, hernia sometimes occurs. Strangulation or incarceration is extremely rare in such hernias. The defect is uncomfortable and annoying at times, especially when the patient coughs or sneezes, because there is a perceptible bulge whenever intra-abdominal pressure is increased.

Ventral hernias are repaired by imbricating the sacs and employing whatever fasciae are available and overlapping them. Sometimes the ingenuity of the surgeon is taxed in an effort to find suitable fascia to use. In such instances, a fascial graft may be necessary. Usually, however, by mobilization of the adjacent fascia the defect may be satisfactorily closed. However, the lumbar types are particularly difficult to cure.

Undescended Testes (Cryptorchidism).—The testis grows from the genital ridge on the posterior wall of the abdomen behind the peritoneum and anterior to the transversalis fascia. By the seventh month of intrauterine life it starts its descent, directed by the gubernaculum testis, which is a fibromuscular band of tissue at the inferior pole of the testis. By the eighth month the testis is in the inguinal canal, and by the ninth month it should be in the scrotum. Sometimes the testis is arrested in its descent, or fails to move from the abdomen, or is attached at vicarious sites. These abnormally located testes (cryptorchidism) are usually associated with a hernia. In certain lower animals, such as the bat and the elephant, cryptorchidism is normal. Many infants are born with the testes in the inguinal canals. These usually descend spon-

peritoneum and other layers with it; these form the snug covering of the cord. Should the opening fail to contract or remain open (as is normal in the rabbit), a hernia will develop. Other etiological factors are sudden increase in abdominal pressure, failure of the "inguinal shutter" (external oblique and the internal oblique and the transversalis), congenital absence of falx aponeurotica inguinalis, short and less oblique inguinal canal with external and internal rings more or less over each other—in this sense congenital predisposition. Intra-abdominal pressure forces viscera into it. Acquired (direct) hernias occur after operations and from strain and may occur even in the inguinal region. The mere

Fig. 269.—Huge right-sided indirect inguinal hernia, as shown by x-ray after a barium meal. The scrotum hung to the level of the knees and contained almost the entire intestinal tract. The patient was 35 years old and weighed 205 pounds. He had had the hernia for about twenty-seven years and had been unable to reduce it for fifteen years. Weight reduction of fifty-five pounds and gentle manipulation performed daily by the patient in the recumbent position finally resulted in a reduction which was almost complete before surgery. At operation the vaginal type of congenital hernia was found and was successfully repaired.

presence of an enlarged opening does not constitute a hernia, even though it may have such potentialities, for there is no protrusion of peritoneum. Such a protrusion is called a sac. The contents of this sac may vary greatly in different types of hernia and at different times. If it contains omentum, it is known as an epiplocele; if intestines, an enterocele; if peritoneal fluid alone is present, a cystocele. However, almost any organ may be in the sac, so that the surgeon must be on his guard lest he injure it. For example, the bladder, the appendix, the

tinguished from this by a careful history, thorough examination, and urethral smears. The condition requires immediate operation in order to prevent gangrene. Should the testes be destroyed, orchidectomy is necessary. Still more rare is a *torsion of the appendix testis* or the hydatid of Morgagni. This is a remnant of the degenerated Müllerian duct as described in Chapter 23. Should this become twisted on its pedicle, a similar condition of swelling and tenderness would occur. The diagnosis between this and the torsion is difficult and is usually not made until time of operation, when the twisted remnant is removed.

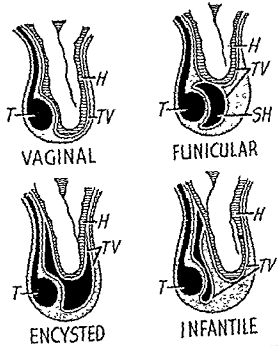

Fig. 268.—Types of congenital inguinal hernia. *T*, testicle; *H*, hernia; *T.V.*, tunica vaginalis, *S.H.*, site of hydrocele. The testis is originally an abdominal organ. By the third month it lies in the iliac *fossa*; by the *seventh month* at the internal abdominal ring; it is usually in the scrotum before birth. This descent is due to the unequal growth or active shortening of the gubernaculum. Preceding this descent a pouch of peritoneum (processus vaginalis peritonei) grows downward through the anterior abdominal wall, carrying a covering from each of the layers through which it passes. The testis originally lies behind the peritoneum and consequently descends posterior to this process, which becomes the tunica vaginalis. The visceral part is closely adherent to the testis, whereas the parietal part lines the scrotum (cf. the peritoneum and the pleura). The tunica vaginalis normally is obliterated from the internal abdominal (funicular) ring to the scrotum. Rarely, a rudimentary cord of tunica persists in this region. Should the vaginal process fail to close, a vaginal type of hernia occurs. If the funicular ring closes at a lower level, a hernia exists *above* and a hydrocele may develop *below* the occlusion. If the lower portion does not contain fluid, the funicular ring is invaginated into the part below (encysted type); or it may push down in *front* of the lower portion of the tunica (infantile). (Modified from Davis: Applied Anatomy.)

The word *hernia* is said to come from the Greek word meaning a branch. As used here, it may be defined as a protrusion of peritoneum, congenital or acquired, with or without visceral contents and covered with skin. There may be a protrusion from the abdomen not covered by peritoneum or skin which is known as evisceration. Most hernias are caused by a congenitally preformed protrusion. This is easy to understand in the inguinal hernias, for the testis is originally an intra-abdominal organ and must descend into the scrotum. In doing so it drags the

anisms may be active in those sliding hernias associated with mobile cecum and sigmoid. It is important to recognize sliding hernia because the surgeon may injure the cecum or the bladder or the sigmoid in an effort to tie off a sac which is really composed partly of bowel wall.

The treatment of this type of hernia is extremely difficult, because the peritoneum cannot be dissected off of the viscera. Many types of repair have been advocated for it. The most popularly accepted type is that described by Zimmerman and Laufman, who advocated dissecting the sac loose from the cord, pushing it back behind the transversalis fascia, and then closing this fascia tightly around the cord and doing a herniorraphy. It is not necessary in this maneuver to open the sac. It has been the custom to imbricate the sac by silk sutures, using an accordian pleat technique. Some authors have advocated dividing the spermatic cord and dropping the central end back into the properitoneal space and completely closing the canal. This is the best method of curing sliding hernia.

Hernias occur in many places and each has its anatomic peculiarities. Inguinal hernia may be direct and, if so, it is usually acquired. It is seen in obese men, 40 years of age or more, and comes through Hesselbach's triangle, medial to the inferior epigastric artery. The triangle has as its medial border the lateral edge of the rectus muscle and is divided into an inner and outer compartment by the obliterated hypogastric artery. If the direct hernia protrudes through the medial side of this structure (internal inguinal fossa), the coverings will be peritoneum, properitoneal (bladder), fat, transversalis fascia, falx inguinalis, aponeurotica, and external spermatic fascia and protrude medial to the external ring. If it protrudes through the middle inguinal fossa (lateral to the obliterated hypogastric), which is the common site, the coverings are the falx inguinalis and external spermatic fascia, and it protrudes through the external ring. If very close to the inferior epigastric, the cremasteric fascia instead of the falx covers it. It may be indirect and is usually due to a congenital defect (lateral to the deep epigastric artery), coming out through the external inguinal ring in the male (or less commonly in the female), or it may protrude lateral and mesial to the epigastric vessels (saddle or pantaloon hernia). Femoral hernia is a protrusion into the femoral canal, which normally is filled with loose areolar tissue. Its coverings are peritoneum, subperitoneal tissue (septum crurale), and transversalis fascia (femoral sheath) and makes its appearance at the saphenous opening if it descends this far, being covered by the cribiform fascia, subcutaneous tissue, and skin. It is more common in women than in men, but inguinal hernia is seen in women more frequently than the femoral type. Umbilical hernia occurs at the umbilicus. This has been described earlier in the chapter. Postoperative incisional or ventral hernia may occur wherever an incision has been made. This is usually seen after infected wounds (see Chapter

tubes, the ovaries, the colon, and sometimes most of the gastrointestinal tract may be in the hernial sac. The coverings of a hernia may vary in different regions. For example, in incisional hernia, peritoneum, superficial fascia, and skin may be the only layers present, whereas in the inguinal region the congenital hernia pushes before it all of the tissues that the testes brought down: peritoneum (processus vaginalis), extraperitoneal fatty tissue (areolar fatty tissue), transversalis (internal spermatic or endo-abdominal or infundibuliform), internal oblique and external oblique (cremasteric), external oblique (external spermatic or intercolumnar), superficial fascia, Camper's (fatty) and Scarpa's (membranous), and skin.

If the hernia may be replaced into the abdominal cavity, it is said to be *reducible*; if it cannot be replaced, it is *irreducible*, or *incarcerated*; in this type the blood supply is not impeded, but the function of the organ (for example, the fecal current) may be, in which case there results a bowel obstruction. Rarely, the sac and contents become *inflamed*, due to infection. This is dangerous because of the possibility of peritonitis. Should the intestine within the sac be irreducible and should its blood supply as well as its function be impaired, the hernia is said to be *strangulated*. Obviously, the danger of this situation is gangrene of the bowel, with perforation in addition to intestinal obstruction. There are also some special varieties of hernia; for example, a partially strangulated loop of bowel (Richter's hernia), a hernia of Meckel's diverticulum which forms a small pouch off of the ileum (Littre's hernia), and a sliding hernia (incomplete sac with the bowel forming part of it).

Sliding Hernia.—The term sliding hernia has been applied to two varieties, the more common of which is designated as the parasaccular or partial extrasaccular variety. This type corresponds to the pulling mechanism theory advanced many years ago. This is really not a sliding hernia as popularly described. It is seen in large indirect hernias which, as they increase in size, make traction on the parietal peritoneum and ultimately on the visceral peritoneum until some portion of retroperitoneal viscera, usually the cecum or descending colon, is drawn into the sac. If the hernia is a direct hernia, the posterior wall, instead of being made up of bowel, may be made up of bladder. The second type which is much less common, but which is the type popularly known as sliding hernia, is the extrasaccular or sacless hernia. This variety is due to a pushing mechanism, and in this type the viscus, together with the peritoneal covering, is pushed directly through the hernial orifice. This kind of sliding hernia cannot occur in indirect hernias if the saccular explanation for the genesis of oblique inguinal hernias can be accepted. It is possible, however, for such hernias to protrude through direct hernial orifices, and herniation of the bladder is not infrequent in this type of hernia. Since the pulsion type probably occurs in indirect hernia also, it is likely that both mech-

(Poupart's) ligament; in femoral hernia, at the femoral canal (saphenous opening), below the inguinal ligament and on the anteromedial aspect of the thigh; in umbilical hernia, at the umbilicus; in incisional hernia, at the site of the incision, etc. The obturator variety appears on the medial aspect of the thigh and the sciatic below the gluteus maximus muscle. Diaphragmatic hernias are usually discovered by x-ray studies but may first manifest themselves by partial obstruction of the stomach or bowel.

Fig. 270.—Diagram illustrating a type of internal hernia proximal to the cecum, one of the so-called paracecal varieties. The hernial sac was formed by the mesentery of the terminal ileum, cecum, and lower portion of the ascending colon. The orifice was about 5 cm. in diameter. The contents were mostly ileum. The angulation of the ileum produced an acute intestinal obstruction. This illustrates, then, a hernia into the mesentery of the terminal ileum and a persisting ascending mesocolon.

Complicated types of hernia present, in addition to the above, special symptoms and signs. The irreducible type presents a swelling which is painful and cannot be reduced; the strangulated type has, in addition, all of the symptoms and signs of acute intestinal obstruction. Although the rare inflamed variety may cause obstruction, the outstanding symptoms are heat, redness, and tenderness over the protrusion.

The treatment of hernia depends upon the age and general condition of the patient and the pathological variety present. Palliative treatment in the uncomplicated case consists of reduction of the hernia and its retention by a mechanical device such as a truss. In infants a pad held

3) or in badly debilitated individuals in whom repair is extremely slow. It is usually prevented by making incisions parallel to the fascial and muscle fibers, as in the McBurney incision, although inguinal hernia follows this incision more often than could be called coincidental. Some have thought this due to injury of the ileoinguinal and ileohypogastric nerves, but there is no proof of this. Rarely, an incisional hernia in the lower abdomen may protrude through the inguinal canal. McBurney incision hernias are rare unless there has been drainage and infection. Occasionally the surgeon will encounter an epigastric hernia, due to a congenital weakness between the recti muscles in the epigastrium, or a hernia through the linea semilunaris, and, more rarely, a hernia in the lumbar region through Petit's triangle. Also rare are those hernias occurring deep in the pelvis—through the obturator foramen (which permits exit of the obturator vessels and nerve) and through the sciatic foramen (which allows for the egress of the sciatic nerve). The diaphragm is occasionally the site of hernia. This has been discussed in Chapter 19. Accidental wounds in the diaphragm may cause an acquired type of hernia also. Internal hernia occurs as a result of congenital defects in the mesentery, or abnormal openings, or enlargement of normal foramina and is usually encountered about the duodenum or cecum.

Internal Hernia.—Internal hernias are due to congenital defects within the abdomen which may cause an intestinal obstruction and should be remembered in intestinal obstruction which cannot be readily accounted for. The sites for these hernias are as follows: (1) left mesenterico-parietal; also called paraduodenal hernia. The opening is below and to the left of the duodenojejunal juncture and leads behind the descending mesocolon and the descending colon. (2) Right mesenterico-parietal or paraduodenal hernia. The opening is below and to the right of the duodenojejunal juncture and leads behind the mesentery and possibly behind the ascending colon. (3) Defect in the mesentery, about the terminal ileum. (4) Hernia into the ascending mesocolon. (5) Defects in the omentum. (6) Defects in the broad ligament. (7) Herniation through the gastroepiploic foramen into the lesser peritoneal cavity. Of this group, Numbers 1, 2, 3, and 4 are uncommon, but important. Number 3 is perhaps the most common type.

The treatment is exploration, release of the obstruction if possible, and, if the bowel is gangrenous, resection with anastomosis. The aperture should be closed.

The sign of uncomplicated hernia is a soft protrusion or swelling which is slightly painful at times. This bulge is increased on standing, straining, or coughing and disappears when the patient reclines. By examination the surgeon can feel the opening and push the protrusion back with his finger. This soft swelling appears at the anatomic site of the hernia; in inguinal hernia, at the inguinal ring above the inguinal

cerning cotton and silk, tantalum and other kinds of wire. It is our opinion that a nonabsorbable suture should be used, although small catgut, which is chromacized, will do as well if the proper technique is observed. Recently, the use of preserved heterogenous grafts of fascia have been advocated. These grafts of fascia when transplanted into living human tissue have been observed to remain viable for a period of years. Such fascia is gradually replaced by the ingrowth of fibroblasts, capillary loops, and the formation of human connective tissue. This takes place over a period of years. Also, the use of patch fascial grafts for very large hernias has been advocated. The patch graft is a transplantation of a large section of fascia lata sewed into the defect in the abdominal wall. We have used this method occasionally and found it extremely valuable in very large postoperative hernias where there is insufficient adjacent fascia to use. A third type is that of a pedicle fascial graft in which the upper end of a graft is left attached to the fascia lata and the distal end is swung into the abdominal wall defect. It would seem that such a pedicle would carry very little blood supply, if that is the purpose of it, and therefore would have no advantage over a free transplant.

Last, the fascia may be used as suture material according to the methods advocated by Gallie. This material is said to live and form a permanent type of fascia. Still other methods of repair have been advocated. The method of McVey, which employs Cooper's ligament instead of the inguinal ligament, is an excellent suggestion. However, the older surgeons employed this ligament as well as the periosteum of the pubic tubercle in an effort to completely close Hesselbach's triangle.

The general rules for the repair of hernia includes the principles of wound healing as emphasized in Chapter 3. These consist of the following: (1) Careful dissection of the protruding sac should be done. (2) There should be complete obliteration of the sac, either by extirpation or imbrication. (3) The defect in the body wall should be covered by adjacent tissue if possible; that is, by mobilization of this tissue so that tension will not be present on the suture line. This has been discussed previously in Chapter 3; also wherever the discussion of suture has been mentioned within the text. (4) Sutures should not be tied too tight so that they strangulate the tissue. If all the factors considered in wound healing are carefully observed, good results will follow the repair of hernias. (5) The use of fascia has its place and it is perhaps most useful in the very large types of hernia in which no degree of mobilization is possible to close the defect. In such cases, however, if fascia should fail to take, some men have advocated epithelial transplants of skin. We have not used this method because of the danger of malignant degeneration of the misplaced squamous epithelial cells. (6) Last, very large defects may be closed in stages. We have frequently employed this method in the repair of postoperative hernias, closing

by an elastic belt may be used. The complicated varieties usually require operation, and if strangulated or incarcerated (with intestinal obstruction), this must be done immediately to save life. Occasionally in children or adults an incarcerated hernia is reduced so that operation may be deferred for a more favorable time. This is not without danger because the injured bowel may be ruptured, or, due to the trauma of reduction, may become gangrenous. Sometimes the protruding mass seems to be reduced when in reality it has simply been displaced under the deep fascia (reduction en masse). This obviously does not relieve obstruction. If an immediate operation is not practicable, the patient may be placed in a warm bath and urged to attempt gentle reduction himself. This is useful only in hernias of long standing where the patient has done this many times and has, by experience, learned how to accomplish it. An analgesic to relieve the intense pain may help him. Should reduction fail, operation is imperative. Injection methods of treatment which attempt to obliterate the sac by the introduction of sclerosing substances are advocated by some surgeons. However, this method is dangerous and ineffective—the former, because of injury to the bowel, blood vessels or peritoneum; the latter because the best that results is a large amount of scar tissue which subsequently stretches.

Operation is the method of choice for the permanent cure of hernia; the sac is completely extirpated and, in the case of inguinal hernia in the male, the inguinal canal is reconstructed; in hernias other than of the inguinal type, the canal is occluded. Silk or linen sutures are used. In very large hernias the sac wall is used to reinforce the wall of the abdomen. In extremely obese people it is well to defer operation until weight reduction has been accomplished. Other possible contraindications are in extremely large hernias where the intestines have been out in the scrotum for years and have, so to speak, "lost their right of domicile," although even these, after weight reduction, may be cured by operation. In patients with a chronic cough, there is apt to be dehiscence of the wound. Ascites, in addition to its mechanical disadvantage, usually implies a cirrhosis of the liver or other debilitating condition. Extreme youth does not in itself constitute a contraindication to surgery, but when inguinal hernia occurs in the newborn, because of the delicate structure of the sac and the spermatic veins and the liability to postoperative infection in infants due to soiling, operation may be deferred until the child is 4 or 5 years old. Because of the great tendency to incarceration in infants, we are now operating upon hernias much earlier than formerly, often immediately after birth. In late strangulated cases the treatment may have to be directed entirely to the obstruction (enterostomy, resection with double barrel enterostomy, q. v.) and the hernial repair done later.

Special Types of Repair.—*Much has been written recently about the* special qualities of different types of sutures. Particularly is this true con-

has been prepared for surgery. This consists of decompression with a Miller-Abbott tube at once or at least a Levine tube with suction, and restoring the electrolytes, giving transfusions of plasma or whole blood. If the patient is in a serious condition and the bowel is gangrenous, it is perhaps well to simply introduce a tube into the gangrenous loop and allow it to remain exteriorized. The Miller-Abbott tube will deflate from above. After the patient has recovered from this procedure, in seven to ten days, a second operation should be done with resection, anastomosis, and closure of the hernia. These patients are prepared with sulfasuxidine and the results are uniformly good.

(2) Umbilical hernias in obese individuals. The bowel may be incarcerated yet not strangulated. Such patients are poor surgical risks, yet it is imperative that immediate action be taken in order that the viability of the bowel be preserved. In such cases a simple herniotomy is done, increasing the size of the hernial opening and thereby relieving pressure on the incarcerated loop of bowel. Later, when the patient is greatly improved (within ten days to two weeks), the herniorraphy may be done in the routine manner. In dealing with any type of abdominal hernia, the fasciae which line the abdomen and pelvis should be looked upon as continuous layers. The transversalis fascia is not limited to the inner surface of the transversus abdominus muscle but is continuous with the intrinsic fasciae of the other components of the abdominal wall.

Injuries to the Abdominal Wall

Injuries to the abdominal wall are of importance chiefly because of the danger of injury within the abdomen. Incised wounds, lacerated wounds, contused wounds, and punctured wounds occur on the abdominal wall as elsewhere in the body. Contused wounds need some amplification. As a result of a contusion, there may be a hematoma. This may cause swelling, induration, pain, vomiting, and rigidity. These symptoms may so mimic intra-abdominal injury that it may be difficult to determine whether or not there has been injury within the abdomen. Sometimes injuries of the abdominal wall occur spontaneously. This is particularly true in pregnancy, during labor, or after debilitating disease, particularly typhoid fever. Here the injury is usually in the lower abdomen, and a hematoma may form as a result of a tear in the epigastric vein or artery. Rarely these vessels may be torn, together with muscle tears, in violent exercise. Any of these injuries may cause symptoms which resemble those of intra-abdominal injury. It should be said in summary that contusions and injuries to the abdominal wall are important not only because of their intrinsic damage, but also because of what may be present in the abdomen.

Injuries to the abdominal wall may be produced by the following: (1) External factors. These may be single or multiple and may be listed as follows: (a) penetrating wounds caused by pins, knives, daggers,

one-fourth to one-half of the opening at one time and then proceeding to close from each end until the entire area has been approximated.

Recurrences Following Repair of Hernias.—Recurrences do occur. The incidence is variously estimated as 2 to 8 per cent. Factors which contribute to recurrence may be listed as follows: (1) The body build of the patient. This would include very poor musculature, the poor development of the falx aponeurotica inguinalis, stretching out of fascial structures, the length of the canal (that is, the short canal with superimposed rings is more liable to recurrence). (2) Systemic factors, such as anemia, great weight loss, general debility. (3) Local factors. These are probably the most common offenders and they include infection in the wound, the breaking of sutures, perhaps due to insertion of the sutures under tension, failure to obtain fascial approximation due to the interposition of fat areolar tissue, the failure of complete removal of the sac, the presence of a hematoma, and nerve injury resulting in muscular weakness. Complications such as postoperative cough, abdominal distention, and direct trauma play a role. (4) Miscellaneous local causes—bilateral one-stage operations in which tension is placed on one side and at the same time on the other. This may result in a pull toward the center from both directions, putting a stretch on the suture line. In large hernias the intra-abdominal pressure may be too great. Also something else should be said about double operations in one stage. Unless the surgeon is extremely careful, he is apt to do one side and then more or less hurry through the other side, leading to incomplete work. It is better in large hernias especially to do one side at a time and this is our practice, except in children. Among local factors that should be mentioned is an unrecognized direct hernia. Usually the indirect component is recognized, but the direct part of the hernia has not been repaired. In the Halstead type of repair, where the cord is transplanted beneath the superficial fascia, the internal ring may lie directly beneath the external ring unless the surgeon is aware of this difficulty. In that case, recurrences are very apt to occur. It has been our practice when using this type of repair to be sure that the two rings are not superimposed one on the other.

The type of work that an individual does has been used as an explanation for recurrence. This is particularly true of those who do heavy lifting. Some observers have stated that the practice of getting patients out of bed too early after surgery may play a role. It is our custom to permit our patients, particularly male patients, to stand up to void as soon as there is an urge to urinate, and we do not consider early rising in any form as a cause for recurrence. In fact, recurrences have been decreased since the practice of early mobilization of the patient has been invoked.

Complicated Hernias.—(1) The most common of these is a strangulated loop of bowel. Operation should be done as soon as the patient

has been prepared for surgery. This consists of decompression with a Miller-Abbott tube at once or at least a Levine tube with suction, and restoring the electrolytes, giving transfusions of plasma or whole blood. If the patient is in a serious condition and the bowel is gangrenous, it is perhaps well to simply introduce a tube into the gangrenous loop and allow it to remain exteriorized. The Miller-Abbott tube will deflate from above. After the patient has recovered from this procedure, in seven to ten days, a second operation should be done with resection, anastomosis, and closure of the hernia. These patients are prepared with sulfasuxidine and the results are uniformly good.

(2) Umbilical hernias in obese individuals. The bowel may be incarcerated yet not strangulated. Such patients are poor surgical risks, yet it is imperative that immediate action be taken in order that the viability of the bowel be preserved. In such cases a simple herniotomy is done, increasing the size of the hernial opening and thereby relieving pressure on the incarcerated loop of bowel. Later, when the patient is greatly improved (within ten days to two weeks), the herniorraphy may be done in the routine manner. In dealing with any type of abdominal hernia, the fasciae which line the abdomen and pelvis should be looked upon as continuous layers. The transversalis fascia is not limited to the inner surface of the transversus abdominus muscle but is continuous with the intrinsic fasciae of the other components of the abdominal wall.

Injuries to the Abdominal Wall

Injuries to the abdominal wall are of importance chiefly because of the danger of injury within the abdomen. Incised wounds, lacerated wounds, contused wounds, and punctured wounds occur on the abdominal wall as elsewhere in the body. Contused wounds need some amplification. As a result of a contusion, there may be a hematoma. This may cause swelling, induration, pain, vomiting, and rigidity. These symptoms may so mimic intra-abdominal injury that it may be difficult to determine whether or not there has been injury within the abdomen. Sometimes injuries of the abdominal wall occur spontaneously. This is particularly true in pregnancy, during labor, or after debilitating disease, particularly typhoid fever. Here the injury is usually in the lower abdomen, and a hematoma may form as a result of a tear in the epigastric vein or artery. Rarely these vessels may be torn, together with muscle tears, in violent exercise. Any of these injuries may cause symptoms which resemble those of intra-abdominal injury. It should be said in summary that contusions and injuries to the abdominal wall are important not only because of their intrinsic damage, but also because of what may be present in the abdomen.

Injuries to the abdominal wall may be produced by the following: (1) External factors. These may be single or multiple and may be listed as follows: (a) penetrating wounds caused by pins, knives, daggers,

screw drivers, etc., (b) perforating wounds caused by bullets or shrapnel, (c) wounds caused by blunt trauma (this is particularly true in automobile accidents), (d) wounds caused by immersion blasts, (e) wounds following surgery (by this we mean dehiscence or evisceration). (2) Internal factors. These are seen in cases of air introduced into the rectum, usually as a prank, followed by direct results, with perforation of the large intestine. Internal injury may also be caused by immersion blasts in which case it is assumed that water is forced into the anus, causing a rupture of the large intestine only. This has been called hydraulic abdominal concussion. A word should be said in connection with immersion blast. The subject has been reviewed in Chapter 12. It will be recalled that the force transmitted by an explosion in the water is four times that in the air. Usually it affects the abdomen because the victim is swimming in the water or is being held up by a life belt. However, injury to the lung may also occur unless the victim is swimming on his back. Consequently during World War II, sailors were advised to swim on their backs as much as possible and to stay out of the water as completely as they could by hanging to life rafts. The injury produced may be severe, including wide tears and lacerations and hemorrhage. The bowel may be completely torn in two.

The abdomen may be injured by penetrating or perforating wounds at any level, namely, in the epigastric, umbilical, or in the pelvic region. However, injuries of the abdomen can take place through the chest or through the buttocks. Consequently, it must be always borne in mind that the important thing is not the site of entrance, but the path which the penetrating or perforating objects have taken. This may involve the abdomen or parts of the chest or both. This has been particularly true in wounds of the buttocks by bullets which may penetrate into the lower abdomen, causing trauma to the bowel and hemorrhage in the abdomen.

Pathological changes: The pathology in wounds of the abdomen may be divided into general and local. The former includes shock and septicemia. The latter includes the local damage to the organ or organs by the object. There is an old dictum that wounded men die from hemorrhage, shock, or infection. The first two hours death is due to hemorrhage, and the first two days it is due to shock, but the shock is caused usually by hemorrhage. Later it is from infection. Bearing this in mind, the general pathological changes will be those which are incident to hemorrhage or to infection with dissemination.

Very often the injury to the bowel or to the solid viscus is not complete. This is particularly true of the bowel wall. The bowel may be grazed by a bullet or a foreign body of any kind, causing a hematoma or brush burn, or at least it corresponds to a brush burn, making a weak spot due to devitalization from the direct trauma or anoxemia from the thrombosed vessels or subsequent infection in a hematoma. This may

result in a perforation of the bowel, just as delayed rupture of the spleen occurs from incomplete tearing of the splenic capsule.

Local changes of course are dependent upon the cause of the wound. We may divide these into various headings which we have selected as causative factors:

1. Penetrating wounds by long pins or knives, daggers, or screw drivers produce a jagged wound which is straight in, as a rule, depending upon the angle at which it is introduced.

2. Perforating wounds vary with the distance and the velocity of the bullets or shrapnel. In bullets, the closer the gun is to the victim, the greater will be the damage. The wound of entrance is usually clean. The wound of exit is usually jagged. The wound of entrance may be stained with powder marks or burned if the gun is held close enough. The bullet as it leaves the barrel rotates on its long axis due to the rifles, particularly at its blunt end. It is this motion (movement of rotation) that keeps the point of the bullet toward the front. If a cylindroconoidal bullet were fired from a smooth bore, it would rotate on its short axis even at nine yards, thereby diminishing range and striking force but producing a bad wound. It revolves at a greater degree when it first leaves the barrel than after it gains momentum. Consequently, a bullet fired at close range will leave a very large wound of entrance and will actually tear an organ through which it passes (explosive effects). In fact, deep lacerations and bursting wounds occur in solid organs as a result of bullets fired at close range. At a distance and at a high velocity the wound of entrance and exit may be perfectly clean. Obviously the bullet which is soft and at a low velocity will produce a greater degree of damage than will a hard bullet at a very, very great velocity. Also, it is a well-known fact in ballistics that no matter how soft the bullet, velocity is the important thing. If the velocity is great enough, even a soft bullet will produce a comparatively clean wound. Even a straw may be driven through a solid tree trunk by the wind with great enough velocity. This is also true of bullets.

3. Blunt trauma usually produces a hematoma on the abdominal wall, or no mark at all, yet there may be a lacerated wound of the intestine. Usually this occurs on the mesenteric border and usually in the jejunum. However, we have seen lacerations in the colon and other parts of the intestinal tract.

4. Immersion blasts introduce laceration of the viscera, accompanied by hemorrhage. It is less likely to produce a tear in one of the larger vessels. Although the abdomen may be filled with blood, it will be from a tear in the walls or the solid viscera rather than from the vessel wall itself, as is the case in perforated wound.

5. Dehiscence of a wound or postoperative traumatic wounds correspond to eviscerations made by incised wounds by sharp instruments.

However, they occupy a special place in that they occur postoperatively and the pathology is somewhat different.

Dehiscence of a wound has been discussed previously. However, we are interested here in including it because it is in effect a postoperative laceration of the abdominal wall and injury to the viscera. The mechanism for this is a failure to secure healing and is due to one of the six factors which are known to delay repair (Chapter 3). As we have said previously, it is not so much the kind of suture material that is used, although there are extravagant claims for the various types, it is more dependent upon the general condition of the patient and the meticulous care with which the abdominal wall is closed. Such factors as abdominal distention, coughing, and intra-abdominal pressure play a role. However, in most instances the cause of the wound dehiscence will be found in the six factors which have been mentioned.

Recently, much has been written about the type of incision, early mobilization, and types of suture as causes for dehiscence. In our experience, early mobilization does not in any way predispose to dehiscence in a wound properly sutured, regardless of materials used, if the various layers of the abdominal wall are carefully approximated. It has been our practice to use nonabsorbable sutures. Following the dictum of Halsted, we do not believe that the suture material need be any stronger than the tissues being sutured. For that reason we have used silk, cotton, and linen. Silver wire, stainless steel, and tantalum wire may be just as good. We have also felt that a stay suture is not only unnecessary but is apt to strangulate tissues and interfere with blood supply. In that way it may be disadvantageous to use them. We are opposed to closing the abdomen with through-and-through sutures, preferring to close each layer carefully. The type of incision is definitely a factor.

A transverse incision has many advantages. A few may be listed here. (1) The blood supply of the abdominal wall is interfered with but little. (2) The nerve supply is not damaged. (3) The wound edges come together naturally. (4) If postoperative distension is present, it puts less strain on the wound than does a longitudinal incision. (5) The patient resists less during surgery and thereby affords better exposure. (6) The wound disruption is less frequent and is more easily repaired when it does occur. (7) The danger of postoperative hernia is less. (8) The patients may be allowed out of bed very early. However, there are disadvantages. They are not unique with this type of incision. We have found that the most important factor is the preservation of the transversalis fascia. The fascia may be incised parallel with its fibers and in this way the wound gains strength. One thing is sure concerning transverse incisions wherever they are made. They must be approximated accurately, and there must be no blood clot left in the wound to interfere with healing. Whatever the type of incision, if approximation is accurate and foreign bodies are avoided, union will occur, provided that the general condition of the patient

permits. All the surgeon can do is to adhere to sound surgical principles and try to improve the general condition of the patient by attention to those vital factors which he lacks such as water balance and blood volume. However, it should be said that the more nearly anatomical the incision, the better the healing. This is true not only of the abdomen, but elsewhere as well. Since the muscle-splitting incision adheres to the plane of the various layers, it is perhaps the strongest and it also has the advantages of having the suture lines in different directions.

Symptoms and Signs of Abdominal Injury

The symptoms and signs of abdominal injury are those of peritoneal irritation. These include (1) shock and (2) pain which may be moderated by shock, morphine, or stupor or confusion or intracranial injury. In civilian practice the symptoms may be confusing because of the frequent associated head, chest, and abdominal injuries. These have been discussed in Chapter 19 under Effects of Thoracic Injuries. However, in the patients who are not in profound shock, pain is an important symptom. Tenderness is variable and misleading due to superficial wounds. Rigidity is an important sign. However, even where there has been a thoracic wound with or without an abdominal wound, rigidity may be present. One of the most valuable signs is the presence of bowel sounds. In almost every instance of bowel perforation, there is an absence of bowel sounds. However, the absence of peristalsis is not a reliable indication that an abdominal viscus has been perforated because a silent abdomen frequently exists in connection with free blood in the peritoneum, retroperitoneal hematoma, severe contusion or blast injury, severe back injury, and severe thoracic injury. Therefore, it is a reliable sign when there is active peristalsis; it is not a reliable sign when there are no sounds present. In other words, we may say that when active peristalsis occurs, usually there is no perforation of a hollow viscus. Other factors in diagnosis are the careful history of the patient, if he can give it, a study of the urine, the anchorage of a Levine tube and study of stomach content, rectal examination and careful inspection of the examining digit to see whether there is free blood or not, proctoscopic and sigmoidoscopic examination, x-ray examination and this is important.

It may be assumed that all missiles maintain a straight course through soft tissues. Bony structures may divert the course. However, as a rule, if the wound of entrance and wound of exit have been established, the organs which may have been perforated may be carefully mapped out by the trajectory of that bullet. One important fact should be mentioned. The viscera may take a different position, depending upon the attitude of the patient's body at the time of the wounding. Particularly is this true with regard to the stomach and transverse colon which may hang down in the pelvis, and, therefore, a pelvic wound may actually cause perforation of the stomach. An x-ray film in the two planes will reconstruct very ac-

curately the track of the bullet, and this will enable the surgeon to anticipate the organ or organs which have been traversed. Rarely, a bullet takes a capricious course and may confuse the observer completely. Infrequently the bullet will lodge in a position that one may assume was caused by gravity after it came to a standstill.

Sometimes, in spite of the most careful observation, examination, and blood determinations, one is unable to make an accurate diagnosis. In such cases exploratory laparotomy is indicated. However, this should not be undertaken lightly. In civilian practice as a rule the questionable cases involve injuries to the head, thorax, and abdomen and they are caused by automobiles. It is no trick to make a diagnosis of surgical or nonsurgical abdomen in a penetrating wound, although this too at times becomes confusing, particularly high up in the chest, in which the bullet traverses the abdomen and diaphragm and may nick the cardiac end of the stomach or even the celiac axis, and low down in the buttocks, in which the pelvic viscera may be damaged. Even so, the chances of making a diagnosis is good, but in compound injuries of all kinds, including head, chest, and abdominal injuries, it is very difficult. This subject has been discussed in Chapter 19. Under such conditions, it becomes hazardous to do an exploratory laparotomy and, therefore, this should be reserved as a last resort. The highly questionable case many times requires a small incision in the abdomen done under local anesthesia to see whether or not free blood is present, and, if present, this would warrant exploratory laparotomy.

Summary.—A patient with an abdominal injury, no matter what the etiological factor may be, is first given resuscitative measures, particularly if in shock. While he is receiving blood or plasma or both, if conscious a careful history is taken and examination is made. This is routine and includes the general examination as well as the part which seems to be injured: the blood pressure, pulse rate, temperature, the abdomen carefully examined for rigidity, for masses, for tender area, auscultation to reveal the presence or absence of sounds, then a careful outline of the trajectory of the bullet, if it is a penetrating wound. Eviscerations of all kinds need very little examination except to determine the extent of the evisceration, and they require immediate action. Following this examination, the urine is examined; if the patient cannot void, a catheter is anchored and the urine is taken. Rectal examination is done to see whether or not there is any blood. If so, a proctoscopic examination can be done very quickly and sometimes is very informative. A scout film of the abdomen to determine the presence or absence of free air in the lateral decubitus position is very satisfactory. Shadows caused by the presence of blood may be mapped out by the roentgenologist.

Blood counts are done and plasma proteins and the hematocrit are determined by the copper sulfate method. These tests are a guide to therapy, but more important they help in the diagnosis of active hemorrhage. These tests are repeated at half-hour intervals if necessary.

It has been our observation that the higher leucocyte counts are indicative of liver and splenic injury. Leucocytes may reach 25 or 30,000 very quickly with the patient in shock and the temperature subnormal.

Having made the diagnosis, therapy is instituted as follows: A few general rules may be given concerning the treatment. (1) Arrest hemorrhage first, then treat the patient for shock. Operation may be necessary to stop bleeding. Therefore, when we say arrest hemorrhage first, we mean that resuscitation must be followed or accompanied by surgery. Therefore, while resuscitation is being affected, operation goes on. It is our practice to have two veins available for blood which may be used while the abdomen is being explored. In this way the blood volume may be restored as fast as it is lost. This is important because very frequently when the abdomen is opened a gush of blood ensues and the patient quickly bleeds to death unless a large volume of blood is available. We usually use an ankle vein and an arm vein, and we have our transfusion sets equipped with a bulb so that positive pressure may be used if necessary.

The incision should be simple and adequate. Since one does not know the exact location of the injury, the vertical incision is preferred to a transverse. The incision need not be restricted because plenty of room will be needed.

The plan of the operation may be briefly outlined as follows: Upon opening the abdomen, blood usually pours forth rapidly. Having mapped the course of the bullet, the surgeon is able to anticipate the possible blood vessels which have been severed or injured. Therefore, for example, in the upper abdomen, in a bullet wound from left to right, he would first look for an injury of the splenic pedicle, then the superior mesenteric perhaps, and so on. Higher, it might be the renal pedicle. In other words, he is prepared to arrest hemorrhage first insofar as possible. A major vessel cannot be identified without careful search in a pool of blood, which is difficult. Therefore, our practice is to have large perforated suction tubes available. The blood is mopped and sucked out and at the same time the surgeon will stop the bleeding with his fingers until he can clearly see its origin. Sometimes this is difficult because more than one vessel is bleeding at the same time. A clamp is placed upon the bleeding vessel until the whole area may be surveyed. Bleeding of very profuse nature means that a large artery has been torn. This must be seized and clamped before anything else is done. In fact, it is useless to attempt to survey the abdomen in a pool of blood, and it is equally dangerous to clamp blindly. The best clamp is the surgeon's fingers. Hemorrhage in the mesentery may give rise to a great amount of bleeding, and such bleeding requires careful control since the hemorrhage usually occurs from many small vessels. These vessels should be individually clamped and ligated. A transfixed ligature is good if the surgeon is able to see what he is doing. Mass ligatures are bad because they cut off blood supply which may impair adjacent loops of bowel and therefore should not be used.

Bleeding from the spleen cannot be stopped without ligating the pedicle of the spleen and that requires splenectomy. Bleeding from the liver may be arrested by pressure of gauze which may be poked into the rent temporarily until the abdomen may be surveyed. After the bleeding has been carefully controlled, the surgeon may turn his attention to inspection of the entire abdomen. Our plan is to find the holes in the intestine, remembering that if there is a hole of entrance, there is usually one of exit. This is particularly true of the stomach. Holes in the intestine cannot be felt and consequently the entire gastrointestinal tract must be stripped from the cardia down to the reflection of the peritoneum in the pelvis.

The surgeon uses a plan, starting in above and working his way down, and as he runs the bowel through his fingers, if an injury has been found or if a contusion has been found, it is repaired. Where one hole has been found, usually there are two and usually there are more. Simple suture is better than resection. If resection is done, however, single layer end-to-end anastomosis is better than side-to-side, because the patient's condition does not permit the more stable and stronger type of anastomosis. In general, drainage is not used. However, on the battle front, it is just exactly the other way. "Surgeons who drain most often save the most lives." In civilian life, however, it has been our rule not to drain unless there is a liver injury, and here only as a prophylatic measure to take care of the possibility of bile peritonitis. Under battle conditions, colon injuries certainly should be treated by exteriorization. In civil life this is not necessarily true, particularly if the injured person is seen within eight to ten hours after the accident. We routinely close wounds of the colon without exteriorization with good results. As a general rule, however, where a large tear has occurred within the colon, or if several tears are present, a proximal colostomy or appendicocecostomy is indicated. This is also true of the rectum. No matter how trivial the rectal injury, it probably will not heal unless a proximal colostomy is done and the hole in the rectum is repaired. This will be considered again later. Also, it is a fundamental maxim that in the extraperitoneal injuries, the retrorectal space should be drained through a posterior incision, anterior and lateral to the coccyx which may be removed to facilitate drainage.

The picture of shock may be produced by mere contamination of the peritoneum with a large amount of stomach or intestinal content. This implies a large hole in the bowel with peritoneal flooding. Shock may be produced also by associated chest and head injuries. It is our practice here to do an immediate plasma protein, hematocrit, and blood count and then replace the blood loss; then, in an hour or less, repeat the studies which will show us whether or not there is a continued hemorrhage or overwhelming infection of the peritoneum. The disturbance of the cardiorespiratory mechanism will be indicated by the symptoms and signs of anoxemia and circulation failure. The difference between continued hemorrhage and overwhelming infection of the peritoneum is apparent if

the patient is observed for an hour or two. In the latter case, there will be hemoconcentration with loss of plasma; in the former case, hemodilution with the loss of whole blood.

Treatment of Various Injured Organs in the Abdomen

The injuries to the various viscera of the abdomen will be considered under their respective headings. However, here we may consider general principles of handling specific injuries. **Penetrating and perforating wound of the bowel.** These must be carefully sutured. We usually employ an inner row of catgut and an outer row of silk sutures if the patient's condition will permit. If not, mattress sutures of silk are used of the Lembert type.

The suturing of a wound in the intestine is preferable to resection, but it must be ascertained that the lumen is adequate after suture so that obstruction will not occur. The blood supply to the segment of bowel should be carefully determined because a large hematoma from a rent in one of the mesenteric vessels may interfere with the blood supply and necessitate a resection. Injuries to the duodenum have been considered, and the importance of suturing wounds of the pancreas and biliary tract, stomach, and colon in connection with duodenal wounds should be emphasized. A word of caution should be sounded concerning so-called brush burns. The area may be small and seem superficial. However, later this may undergo a necrosis and a perforation may ensue. This is termed delayed perforation of the bowel. To avoid this, interrupted sutures of silk should be used. The devitalized area need not be exercised. Linear tears are closed transversely, but great distortion should be avoided because intestinal obstruction may occur and patients who have been severely wounded stand this complication poorly.

The Colon.—Exteriorization of the colon is necessary in war because of the large holes made in the colon by explosives and high velocity missiles and the time factor. In civilian practice the surgeon usually sees the patient early and may close the rent, although it is probably wise to do a proximal colostomy after such a closure has been effected. Exteriorization even in the Army was not practiced routinely for the right colon or the ileum. Here a repair was done or resection if necessary with an ileotransverse colostomy in an end-to-side fashion. If the patient's condition was poor, a Mikulicz type of exteriorization was done, making a spur four or five inches long. If this is done the dangers of secondary bowel obstruction are not so great; the spur permits crushing later and suturing by Mikulicz technique. In civilian practice, however, this is rarely necessary because the wound is usually not especially large or of such a nature that exteriorization is called for. Also, under battle conditions drains are used frequently. In civilian practice surgery usually is instituted before eight hours and drains are not used. This is especially true now with the aid of streptomycin, the sulfonamides, and

penicillin. Perforations of the sigmoid and the retrosigmoid and the rectum should be repaired, but proximal colostomy is practically always done under battle conditions. In civilian life, in injuries of the extraperitoneal portions of the large bowel, namely, the rectum, a proximal colostomy is done and the true nature of the injury ascertained. In other words, at the time of the colostomy, careful exploration is also done to determine whether or not there has been an injury to the bladder or to other viscera. After the damage has been repaired, the colostomy is completed and the patient is returned to his room. At the second stage, the extraperitoneal portion of the operation is done by suturing the rent in the rectum. This prevents fistulae from forming in the perineum. It should be said at this time, however, that not all observers are agreed that this rent in the rectum should be sutured. Some prefer to allow it to close itself after a proximal colostomy has been done. It has been our practice to suture this rent. A cecostomy is ineffective in defunctionalizing the large bowel. Therefore, a transverse colostomy, sigmoidostomy, is done. The fecal fistula which occurs through bone always requires excision. The other fistulae may heal but not those through bone. If there is an injury to the bladder, the same principles are observed; namely, the bladder is put at rest by diversion of the urinary flow and the opening in the bladder is closed. In civilian practice injuries to the rectum have been dealt with as colon injuries except that in addition to primary suture, a proximal colostomy is done to divert the fecal current until the wound heals. Also, we have used perineal drainage, but we have not found it necessary to resect the coccyx in order to institute it. Our reasons for closing the perforation of the extraperitoneal portion of the rectum are that although the colon is drained to prevent further contamination, yet a widespread infection may ensue in the retroperitoneal space and cost the patient's life. Furthermore, if the infection is controlled by chemotherapeutic agents, persistent fecal fistula may result which will require excision later on. For these reasons our custom has been to do a limited abdominal exploration and colostomy through a lower oblique incision; having found no injury within the abdomen, we next proceed to find the extraperitoneal wound. This is closed, the peritoneum covered over it, and a colostomy is done. The patient is then placed in the lithotomy position and the retrorectal space is drained. If the wound is directly in front of the coccyx, it may be necessary to do a coccygectomy at that time.

Wounds of the liver, no matter how they are produced, may be extremely dangerous. This is particularly true of the large comminuted lacerations of the liver that are ordinarily seen as a result of an automobile accident. Not only will the anterior portion of the liver be lacerated by the steering wheel, but due to fractured ribs the posterior portion of the liver also may be torn. There may be prodigious bleeding and the liver substance may be macerated. Such livers are difficult to suture and various methods have been adopted to control hemorrhage:

(1) Gauze packs will control bleeding, but when they are removed secondary hemorrhage may occur. (2) Skeletal muscle may be sutured into the liver tear. This works well in small wounds or surgical wounds made for biopsy. (3) The macerated wounds may be sutured by introducing a piece of omentum. We have used this method frequently. The omentum is placed into the rent and loosely sutured. This gives the stitches stability. The omentum may be laid over the torn area kept in contact by gauze packs. However, this predisposes to infection and when the pack is removed there may be secondary hemorrhage. (4) More recently the use of cellulose acetate gauze which is absorbable has been made available and works very well. This gauze which is sutured directly into the wound is absorbed. Suturing is really unnecessary in many cases when this gauze is employed. However, where large vessels are involved, it is risky. These should be tied and the gauze sewed in place. (5) *Through-and-through* sutures using a large blunt needle and taking large bites is useful if there is not too much contusion. Perhaps the most important point to make in regard to injuries to the liver is adequate drainage of the subphrenic space and Morrison's pouch. The reason for this is that all liver damage of any proportion causes a considerable leakage and may produce a bile peritonitis. We have frequently closed up the abdomen without drainage in civilian practice where the injury has been modest and the tear adequately sutured and where the lesion has been repaired within the first eight hours.

Injuries to the spleen usually require splenectomy. Sutures in the spleen are unsatisfactory and secondary hemorrhage may occur. Therefore, splenectomy is the treatment of choice.

Injuries to the kidney require nephrectomy. However, small wounds of the kidney may be treated conservatively and may be sutured. If the major blood supply is injured or if an injury is near the hilus, usually the kidney must be removed. Injuries to the ureter are closed by sutures. In battle areas, the ureter was usually injured so extensively that the primary repair was very difficult and nephrectomy was the procedure of choice. In civilian practice, however, where adequate facilities are usually available, primary suture or excision and anastomosis are attempted.

Wounds of the great vessels have been discussed in Chapter 17, and thoracoabdominal lesions have been adequately reviewed in Chapter 19. Other injuries which may occur within the abdomen such as the gall bladder and the pancreas, require special consideration.

The **gall bladder** may usually be saved by draining it. The **pancreas** should be sutured and a drain should be placed through the gastrohepatic or gastrocolic ligaments.

Treatment of **intra-abdominal injuries due to blunt trauma** will be discussed under injuries of small intestines. However, it may be said at this time that in severe abdominal contusions, especially in children with all the symptoms and signs of peritoneal irritation, together with

shoulder pain, an injury to the bowel should be suspected and primary suture should be done. If seen within eight hours, drainage is unnecessary.

Postoperative dehiscence is a form of injury which results in an evisceration and must be treated promptly. The treatment of postoperative separation, if it is complete, requires, first of all, recognition, and this is usually evident by the fact that in a normal wound there should be no perceptive amount of drainage. Dressings are not usually disturbed for eight days unless there is pain, fever, or appreciable exudate. In the latter case one should always suspect dehiscence, particularly if serous or if accompanied by vomiting and by signs of shock. Although some have advocated the use of adhesive to hold the skin edges together, particularly in bedridden patients, it has been our experience that where dehiscence has occurred the best method is to resuture the wound immediately. This is a life-saving measure. Our plan is to start transfusions immediately and to introduce a Levine or Miller-Abbott tube to empty the bowel of gas as much as possible. Under local anesthesia, the wound edges together with all the layers of the abdominal wall, are brought together by through-and-through sutures. We have used heavy silk or silkworm gut, although some have preferred through-and-through sutures of silver or other wire. It is rarely possible to suture the abdominal wall in layers because of their friability. In addition, hematomas have formed and infection is present. The time consumed in separating and identifying the layers would be more than the patient could stand. After cleansing the skin margins with physiological saline in large quantities, the eviscerated organs are washed with the same solution and replaced. If necessary, a little Pentothal sodium may be used intravenously. The through-and-through sutures are introduced, *and in addition the skin is closed by interrupted silk* sutures. In bad-risk patients, until blood transfusion has been done and the bowel has been emptied of its gas, adhesive strips may be passed from side to side and the wound edges held together. It is surprising under such conditions that very frequently the wounds will heal, and we have observed very few instances of postoperative hernia. It should be emphasized that the local conditions which caused the breakdown be rectified insofar as possible. This will usually be the presence of a small portion of extruded omentum. Obviously the general condition of the patient should be improved by attention to water balance and blood volume. Vitamins should be given, particularly vitamin C.

The immersion blast injuries are treated by immediate exploration and all rents sewed promptly and bleeding controlled. The entrance of water into the rectum may produce a very long jagged rent in the colon. This is dealt with under battle condition by exteriorization. In civil life occasionally an air hose is introduced into the rectum as a prank. This may produce a tear in the colon requiring laparotomy and suture of the torn bowel or its exteriorization if too badly torn. There is much bleeding in the coats of the bowel wall so that approximation *of the layers*

may be difficult and insecure. Three plans are available. (1) The devitalized area if limited may be excised. (2) Resection may be done or the colon may be exteriorized. (3) A proximal colostomy is indicated if there is any doubt about the suture line. Rarely, the colon may be injured by the introduction of a glass bottle or stick in the rectum in sexual perverts, causing a tear. This requires immediate operation and suture of the rent. The postoperative care of all abdominal wounds includes attention to water balance and blood volume; also the prevention of distention by the use of the Levine tube with suction. The use of chemotherapeutic agents and antibiotics help. Streptomycin will help in the control of colon bacillus infection and its prevention. Penicillin and sulfadiazine help in the control of streptococcal and staphlococcal infections.

In **combined thoracoabdominal injuries,** oxygen is used postoperatively. Also, it should be added that very frequently an abdominal injury is accompanied by a diaphragmatic tear or laceration. This should be repaired so that pneumothorax, empyema, and diaphragmatic hernia may be avoided.

A consideration of injuries to the abdominal wall must include the subject of **external fecal fistula.** Although they have a variety of causes and they are not, strictly speaking, an abdominal wall pathological entity, yet they are a group which may be properly considered at this time. The law of fistula as given in Chapter 5 states that if the normal channel is open, the artificial channel will close with the following exceptions: (1) fistulous tract lined with mucous membrane, continuous with the skin; (2) tuberculous fistulae; (3) mycotic fistula; (4) new growth; (5) foreign bodies.

Fistulae may be internal as well as external, or there may be an internal opening in addition to the one on the outside. The term fecal fistula is not entirely proper because it includes drainage from the intestinal canal whether it is fecal or not, such as duodenal content. Also, there may be biliary or urinary fistulae. If possible, the organ from which the tract originates should be used, such as gastric, duodenal, cecal, urinary vesical, gall bladder fistulae, etc. Nor is it proper that we speak of them as abdominal since some of them occur in the sacral, lumbar, or even in the thoracic region, depending upon their cause and their situation. Most fistulae do occur in the colon or ileum because of the lesions which occur in these parts.

The treatment of fistula depends upon its cause and its duration. Therefore, it is important that the cause be determined if possible. In a penetrating wound or a perforating wound or a stab wound, the fistula is established by the injury and is closed immediately. However, if it is not seen within forty-eight to seventy-two hours, it is perhaps best to wait and close it later. This also applies to fistulae which occur postoperatively. The reasons for postponing the closure of such fistulae is, first of

all, to permit local immunity to become established. Following the injury there is much inflammation in the bowel wall and peritoneal cavity. Repair at this time might spread the infection. If other conditions do not warrant immediate surgery, it is perhaps best to let the fistula remain as a safeguard against obstruction and later go in and close it. Another reason for waiting following wounds is that many of these fistulae will close spontaneously. Most wounds are made within organs which are not previously diseased. A normal channel is open and chances are that the fistula will close.

Postoperatively and as a result of disease it is a good idea to attempt to establish the cause. However, in many cases, this is difficult. In addition to traumatic wounds which may cause a fistula, many other causes should be be mentioned at this time.

Etiology of persistent fistula: Persistent fistula may be caused by the following: (1) Inflammatory lesions of the bowel. In this group are included diverticulitis, regional enteritis, ulcerative colitis, and appendicitis. Also in this group are the specific types of infection; namely, tuberculous enteritis and actinomycosis. (2) Inflammations outside the bowel; namely, pelvic inflammatory disease, tuberculosis of the abdominal cavity or tuberculous abscess, retained foreign bodies, osteomyelitis. (3) New growths which ulcerate and perforate, producing a persistent fecal fistula. (4) Obstructions from various causes with spontaneous or surgical establishment of a fistula, thereby relieving the obstruction. This fistula will remain open. (5) Postoperative fistula may occur without any apparent cause. It is assumed that in most cases some injury or severe infection was present at the time of operation and a foreign body was left in the abdomen or that the bowel was traumatized and not recognized so that repair was not done, thereby causing a fistula. Sometimes the cause of fistula cannot be determined, even after careful microscopic examination.

Diagnosis as to the Type of Fistula.—The history of the cause is important; trauma, operation, purposeful fistula are all obvious. The diagnosis as to the cause may also be ascertained by taking a biopsy and studying the fistulous tract. Not infrequently the surgeon will discover actinomycosis or tuberculosis or even carcinoma. If no specific cause can be found, careful examination by x-ray with Lipiodol injected into the tract or barium meal or enema to determine the presence of an obstruction should be done. This method may also provide valuable information concerning the course and communications of the fistula and, above all, the patency of the normal channel.

The Treatment of Fistula.—If the normal channel is open and the fistula remains, then the cause of the fistula must be sought because the treatment will depend on the cause. The treatment may be divided into the preoperative preparation and the surgical procedure and will vary according to the pathology that is determined. All patients with bowel fistula are fed a nutritious diet and attention is given to the water balance

and blood volume. In addition, succinylsulfathiazole, 1/4 Gm. per pound of body weight, is given by mouth and an equal amount is injected into the distal portions of the bowel. Sulfathaladine may be used in smaller doses, approximately 1/10 Gm. per pound of body weight. If the fistula tract is short and if found to contain only mucous membrane which has grown to the skin, a conservative operation may be done which consists of curettement of the fistula tract. This may result in a cure. Sometimes this may be accomplished by use of silver nitrate which is not as reliable or successful. The second most common method of dealing with fistula is excision. This is done by making a semilunar incision around the opening and sewing the skin over the fistula so that the bowel wall is turned in. This is done in the so-called aseptic manner. However, with the advent of *antibiotics and chemotherapeutic agents, the bowel wall is freed and turned* in, in a surgical manner and the abdomen closed without drainage. In compound fistulae it is necessary to do a preliminary colostomy or enterostomy, or a short circuit may be made around the fistulae. This may be a definitive procedure or it may be a first stage. As a rule it is the latter. For example, a fistula of the ileocecal region may be temporarily interrupted by dividing the ileum and doing a transverse colostomy. The second stage consists of removing the entire area just as in carcinoma. In fact, neoplasia may be the cause of the fistula and may warrant wide excision. If the short circuit is to be temporary, the ileum is not divided and a lateral anastomosis is made between the ileum and transverse colon. At a later date this may be rectified after the fistula has been closed or it may be left in situ. This procedure is frequently done in regional enteritis. In fistulae due to severe chronic ulcerative colitis, ileostomy may be done as a definitive operation, as a preliminary stage to colectomy. We have many cases of ulcerative colitis with fistulae which have closed after the ileostomy and no further surgery was necessary. For fistulae of the sigmoid, a transverse colostomy may be necessary to improve the patient's condition and to give the fistula a chance to close spontaneously. More important, these side-tracking operations permit the patient's condition to improve and allow the local inflammatory reaction to subside. Simple fistulae may be excised by elliptical incisions, closure of the fistula, and then resection. Usually, however, it is better to make an adequate incision where the cause of the fistula is not known for the purpose of exploration. After careful preparation, this may be done with safety, and the fistula itself is not removed until the cause of it is ascertained. In seriously ill patients, the side-tracking operation will have been done, and the fistulous *opening may be carefully dissected* out and a resection of all diseased tissue, even that which is remotely diseased, may be accomplished so that primary union may occur. In case of carcinoma, wide excision is necessary, not only around the fistula, which may contain malignant cells, but of the involved bowel as well. The wound where the fistula was excised should be closed very loosely so that abdominal wall infection will not ensue.

The plan of removal of the fistula should be by adequate exposure and sharp dissection because the bowel that becomes attached to the fistula is very friable, and in separating the loops they may be torn. Fistulae which pass through bone, as has been said, will not close unless they are excised. They are particularly hard to heal. These are seen in the region of the buttocks following gunshot wound which has penetrated the rectum or colon.

In summary, the treatment of fistula reverts back to the cause, and the law of fistula will hold in fecal fistulae as elsewhere. The postoperative care of the patients with fecal fistulae is the same as those treated with bowel resection. They should be given large doses of penicillin and sulfonamides and streptomycin as indicated. Nothing is given by mouth; a Levine tube is passed with Wangensteen suction. Fluid balance and blood volume balance is maintained. These patients usually do very well and the percentage of recovery is high.

Inflammation of the Anterior Abdominal Wall

In the newborn, inflammation of the anterior abdominal wall is seen as an *omphalitis.* Although this condition now is extremely uncommon, it is encountered often enough to warrant some description. The umbilical vein pierces the abdominal wall and continues inward at the inferior edge of the falciform ligament, communicating with the portal system and also with the inferior vena cava by the way of the ductus venosus. After birth the ductus venosus becomes obliterated and forms the ligamentum venosus, and the anterior portion of the umbilical vein becomes obliterated and forms the ligamentum teres. The two umbilical arteries pass through the abdominal wall and then course downward. They become the hypogastric vessels between the transversalis fascia and peritoneum and join the internal ileac arteries. Soon they become obliterated also, and as we shall see they form the obliterated hypogastric artery bounding a space through which a direct hernia may find its way. These venous and arterial channels may remain open and, if they do, infection may find its way upward because of thrombophlebitis or downward through an infected arterial embolus. Furthermore, the lymphatic drainage as we have seen is prodigious, permitting infection to spread along the lymphatics downward and upward into the inguinal and axillary regions, respectively. Last, the infection may spread by direct extension into the abdominal cavity.

Omphalitis is caused by infection of the umbilical cord stump. As in gangrenous stomatitis and other severe infections, "it takes two to make a bargain." Namely, "it is the soil rather than the seed" which is at fault. The organism most frequently encountered is the hemolytic streptococcus; next, the *staphylococcus aureus.* Rarely the colon bacillus is at fault, although, theoretically at any rate, the colon bacillus is not found in the gastrointestinal tract until eight to ten hours after birth.

The pathology is as follows: Granulation tissue seems to persist in the umbilical stump and there is a preumbilical cellulitis that seems to

spread. This occurs within the first few weeks of life. The redness and the induration is extensive, and soon the entire preumbilical area is involved. The infection may follow one of several courses: (1) The infection may remain local and form an abscess. This may break and the entire process may undergo resolution. (2) Resolution without abscess formation may occur. (3) Necrosis and sloughing may result. (4) Necrosis with absorption may be the reaction. (5) There may be blood stream invasion with severe septicemia and septic pylephlebitis, involving the portal vein, and a multiple abscess of the liver. (6) The infection may spread by direct extension into the peritoneum, causing peritonitis. The cases which we have seen have included all of these types. Most cases of omphalitis will subside under treatment of large doses of penicillin, 50,000 units given intramuscularly every three hours. Locally, protection of the inflammatory lesion with penicillin ointment has been our treatment of choice. Local types of infection have been encountered, but rarely. Usually the blister will break without surgical intervention. *Cellulitis* with involvement of fascial planes is very serious and may cause a great deal of sloughing. This type of reaction is seen in babies who are malnourished and in poor physical condition; also in children who have had scarlet fever or measles or other infectious diseases in early life. In these cases with extensive undermining, the skin must be excised overlying the necrotic tissue, and after granulation forms, skin grafting in stages is pursued. Severe bacteriemia or septicopyemia may result in metastatic abscesses. These may be seen in the fingers and legs. If a septic pylephlebitis occurs, there may be jaundice with multiple abscess of the liver. In those cases which spread to the peritoneal cavity, the mortality rate is extremely high. Peritonitis starts very rapidly. However, here again, with the use of penicillin, streptomycin, the sulfonamides, and peritonitis regimen, the results have been better.

Omphalitis in older children occurs not infrequently. This may be due to the fact that the umbilicus is perhaps the filthiest part of the body and in many children rarely, if ever, is washed. Furthermore, children have a habit of introducing foreign bodies in the umbilicus, such as small pieces of gravel, sand, or toys, setting up an inflammatory reaction. Often the first sign of an omphalitis consists of swollen inguinal nodes. These lesions heal very readily after the causative foreign body is removed and the navel washed with soap and water.

Other infections of the anterior abdominal wall occur under the following circumstances: (1) Injuries. (2) Postoperatively. (3) As a result of visceral infections.

Injuries of the abdominal wall have already been discussed. The infections which follow such injuries are usually complicated by an injury to the colon or intestinal tract. Very rarely a superficial injury becomes infected. However, in most instances this is due to the presence of a foreign body and follows the rule of skin infections as discussed in Chapter 16.

The treatment of injuries to the abdominal wall is the same as injuries elsewhere on the body. However, it must be borne in mind that injuries on the abdominal wall, although merely contusions, may be accompanied by injury within the abdomen.

Postoperative infections of the abdominal wall have been discussed under Clinical Types of Suppurative Inflammation, Chapter 5. Here we discussed stitch abscess caused by the *Staphylococcus albus* and *aureus*, the colon bacillus infections, and also the symbiotic infections which occur in badly debilitated individuals, following operations and particularly following colostomy or enterostomy. Infections of the abdominal wall which follow visceral infections usually occur after the viscus has become attached to the parietal peritoneal surface; then by erosion and secondary infection, the abdominal wall is involved. Sometimes an abscess will point over the gall bladder area following perforation of a gangrenous gall bladder. This is also seen in perinephric abscess which points in the loin, or for perforating carcinoma with abscess formation, appendicitis, and diverticulitis with abscess. The abscess may be recognized and drained surgically, at which time its origin may be ascertained, or later, after careful study by x-ray and the injection of Lipiodol through the sinus tract.

Rarer causes of infection of the abdominal wall include *cellulitis due to extravasation of urine* from the male urethra below the triangular ligament which spreads through the subcutaneous tissue of the external genitalia and directed by fascial attachments to the pubic arch and inguinal ligaments, sometimes passing up into the abdominal wall.

Another rare form is cellulitis of the properitoneal fat. This may be associated with perinephric abscess or a perivesical abscess through an infection in the properitoneal fat posteriorly from retroperitoneal hematoma following the injury. Cellulitis of the abdominal wall is more likely to occur from a kidney or colon lesion than any other source.

Of the specific types of infection of the abdominal wall, we must include tuberculosis, actinomycosis, and, last, a carcinoma of any variety is apt to cause infection due to the formation of fistulae.

Abdominal Incision

The diagrams will show the various types of abdominal incisions which have also been discussed in Chapter 3, Figs. 4-7. The principles involved in wound healing must be scrupulously observed in abdominal incision. The so-called anatomical types offer much in facilitating wound healing and in the prevention of dehiscence.

Neoplasms of the Anterior Abdominal Wall

Neoplasms of the anterior abdominal wall may be divided into benign and malignant tumors. The latter may be subdivided into primary malignant tumors which may be carcinoma, sarcoma, or melanoma, and a second subdivision of the malignant group include metastatic malignant

neoplasms which may be implantation cancer, malignant lymphomas, and metastatic growths from intra-abdominal organs. The last group includes a group of miscellaneous lesions which simulate tumors in the anterior abdominal wall.

Group 1. Benign tumors of the anterior abdominal wall. This group consists of many varieties including lipoma, neuronevus, hemangioma, epithelial papilloma, fibroma, neurofibroma, teratoma or teratotic papilloma, desmoid tumors, lymphangioma, dermatomyoma, Schwannoma, and lymph gland adenoma. Some of these lesions have been considered in other chapters, particularly Chapters 15, 16, and 17. A few of this group deserve special attention.

The neurogenic group of neoplasms all demand careful surgical eradication. This is true of others of the benign group such as the lipomas, the neuronevi, the hemangiomas, epithelial papillomas, the fibromas, neurofibromas, the teratomas, and teratotic papillomas. Lipomas are by far the most common of all tumors seen in the abdominal wall. The nevus unius lateralis or neuropathic papilloma demands wide excision because it may undergo malignant degeneration or transformation. This is true also of the neurofibromas. Neurofibromas may be located within the abdominal wall or within the abdominal cavity. The vascular group of benign neoplasms, if very superficial, may be treated with carbon dioxide snow, but if they are elevated, they should be excised and a skin graft placed over the excised area or a skin flap should be cut.

Lymphangiomas are best treated by excision in stages if they are extremely large. Desmoids constitute a very interesting, though rare, entity. They occur in children as well as adults and are seen as hard fibromas in the flat muscles of the anterior abdominal wall. They are more common in young women, although we have seen some desmoids in young males. The tumor has been described as an unincapsulated infiltrating fibroma of fascial or aponeurotic origin. Its microscopic appearance varies from that of a cellular fibroma to that of a low-grade cellular fibrosarcoma. These growths are said to occur in skeletal muscle elsewhere, but they are extremely rare. It is a characteristic finding that when one encounters a desmoid, one is apt to make the mistake of calling it a fibrosarcoma. The cause, of course, is unknown. Most of these growths occur in young parous women; therefore pregnancy has been said to be of etiological significance. Since the growth does occur in young males, this certainly could not be the only predisposing factor if it has a bearing at all. It is perhaps more correct to assume that during pregnancy tension on the fascia and the aponeurotic fibers may play a role. Desmoids are dense, hard, and fibrous, and although they may be fairly circumscribed, more often a definite capsule cannot be found. They are usually solitary. When these tumors are found elsewhere in the striated muscle, they have a tendency to infiltrate into the joints and become adherent to bone. The desmoid tumors having their origin in the

posterior sheath of the rectus may become firmly attached to the parietal peritoneum. They rarely involve the skin, although cases have been reported where the skin ulcerates. They are not vascular, yet they do not undergo necrosis or liquefaction. The microscopic appearance is that of a fibroma plus bundles of striated muscle fibers in various stages of atrophy. Desmoid may be confused with neurofibroma or a neurofibrosarcoma. Some pathologists think that a desmoid tumor is really a perineural fibroblastoma, and some specimens suggest this origin, but there is no proof of this.

The treatment is complete surgical excision, and this must be wide and radical because there is a great tendency for local recurrence. In most cases the patient should be warned against subsequent pregnancy because of the high rate of recurrence following childbirth. Strangely enough, the desmoid does respond to x-ray therapy, particularly in the female. This is thought to be due to the effect of the therapy on the ovary which stops the production of ovarian hormones. It is more resistant to radiation in the male. However, following radiation castration in the male, it undergoes regression. Since the growth does not metastasize to regional lymph nodes, the prognosis is extremely good if local extirpation is complete.

Malignant tumors of the anterior abdominal wall include carcinoma of the epidermoid and basal-cell type and adenocarcinoma; also sarcoma which may be neurogenic, spindle-cell, rhabdomyosarcoma, dermatosarcoma, liposarcoma, and granulation tissue sarcoma, and the melanomas; melanocarcinoma of the skin is common, yet in the anterior abdominal wall it is relatively rare.

Chronic irritation such as that seen in burn ulcers of the lower extremities may produce carcinoma (Marjolin's ulcer), and kangri burn cancers of the Japanese are examples of epidermoid cancer brought about by repeated application of heat. An earthenware bowl heated by wood charcoal is worn under a single loose garment by the poorer class of Kashmir. The habit of wearing a portable oven against the abdominal wall for the maintenance of body heat is also prevalent in Japan. Carcinomas of the abdominal wall in America are extremely rare except following radiation dermatitis. Rarely sebaceous and sweat gland adenoma may be precursors to adenocarcinoma.

Primary carcinoma of the anterior abdominal wall metastasizes slowly. Complete extirpation by surgical means followed by radium or low or intermediate voltage x-ray gives good results. Cancer which arises postoperatively and results in chronic draining sinuses or fistulae offers the most serious prognosis. In this way it resembles the marginal ulcer resulting from a burn in the lower extremities. *Granulation tissue sarcoma*, according to Ewing, is a process arising from lacerated chronically infected wounds or in reactive organization of hematomas. These must be thoroughly excised. *Malignant melanomas* are even more malignant when they occur on the anterior abdominal wall than elsewhere.

This is due to the fact that both lymphatic and venous components are involved, and since the abdominal wall is well fortified with lymphatic and blood vessels, metastasis is early. The growths, together with all *related lymph nodes that may become involved, should be removed.* X-ray and radium have little effect.

Metastatic malignant tumors of the anterior abdominal wall are fairly common. They may arise from carcinoma of the ovary, stomach, uterus, lung, kidney, breast, sigmoid, cecum, rectum, liver, pancreas, gall bladder, vulva, and undetermined sources. In Chapter 15 we discussed the possibility of implantation cancer, and this was particularly true in exteriorizing operations for carcinoma. We have also seen it following excision of carcinoma of the breast with skin-grafting implantation.

The *metastatic sarcomas include melanoma*, teratoma of the testis, mesodermal mixed tumor of the vulva, and liposarcoma. Endothelioma and multiple myeloma rarely involve the abdominal wall secondarily. The treatment for secondary carcinoma or metastatic carcinoma and metastatic sarcoma is purely palliative since the origin of the growth is evidently still present or has not been completely removed. However, in implantation carcinoma or in direct extension of carcinoma from an abdominal organ, a wide excision of the abdominal wall, together with the primary growth, may prolong life and occasionally result in a cure. We have seen one such case of carcinoma of the cecum in which the abdominal wall was involved. A radical operation included the terminal ileum, cecum, ascending colon, half the transverse colon; and the right lower quadrant of the abdominal wall, where a fistula had established itself, was excised and flaps were swung over it to close the abdominal defect. This resulted in temporary arrestment of the disease and the patient survived for over four years.

Malignant lymphomas occur in the anterior abdominal wall. These include lymphosarcoma, Hodgkin's disease, leucemia, and, rarely, mycosis fungoides.

The last group consists of miscellaneous lesions which simulate neoplasms of the abdominal wall. In this group may be included the chronic inflammations and cysts including sebaceous cysts, urachocysts, sweat cysts, radiation ulcer, fat necrosis, pyogenic granuloma, tuberculosis, actinomycosis, and spontaneous hematoma. Tuberculosis has been encountered only rarely. Endometriosis involving an abdominal scar following a cesarean section and also in the umbilicus is occasionally seen. Spontaneous hematoma was formerly seen fairly often in typhoid fever but is a comparatively rare lesion now. Of all these lesions, perhaps those which resemble carcinoma most are the radiation ulcers, fat necrosis, and tuberculosis.

Diagnosis can be made only by biopsy. An apparent abscess should be drained, but a biopsy should be taken from its wall. The same is true of sinuses and fistulae. Tumors of the abdominal wall, therefore, may be

primary or secondary. In any event they should not be neglected. They should be removed for biopsy, if for no other reason. Very often a supposedly benign tumor gives a clue to an intra-abdominal lesion which is malignant.

PERITONEUM

Embryology

We have already discussed the development of the somatopleure and the splanchnopleure. It will be recalled that in the very early embryo the mesoderm splits laterally in two layers, the dorsal known as the somatic and the ventral known as the splanchnic mesoderm. These layers persist in the adult, the somatic mesoderm giving rise to the pericardium, to the parietal pleura, and to the peritoneum, while the splanchnic layer forms the epicardium and the myocardium, the visceral pleura of the lung, the mesenteries, and the mesodermal layer of the gut. The somatic mesoderm and the ectoderm with the tissues that develop between them constitute the body wall. This is called the somatopleure. Also the splanchnic mesoderm and the enterderm with the mesenchymal tissue between them constitute the wall of the gut and this is termed the splanchnopleure.

The cavity between the somatopleure and the splanchnopleure is the coelom or the body cavity. Later the coelom is divided into the pericardial cavity, pleural cavity, and the peritoneal cavity as has been previously discussed. The somatic and splanchnic layers of the mesoderm form on their coelomic surfaces a single layer of squamous cells called the mesothelium. This is the covering layer of the pericardium, pleura, peritoneum, mesenteries, serous layer of the viscera, and lining of the tunica vaginalis in the scrotom. From this mesothelium, according to Prentiss, is derived also the epithelium of the genital glands and the ovarian ducts.

Great variations occur in the development of the peritoneum and the mesenteries within it. For example, the various hollow viscera may be normally placed and unattached, or they may be abnormally placed and attached to an abnormal mesentery. For example, the cecum may be attached to the mesentery of the small bowel; that is, the ileomesentery. Sometimes the mesentery is extremely short or long, permitting great variation in the mobility of an organ or of the hollow viscera. The greater omentum normally arises from the stomach and later overlies the transverse colon to which it becomes fused. Sometimes with incomplete rotation of the colon the stomach and colon are not connected with each other by the gastrocolic ligament and the greater omentum hangs only from the colon.

Again various membranes have been described, some of which are more or less common. These were formerly thought to be of importance in intestinal stasis, particularly in the lower ileum, known as Lane's band. A congenital band or membrane may be differentiated from one which forms as a result of inflammation. The con congenital band usually has its vascular supply in lunettes just as is found in the mesentery. The membrane or band of new formation will have parallel lines of vessels so that as the membrane stretches, these may lose their lumen and become obliterated, thereby permitting the membrane to be absorbed. This is not uniformly true. However, as a rule, it is very evident. There is also a congenital membrane often associated with incomplete rotation of the cecum. The cecum may come to lie across the third part of the duodenum and may obstruct the duodenum by its pressure, and the cecum is attached to the upper lateral abdominal wall by an abnormal band. This band of peritoneum is divided and the duodenal obstruction is released by permitting the cecmum to assume a position on the left side of the abdomen.

Other types of congenital anomalies of the peritoneum include internal herniae which have been discussed previously in the chapter; also persistent fetal structures, including persistence of the omphalomesenteric ducts or arteries, persistence of the

urachus, persistence of the umbilical vessels or the urachal vessels. The anomalies of blood vessels are important because of the possibilities of development of intestinal obstruction. In the young embryo the yolk sac is nourished by a network of blood vessels. These soon converge to form two omphalomesenteric arteries and two omphalomesenteric veins. The left omphalomesenteric artery disappears, but the right persists and accompanies the duct in the umbilical cord. This also disappears before birth, except on its mesenteric portion where it ultimately becomes the superior mesenteric artery. The two omphalomesenteric veins disappear before birth except the proximal end of one which becomes the portal vein. The umbilical vessels appear early in the embryo, first as endothelial spaces in the mesenchyma in the body stalk. There are two arteries and two veins which run from the placenta to the embryo to convey blood to and from the fetus. The two arteries persist until birth when they become the obliterated branches of the hypogastric arteries which are important in delineating the inner portion of Hesselbach triangle. One of the veins disappears very early, but the other functions until birth as the umbilical vein, which then becomes the ligamentum teres or the falciform ligament. The urachial artery is a small vessel which arises from the superior vesicle branch of the left hypogastric artery. It courses along the anterior aspect of the urachus and into the cord supplying the allantois. At birth this artery is obliterated and becomes a small fibrous cord in close proximity with the urachus. At operation this cord is frequently encountered.

The peritoneum in the male forms a closed sac (in the female there is a communication to the exterior through the Fallopian tubes). The peritoneum is a continuous layer of serous membrane which is, so to speak, indented by the hollow and solid viscera of the abdomen, to which it is closely attached (the visceral peritoneum). Where these indentations occur there are closely approximated folds which form the mesentery of the small intestine and of part of the colon. The unusually long fold turning back on itself and hanging from the stomach and transverse colon is the greater omentum, and, with these organs, the hepatogastric ligament, and the transverse mesocolon, bounds the lesser peritoneal space. Between the indented parts (the visceral peritoneum) and the free part (the parietal peritoneum) is the general peritoneal cavity. The lesser and general acs are connected through the gastroepiploic foramen (foramen of Winslow). Heavy folds on the peritoneum are also attached to solid organs, forming their ligaments.

Like other mesothelial tissues (pleura, pericardium, synovial membrane), the peritoneum is composed of a thin layer of fibrous tissue covered with endothelial cells (the tunica serosa). A layer of areolar tissue (the tela subserosa) connects the peritoneum with the underlying fascia or viscera. This latter layer varies in amount in different locations, being plentiful under the parietal portion and almost entirely absent on the visceral portion covering the bowel. Normally the membrane secretes only sufficient fluid to lubricate its surface. Except for this small amount of fluid, the sac is empty and its walls lie in contact with each other.

Subdivision of the Peritoneal Cavity

From the surgical point of view, the peritoneal cavity may be divided into four great subdivisions: (1) supracolic, (2) right infracolic, (3) left infracolic, (4) pelvic. All of these subdivisions communicate freely with one another behind the anterior abdominal wall as well as on each side along the paracolic gutters. These gutters are important for the ascent or descent of an exudate which readily makes its way from the upper part of the abdomen along the lumbar region into the iliac regions and thence into the pelvis. Pus from the pelvis or a perforated appendicitis or diverticulitis may ascend along these gutters, reaching the supracolic space.

The supracolic space (phrenocolic) is bounded below by the transverse colon and the transverse mesocolon, above by the diaphragm and laterally by the lateral abdominal wall, anteriorly by the anterior abdominal wall, and posteriorly by the posterior ab-

dominal wall. The supracolic compartment is divided into a right and left portion by the falciform ligament. Within this compartment lie the subphrenic spaces, right and left. These are potential spaces which lie between the liver and the diaphragm on each side of the falciform ligament of the liver. In liver abscess, gall bladder disease, perforation from peptic ulcer, appendicitis, and intestinal injury, collections of pus or exudate may accumulate here, forming a subphrenic or subdiaphragmatic abscess. Suppuration in the right half of the phrenocolic space is generally secondary to leakage from an ulcer of the first part of the duodenum or disease of the gall bladder or bile duct, while the left half of the space is more usually infected from perforation in the stomach.

"*If the general peritoneal cavity is compared to a bag, the bursa mentalis* (or lesser cavity) might be represented as a pocket lying behind the opening into it by a narrow orifice—the foramen epiploicum." (Cunningham.) The omental bursa may be looked upon as a pocket or a diverticulum of the supracolic division of the peritoneal cavity.

The lesser peritoneal space lies behind the stomach, which, with the gastrocolic ligament, forms its anterior boundary. On the right side, it is bounded by the hepatoduodenal ligament, which closes the space between the liver and duodenum. A small opening in this ligament, known as the gastroepiploic foramen (foramen of Winslow), connects the lesser with the greater peritoneal cavities. This *foramen* is important to the surgeon because by putting his finger in it he may palpate the common bile duct, which lies behind it, *with the hepatic artery and protal vein. Below*, the cavity is limited by the transverse colon, on the left by the spleen and lienorenal ligament, and behind by the posterior abdominal wall. Within this cavity is the pancreas. Should the gastroepiploic foramen become sealed by exudate when there is pancreatic disease or posterior gastric perforations, a large collection of fluid would (and frequently does) accumulate.

By adhesions of the transverse colon and the greater omentum to the anterior abdominal wall, this supracolic subdivision of the peritoneal cavity may become more or less completely cut off from the rest of the abdominal cavity, forming a localized, separate compartment. This possibility has been demonstrated by us in some experiments in the study of perforated peptic ulcer. We have shown that this supracolic compartment may be actually squeezed by increasing intra-abdominal pressure in lifting heavy weights. Some of our experiments were as follows: A barium meal was given and the subject was asked to pick up a heavy weight and the barium within the stomach was observed with the fluoroscope. The "magenblasse" or air bubble in the stomach was seen to flatten out as the subject lifted the heavy weight. This we interpreted as due to descent of the diaphragm by taking a deep breath, contraction of the anterior abdominal muscles, and pushing up of the transverse colon and mesocolon, thereby squeezing on the stomach. This shows the more or less isolated subdivision of the peritoneal cavity that the supracolic compartment makes. It is, however, by no means completely isolated from the general peritoneal cavity. In addition, it has connections with the thorax through the subphrenic lymph plexus which communicates by means of lymph vessels piercing the diaphragm with the subpleural plexus on its superior surface. Therefore, pus confined under tension, either in the right or left subphrenic space, is liable to give rise to empyema of infection within the pleural cavity.

A space should be drained of pus or exudate through its most dependent portion. The most dependent portion of the supracolic space is the hepatorenal pouch of Morison. The entrance to this pouch lies lateral to the gall bladder between the lower margin of the liver, which is its superior boundary, and the right flexure of the colon (hepatic flexure). The bottom of the pouch is formed by the reflection of the peritoneum from the superior part of the kidney into the fascia transversalis covering the origin of the aponeuroses of the transversus abdominus muscle below the tip of the twelfth rib. Drainage through a loin incision is the method of choice. However, the drainage tubes

may be brought out through an abdominal incision anteriorly. The lesser peritoneal cavity may be drained through the anterior wall by an incision, either through the gastrohepatic or the gastrocolic ligaments.

The right infracolic subdivision lies above and to the right of the mesentery of the small intestine. It is bounded above by the hepatic flexure and the middle two-thirds of the transverse colon and the corresponding parts of the transverse mesocolon. Laterally, it is limited by the cecum and the ascending colon. At its right inferior angle is the ileocecal junction and the appendix, and at its right upper angle is the inferior part of the duodenum, crossed by the superior mesenteric artery and vein. Leakage from a perforated peptic ulcer and exudates from inflamed organs within the space will gravitate to the right lower quadrant. From here, they may extend upward along the colon into the subphrenic region or downward into the pelvis minor. We have seen that perforated peptic ulcer frequently manifests itself by pain in the right inferior quadrant due to the gravitation of extruded intragastric fluid into this area.

The organs related to this subdivision are the parts of the large intestine which supply its boundary, some coils of small intestines, the inferior part of the right kidney and right ureter, and the inferior half of the descending and horizontal part of the inferior portions of the duodenum. To drain this region at this most dependent point, Penrose drains may be introduced into the right lower quadrant through a McBurney incision. If the pus should be retroperitoneal, an incision in the right loin is preferable, lateral to the ascending colon.

The left infracolic subdivision lies below and to the left of the mesentery of the small bowel, narrows as it passes upward, and reaches to a higher level than the infracolic region on the right side. Inferiorly, it is continuous at the superior aperature of the pelvis with the peritoneal cavity of the pelvis minor. Above, it is bounded by the left third of the transverse colon and transverse mesocolon and still most posteriorly by the pancreas, and laterally by the descending and ileac portions of the colon. At its right upper angle is the duodenojejunal flexure, lying immediately to the left of the vertebral column and in the angle between the vertebral column and the inferior surface of the pancreas. At its left upper angle is the left flexure (splenic flexure) of the colon, while at its left inferior angle is the junction of the ileac with the pelvic colon or the sigmoid colon. This portion of the abdominal cavity contains the majority of the coils of small intestine. In addition, it is related to the inferior third of the left kidney and the left ureter, the lower part of the abdominal aorta, vena cava, and inferior mesenteric and common ileac vessels. Drainage of this subdivision may be established through the left loin or through a tube introduced into the bottom of the pelvis; namely, the rectovesical pouch in the male and the rectovaginal (pouch of Douglas) in the female.

The pelvic space lies upon the pelvic diaphragm below and is bounded by the cecum on the right, the sigmoid colon on the left, and the lower border of the greater omentum above. The peritoneum goes deep into this space. In the female, it covers partially the bladder and uterus and aids the transversalis in the formation of ligaments. Between the uterus and bladder is the uterovesical space; behind the uterus, the pouch of Douglas; and in front of the bladder, the uncovered space of Retzius. These are important surgical landmarks. Pus and exudates gravitate into the pouch of Douglas (posterior cul de sac, Chapter 23) and are sometimes drained through the vagina. This is especially true in pelvic disease. The uterovesical space is important in uterine operations, and the space of Retzius allows the genitourinary surgeons to open the bladder outside the peritoneal cavity. The only communication between the peritoneal cavity and the outside is through the Fallopian tubes.

Thus we see that the general peritoneal space which is enclosed by the horseshoe shaped large intestine and protected in front by the greater omentum is divided diagonally insofar as surgical considerations are concerned by the mesentery of the small bowel.

Therefore, the peritoneum, though not open to the outside (except for the opening to the exterior through the Fallopian tubes), is seen to wind in and out about the intestines (visceral peritoneum) and continue on the anterior and posterior abdominal wall (parietal peritoneum), enclosing a potential space between the two layers. Its extent is said to be equal to that of the skin.

Hertzler estimates the average peritoneal surface in persons averaging 5 feet, 8 inches, in height and weighing 160 pounds as 3,268 square inches (21,986 square centimeters). The cutaneous surface in this group averaged 3,436 square inches (22,167 square centimeters). Its tensile strength and elasticity vary. However, if free from subperitoneal tissue, it will bear a weight of from 1 to 15 pounds.

The peritoneum covers the organs and lines the walls of the abdominal cavity with a few exceptions: the back of the stomach, the caudate lobe of the liver, the left suprarenal gland, the upper surface of the pancreas, and parts of the spleen, left kidney, and transverse colon—all of these, as well as the parietes behind the caudate lobe, are clothed by the bursa omentalis. Therefore, practically all abdominal organs are extraperitoneal. The surgeon will bear this in mind in abdominal operations and he will regard such procedures as transabdominal and transperitoneal, restoring both coverings (visceral and parietal) at the conclusion of the surgery.

Practically the only intra-abdominal organ is the free end of the Fallopian tube and the ovary. The latter is covered by germinal epithelium which is low cuboidal in the adult, and one can see the transition between the peritoneum or the mesothelium and this covering. To all intents and purposes, then, the surgeon should regard his intra-abdominal efforts as subperitoneal in the sense that when he completes his work insofar as possible, he should restore the peritoneal covering which was present before he repaired the organ or removed it. This process is known technically as peritonealization.

Functions of the Peritoneum

The functions of the peritoneum may be summarized under four heads.

Absorptive Powers.—These are due to the capillaries, lymphatics, and macrophages, or tissue-wandering cells. The capillaries of the portal system are more permeable to protein molecules than other capillaries. They may lose these colloids very easily (in ascites) and probably do so normally to a certain extent. The lymphatics are therefore kept busy absorbing this material and returning it to the blood stream by way of the right lymphatic and thoracic ducts. Absorption of colloids (by the lymphatics) and crystalloids (by the capillaries) is rapid and complete. Whole blood and particulate matter are taken up not only by the lymphatics but by the macrophages cells as well. The greater omentum is particularly adept at this, and because of its mobility, it moves or is pulled over to various points of combat, where its capillaries, lymphatics, and cells may absorb great quantities of fluid and semifluid material. Therefore, in spite of the fact that the peritoneum is a closed space, its blood vessels and lymphatics, which extend up through the diaphragm into the mediastinal nodes, provide ample communication with the chest and body as a whole.

Blood clot must be phagocytosed and then the macrophages are carried through the lymphatics to the blood stream. Also a certain amount of decomposition takes place, and the rate of absorption will depend on the extent of reaction produced and the size of the clot. If the clot becomes secondarily infected, as it usually does, the inflammation will, of course, cause an increased absorption, but later this will be slowed down, as is true in inflammation elsewhere. Exudates are absorbed very slowly. This is a defense mechanism and applies to the peritoneal cavity, the pleural cavity, and the tissues in general; that is, the exudate will be absorbed slowly because of the occlusion of the capillaries and lymphatics by thrombi.

Various measures have been suggested to influence absorption. For example, the old Fowler position which consisted of elevating the head of the bed was

thought to delimit absorption. This was based on the idea that absorption was slower in the lower abdomen than in the upper. Recent experiments and clinical observations seem to prove that absorption takes place equally in all parts of the abdomen. It is true, however, that external pressure may play a role. When the abdomen is distended by dilated loops of bowel, as in an acute peritonitis, for example, absorption may be slower, whereas in the less distended abdomen, with much exudate, absorption may be increased.

A frequent observation is that in the intestinal distended abdomens with acute peritonitis, very rapid deflation of the bowel sometimes is accompanied by an increased amount of absorption and an increase in fever and leucocytosis. In a perforated ulcer with gas up under the diaphragm, the exudate may be carried by the free air into this area, and in this way absorption may be earlier simply because the pelvis is farther removed and the flow is upward. The same may be said for pelvic inflammation. It is probably true that the lower abdomen takes care of infection better. However, it is believed by many observers that this is due to the fact that the distance traversed by the infecting agent will be greater in the lower than in the upper abdomen.

The idea of introducing large quantities of saline into the peritoneal cavity and thereby converting the peritoneum into a secreting area rather than an absorptive area in the treatment of peritonitis has been largely disproved. Although it is true that if large quantities of fluid are given intravenously the hydrostatic pressure will be increased and the osmotic pressure decreased, fluid will find its way into the peritoneal and into the pleural or pericardial cavities as well. The Fowler position also is not to be desired because of the danger of thrombophlebitis and phlebothrombosis which may result from the angulation of the ileofemoral veins. Since there already is a stasis due to immobility, the predisposition toward thrombosis is increased by this position. In peritonitis there is also hemoconcentration due to the loss of large quantities of plasms into the peritoneum (Chapter 14). The Fowler position does not in any way influence absorption from the peritoneum, nor does gravity cause exudates to accumulate in the pelvis. This famed position predisposes to thrombosis and possible embolism and, in addition, it makes the patient extremely uncomfortable so that he cannot turn freely or breathe easily. It is therefore better to let the patient lie in bed and turn from side to side, moving his arms and legs. By introducing large quantities of saline intravenously, the peritoneum may be converted into a more or less leaky mesothelial lake, but it must be borne in mind that all tissues will become edematous, including the bowel wall and bowel distention.

It is a well-known fact that the peritoneum is an excellent dialyzing membrane which is permeable to solutes and crystalloids. The transudation of solutes into the peritoneal fluid is probably one of the mechanisms used by the body in an attempt to excrete certain toxic substances. This physiological function of the peritoneum may be used in the treatment of disease. Peritoneal irrigation makes possible the use of its dialyzing capacity for the removal of diffusible substances from the plasma and ultimately from the extracellular fluid. The irrigating fluid will not cause a depletion of plasma constituents below normal levels if a proper adjustment of the concentration is maintained. In an effort to accomplish this extrarenal pathway or excretory function, a modified Tyrodes solution was used. This contains sodium chloride, 8 Gm., potassium chloride, .1 Gm., magnesium chloride, .1 Gm., sodium acid phosphate, .05 Gm., sodium bicarbonate, 1 Gm., and dextrose, 1½ Gm. It was prepared in large volumes by Fine and co workers. Incisions were made in the upper and lower abdomen for the purpose of irrigating the peritoneal cavity. The chief danger of this method is the injury to the peritoneum; also the fact that any foreign body within the peritoneal cavity is soon walled in by adhesions. To overcome this, heparin has been used to prevent formation of fibrin, and penicillin is used in prophylaxis against infection. Sodium sulfadiazine should not be used because of the danger of further renal injury. In this way large quantities of fluid may be used to irrigate the peritoneal cavity. We have had one case of total anuria in a woman who was Rh negative and gave birth to

an Rh-positive fetus with erythroblastosis. This woman was in profound coma and had a complete anuria. The peritoneal irrigation, we thought, had something to do with her ultimate recovery. However, in her case the use of plasma intravenously seemed to help draw fluid from the tissues which were edematous and permitted large quantities of the fluid to find their way through the peritoneum to the outside. Ultimately the kidneys began to function again.

In inflammations of the peritoneum not only are crystalloids and colloids lost, but, in addition, large numbers of leucocytes. We have frequently called attention to the fact that in the face of an extensive peritonitis, the blood leucocyte count may be low. This is undoubtedly due to the large volume of leucocytes that are lost from the circulating blood into the peritoneal cavity. It is surprising that after removing the focus and draining or merely draining, localization is facilitated and the blood count goes up. It has been observed further that after the cause of the peritonitis has been removed, such as a perforated appendicitis, the blood count will rise as the peritonitis subsides. This is almost conclusive evidence that the cause of the leucopenia was the large number of circulating white cells which were lost in the peritoneal cavity. One last statement should be made concerning the so-called secretory or excretory function of the peritoneum. The older surgeons thought that by putting multiple drains in the abdomen and giving large quantities of fluid intravenously, they could convert the peritoneum from an absorbing membrane to a secretory membrane. They also thought that by using the Fowler position and putting most of the drains in the lower abdomen that they could actually reverse the flow. All of this has been fairly well disproved. We have just noted how difficult it is to use the peritoneal cavity as an irrigating membrane when large volumes of solution are forced through. It is even more difficult for nature to accomplish this when multiple drains are inserted. In fact, these drains are soon walled in by a fibrinous exudate so that they drain only a small area immediately surrounding them. With this in mind, the modern trend has been to reverse the old doctrine, "When in doubt, drain" to "when in doubt, do not drain."

Drainage is employed for definite walled-in abscesses or collections or exudate rather than for prophylaxis or with the idea of draining the peritoneal cavity. This concept rests upon the fact that in addition to the almost useless function of a drain, it is a foreign body which will encourage dense adhesions. There are some exceptions to this statement: As a preventive measure in cases where the base of the appendix and cecum are necrotic, a cecostomy and, in addition, soft Penrose drains are used; in perforated appendicitis, the pelvis and right colic gutter are drained to permit exit of exudates; following gall bladder surgery where there is danger of leakage and bile peritonitis, drains are used, although even here some surgeons are now abandoning this type of drainage. Preventive drainage is used only for short periods (twenty four, forty-eight hours). Drainage of a definite abscess follows the rules of absces elsewhere.

Reparative Powers.—We have seen in Chapter 3 how quickly and completely the peritoneum heals. Within one-half hour the suture line is impermeable to fluid and gas, unless these are under pressure. Although the peritoneum is one cell layer thick, it quickly repairs defects due to trauma or disease. Repair here is exactly like repair elsewhere. Fibrous tissue is covered by mesothelium and, if healing is by first intention, a minimal scar is formed. In the presence of severe trauma or infection, repair is by second intention; that is, there is much more scar tissue and often there are dangerous or vicious adhesions or bands. Its modus operandi is by adhesions. These may form between loops of bowel or between the bowel and the parietal peritoneum, or between the bowel and solid organs. These adhesions "splint" the part, or put it at rest, prevent leakage, and allow for complete healing. Then having finished their task, they stretch into bands or sheets, lose their blood supply ultimately, because of this stretching, and are absorbed. This is the reason surgeons will not cut adhesions that are less than three years old, unles they are

dense or in such positions that obstruction results. New adhesions have straight, parallel vessels; congenital bands have networks of capillaries. The greater omentum always takes part in this repair, "splinting" the part, reinforcing the freshly made collangenous tissue, localizing the site of surgery, or injury, or disease, until it is well. Indeed, the greater omentum is the "policeman of the abdomen" and the "surgeon's friend." For this reason the surgeon uses it to cover over the field of operation. It may be seen then, that, contrary to popular opinion, adhesions are indispensable to repair. However, should there be much trauma to tissue, or extensive infection in the peritoneal cavity, these adhesions, like deep injuries to the skin, will be dense and vicious, leading to interference with intestinal function and often obstruction.

The normal covering of the abdominal organs is peritoneum. When a raw surface has been made, it should be covered, just as in the skin, to avoid dense scars. Lacking peritoneum, we may use the omentum as a pedicle or free graft. If this is not available, tabs of mesenteric fat, appendices epiploicae, the broad ligaments, or other available mesothelial-covered structures are used.

Powers of Resistance (Immunity).—The peritoneum, like the pleura, is a mesothelial membrane one cell layer thick, yet its powers of resistance are great (see Chapter 19). This is possible because of local immunity in terms of cells, and although we have no proof for the statement, we are coming to believe that all of these cells may under stress become or give rise to macrophage cells. In experimental animals, pure cultures of bacteria, when introduced into the peritoneal cavity, fail to cause peritonitis. Should the bacteria be implanted in bits of agar or pieces of liver tissue, or should the peritoneum be ruthlessly traumatized, peritonitis results. This explains the surgeon's ability to perform bowel operations without infection in the absence of gross contamination.

It was formerly thought that different portions of the peritoneal cavity manifest a difference in their defense reactions. This gave rise to postures in the treatment of the disease, varying from the Trendelenburg position to favor the reabsorption of the products of the peritoneal effusion and hemorrhage to Fowler's position to hold back the absorpiton of such products. Today we no longer believe in these theories. In fact, the peritoneum manifests the same degree of resistance in all parts of the abdomen. Formerly it was thought that the pelvis had a very high degree of resistance as compared with the upper abdomen. This is due to the fact that the pelvis is frequently the seat of gonococcal infections which have a tendency to become localized. It was noted at the same time that should the pelvic viscera be infected with the streptococcus, the same degree of virulence occurred as was present in any portion of the abdomen. Also, it was formerly thought that infections in the upper portion of the abdomen were particularly virulent because the diaphragmatic peritoneum allowed for almost a spongelike absorption. It is probably more in accordance with the facts that deaths following biliary operations are due to traumatic injury of the liver rather than to any special condition of defense or increase in absorption from the diaphragmatic peritoneum. Also, failures of esophageal surgery and stomach surgery were thought to be due to the lowered resistance of the upper abdomen. There is no basis of proof for this. It is more nearly correct to assume that failures occurred because of leakage or occlusion of the neostomies or because intestinal loop herniations with intestinal obstruction, or just as they do in modern surgery if careful techniques are not employed.

The concept of many of the observers today is that the peritoneum possesses an extraordinary capacity for defense throughout all sections of the abdominal cavity and, here, as elsewhere in the body, it is the particular immunity of the individual locally and generally and the virulence of the invading organism, together with the particular intensity and speed of aggression, which determine the gravity of the process within the abdominal cavity rather than any special capacity for the various portions of the peritoneum to withstand the infection.

The Fowler position formerly was thought to have at least one redeeming feature; namely, that of keeping the patient in a semisitting position, as at least exudates would gravitate down into the pouch of Douglas or the pelvis minor. Even this seems to be more or less hypothetical because it *is a well-known fact that the routes that* exudate will follow are the anatomical planes which have been explained previously in this chapter.

Recent experimental work has shown that the peritoneum does not respond in portions. It is customary to speak of localized peritonitis, a spreading peritonitis, a diffuse peritonitis, and a general peritonitis. These are terms which describe gross reactions rather than pathological entities. The entire peritoneum probably responds as a whole. It is true that the focus may show the greatest degree of reaction. However, the entire peritoneal cavity immediately begins to pour forth large quantities of peritoneal transudate and exudate to help the particular area which is involved. Later, it is perhaps correct to use the term localized peritonitis which abscess is formed. In this way the peritoneal cavity behaves very much like a cellulitis caused by the streptococcus or the staphylococcus prior to localization. The peritoneal cavity is able to cope with ordinary infections unless it is severely traumatized. Its methods of defense depend on local factors in addition to those found elsewhere in the body, as mentioned in Chapters 4 and 5.

Sensory and Motor Nerve Power.—Generally speaking, the parietal peritoneum is supplied with sensory nerves through the intercostal nerves. (See Chapter 18.) Thus, the pelvis is supplied by the twelfth intercostal and first lumbar nerves, and sensory impulses enter the cord at the twelfth thoracic and first lumbar spinal segments. Therefore, pain from the parietal peritoneum is accurately located (although it is referred to the spinal segment involved and hence may be confusing). The visceral peritoneum is only sparsely supplied with sensory nerves, and these apparently run with the sympathetic (splanchnic) nerves. Therefore, pain in the intestines is more general and less accurately located, occurring when tension or crushing force is applied over wide areas. Trimming a colostomy or crushing a spur does not cause pain. Furthermore, the mesentery probably contains most of the nerve supply. This explains why the surgeon must not pull on the mesentery while doing abdominal operations under local anesthesia. However, the greater omentum seems devoid of nerves, yet if pulled on or separated from inflamed viscera, pain results. Violent peristaltic waves produce general, cramplike pains. The early pain in appendicitis may be referred to the epigastrium, through the twelfth spinal segment. Should the parietal peritoneum become involved, pain would be present in the diseased zone. The physician must bear these facts in mind when making a diagnosis of intra-abdominal disease. In addition, there are motor nerves to the peritoneum—not to the membrane itself, but to the protecting muscles over it. Thus, in appendicitis there are pain, tenderness (which is always a more accurate diagnostic sign), and involuntary muscle spasm or rigidity. *By these symptoms* and signs the physician may usually diagnose the site of the lesion, and if the organ is normally situated, locating the site means diagnosing the organ involved.

From the foregoing discussion it would seem that the supply of sensory fibers to the viscera is very small in comparison with other parts of the body. Only about one-fourth of the fibers of the splanchnic nerves are sensory. The pelvic (nervi erigentes) and vagus nerves whose function is more closely related to somatic parts and cerebrospinal innervation, are composed of about one-third sensory fibers. The cell bodies of the sensory visceral nerves are located in the dorsal root ganglia and ganglia of the *cranial nerves.*

Visceral pain is experienced when the nerve endings in the musculature of submucosa of the hollow viscera are stimulated by stretch or pressure. Sudden distention and marked contraction constitute adequate stimuli. These stimuli produce some degree of anoxemia which sensitizes the visceral pain nerve endings. The same is true of inflammation. Pain from the viscera is not well localized and is usually referred to the

surface of the body, innervated by the cerebrospinal nerves originating in those segments of the cord which innervate the viscera. Therefore, in interpreting referred pain, it is important that we know the course of the nerve supply of the viscus and its embryological history as well. An example of this is cited by Ivy who states that pain experienced on irrigation of the right central diaphragmatic pleura is referred to the right somatic area innervated by the third and fourth cervical segments which would be the upper shoulder. However, irritation of the right lateral diaphragmatic pleura may cause pain to be referred to the tenth and eleventh thoracic segments or the appendiceal region. This wide difference is related to the embryological development of the diaphragm which receives a contribution from the third cervical to the twelfth thoracic segment. According to Ivy, the types of pain observed in viseral disease may be grouped under five heads:

1. True visceral pain due to irritation or stimulation of true sensory pain nerve endings in the viscera which is accurately localized by the patient. With training, one can learn to localize with an accuracy of one or two inches the points stimulated in the esophagus, stomach, or duodenum and the jejunum. This phenomenon is related to the experienced learning or conditioning which enables one to localize or project a prick of the finger or the back of the hand to those areas even when the subject is blindfolded. Because of the small number of sensory nerves to the viscera, some individuals will be slightly devoid of visceral sensitivity. These are the persons who will have a silent peptic ulcer and a silent cholecystitis and so forth. Ivy believes that true visceral pain pathways are present in the spinal cord that send impulses to the cerebral cortex for perception. Other observers do not believe that such paths exist. According to the other theory, visceral pain is due to a spread of visceral impulses to the primary or secondary somatic pain neurons in the dorsal root ganglion on the dorsal gray horn, or to viscerosomatic (visceroskeletal) reflexes which cause muscle rigidity or spasm or reflex vasomotor or metabolic changes which in turn stimulate somatic pain nerve endings in somatic tissues. Stated in a different way, these two theories imply that (a) the visceral impulses will find their way through somatic pain neurons in the dorsal root ganglion or the dorsal gray horn or (b) by causing a reflex motor activity in muscle, causing spasm or causing reflex vasoconstriction, pain is referred to the site where such reflex activity occurs. The Lange-Ross theory holds that the impulses go to the dorsal root ganglia cells, and on reaching the gray matter of the dorsal horn, the impulses pass to the secondary neuron of the somatic pain nerves of these segments. This results in the cerebrum interpreting the pain as coming from the segment innervated by the primary somatic pain nerves. MacKenzie holds that true visceral pain does not exist and that the disease process in the viscera gives rise to the increased stimulation of the nerves passing from the viscera to the spinal cord. This increased stimulation affects neighboring centers and so stimulates sensory, motor, and other nerves that issue from this part of the cord. He refers to the stimulation as a viscerosensory reflex, although this is not really a reflex. The expression visceromotor reflex which is used to explain muscle rigidity is a good physiological expression. It is very probable that a true visceral pain pathway exists which makes connection with the cerebral cortex. It is also possible for visceral pain impulses reflexly to cause changes in the somatic tissue which in turn stimulate somatic pain nerve endings.

2. Referred pain in which the pain is not localized in the diseased viscera but in the somatic part deeper than the superficial surface of the skin, the somatic part to which the pain is referred being related phylogenetically to the innervation of the viscera. Head taught that sensations arising from an area of low sensibility are interpreted by the cerebrum as coming from an area of higher sensibility. As an example, if a patient with tabes is pricked in a cutaneous area of low sensibility, he reports that it comes from an adjacent area of higher sensibility which may be located at some distance from the site which is stimulated. According to the theory of the existence of true visceral pain, stimulation of the central portion of the diaphragm

The Fowler position formerly was thought to have at least one redeeming feature; namely, that of keeping the patient in a semisitting position, as at least exudates would gravitate down into the pouch of Douglas or the pelvis minor. Even this seems to be more or less hypothetical because it is a well-known fact that the routes that exudate will follow are the anatomical planes which have been explained previously in this chapter.

Recent experimental work has shown that the peritoneum does not respond in portions. It is customary to speak of localized peritonitis, a spreading peritonitis, a diffuse peritonitis, and a general peritonitis. These are terms which describe gross reactions rather than pathological entities. The entire peritoneum probably responds as a whole. It is true that the focus may show the greatest degree of reaction. However, the entire peritoneal cavity immediately begins to pour forth large quantities of peritoneal transudate and exudate to help the particular area which is involved. Later, it is perhaps correct to use the term localized peritonitis which abscess is formed. In this way the peritoneal cavity behaves very much like a cellulitis caused by the streptococcus or the staphylococcus prior to localization. The peritoneal cavity is able to cope with ordinary infections unless it is severely traumatized. Its methods of defense depend on local factors in addition to those found elsewhere in the body, as mentioned in Chapters 4 and 5.

Sensory and Motor Nerve Power.—Generally speaking, the parietal peritoneum is supplied with sensory nerves through the intercostal nerves. (See Chapter 18.) Thus, the pelvis is supplied by the twelfth intercostal and first lumbar nerves, and sensory impulses enter the cord at the twelfth thoracic and first lumbar spinal segments. Therefore, pain from the parietal peritoneum is accurately located (although it is referred to the spinal segment involved and hence may be confusing). The visceral peritoneum is only sparsely supplied with sensory nerves, and these apparently run with the sympathetic (splanchnic) nerves. Therefore, pain in the intestines is more general and less accurately located, occurring when tension or crushing force is applied over wide areas. Trimming a colostomy or crushing a spur does not cause pain. Furthermore, the mesentery probably contains most of the nerve supply. This explains why the surgeon must not pull on the mesentery while doing abdominal operations under local anesthesia. However, the greater omentum seems devoid of nerves, yet if pulled on or separated from inflamed viscera, pain results. Violent peristaltic waves produce general, cramplike pains. The early pain in appendicitis may be referred to the epigastrium, through the twelfth spinal segment. Should the parietal peritoneum become involved, pain would be present in the diseased zone. The physician must bear these facts in mind when making a diagnosis of intra-abdominal disease. In addition, there are motor nerves to the peritoneum—not to the membrane itself, but to the protecting muscles over it. Thus, in appendicitis there are pain, tenderness (which is always a more accurate diagnostic sign), and involuntary muscle spasm or rigidity. By these symptoms and signs the physician may usually diagnose the site of the lesion, and if the organ is normally situated, locating the site means diagnosing the organ involved.

From the foregoing discussion it would seem that the supply of sensory fibers to the viscera is very small in comparison with other parts of the body. Only about one-fourth of the fibers of the splanchnic nerves are sensory. The pelvic (nervi erigentes) and vagus nerves whose function is more closely related to somatic parts and cerebrospinal innervation, are composed of about one third sensory fibers. The cell bodies of the sensory visceral nerves are located in the dorsal root ganglia and ganglia of the cranial nerves.

Visceral pain is experienced when the nerve endings in the musculature of submucosa of the hollow viscera are stimulated by stretch or pressure. Sudden distention and marked contraction constitute adequate stimuli. These stimuli produce some degree of anoxemia which sensitizes the visceral pain nerve endings. The same is true of inflammation. Pain from the viscera is not well localized and is usually referred to the

that holds the intestine in position by its attachment to the posterior wall of the abdomen. For the small intestine, its root runs roughly from the upper left hypochondrium to the lower right pelvic area and then spreads like a fan to serve approximately twenty-five feet of intestine. It carries the blood supply, nerve supply, and lymph ducts (lacteals). Should it be severely injured, or divided, the corresponding loop of bowel would die, for the vessels are terminal ones, with few anastomoses. The mesentery of the large bowel is known as the mesocolon, the mesosigmoid, etc. *Ligaments* are strong *folds of peritoneum holding solid organs in* position. Examples are the broad ligaments of the uterus, the lienorenal ligament, etc.

Inflammations of the Peritoneum

Should the peritoneum become inflamed, a grave condition ensues. The general term peritonitis is used to denote any inflammation of the peritoneum whether it be local, from which recovery is the rule, spreading, which carries a higher mortality, or general, which is invariably fatal. Furthermore, it is necessary to know whether its origin is bacterial or chemical, and if the former, what the causative agent is, because *different types require different treatment and presage different prognoses.* Individual bacterial types are often impossible to diagnose until an operation is performed and the cause and type are clearly seen or discovered by smear or culture. Even the chemical variety has various causes which are treated differently and also give rise to diagnostic problems. Of the bacterial types, pyogenic bacteria (*Bacillus coli communis,* staphylococci, and streptococci in combinatoin) are the most common offenders, giving rise to pyogenic peritonitis. However, other organisms, particularly the anaerobes, are frequently found. Rarely, actinomycosis is the cause. This usually originates from an intra-abdominal suppurative lesion such as perforative appendicitis or perforative diverticulitis but may occur after traumatic rupture of the bowel, gangrene with perforation, following mechanical obstruction, and even postoperatively (after intestinal surgery) from infection introduced from the outside or excessive handling of devitalized bowel.

The inflamed peritoneum is soon covered with a fibrinopurulent exudate, which in turn is bathed in pus. The loops of bowel are distended, for the exudate limits preistalsis. The greater omentum attempts to act as a pyogenic membrane, and with the matted loops of bowel it usually succeeds in producing a localized peritonitis, with or without abscess. This is frequently seen in perforative appendicitis. Should the infection spread beyond the immediate environs of the appendix (spreading peritonitis), the omentum with new loops of matted intestine may limit it or may fail to do so, with resultant general peritonitis. Then the visceral and parietal peritoneum is red, covered with a fibrinous exudate, loops of distended bowel lie motionless and adherent to each other, the omentum lies unattached, and pools of pus are found in the various dependent portions of the abdomen and between intestinal loops.

General Effects of Secondary Peritonitis.—The surface area of the peritoneum is about equal that of the skin surface. Therefore, a truly

which embryologically originates from the third, fourth, and fifth cervical segments causes impulses of pain which pass up to the portion of the cerebrum which receives pain impulses from the somatic tissues innervated by the third, fourth, and fifth cervical somatic sensory nerves. So the cerebrum interprets on the basis of Head's law, the pain as originating in the shoulder area. The same is true in the lateral diaphragmatic pleura; the impulses pass into the tenth and eleventh thoracic segments. Since the nerves from these segments innervate the somatic areas around the appendiceal region, the cerebrum interprets the pain as coming from the right lower quadrant of the abdomen.

3. Habit reference of pain in which the pain from a newly located focus is referred to an area sensitized by previous disease or injury. For example, the patient has had gall bladder disease or injury and then develops appendicitis. The pain in the early course of the appendicitis is referred to the gall bladder area. This phenomenon is particularly important in cardiac diseases as simulated abdominal disease or the reverse. If a patient has had previous attacks of epigastric pain due to ulcer and then suddenly develops a severe pain, one thinks of not only ulcer but cardiac disease referred to the ulcer area because the patient has had previous experience with ulcer pain. Indeed, some cardiologists state that most acute coronary disease is thought by the person to be merely acute indigestion because he has had experience with the latter.

4. Secondary visceral or referred pain in which the disease of one viscus causes reflex functional disturbance in another which in turn gives rise to pain in an area not primarily diseased. For example, disease of the appendix causes pylorospasm and the pylorospasm causes pain in the epigastrium. Another example of this is the type of pain experienced in kidney colic which at first causes a reflex ileus. Pain is referred to the distention of the intestines rather than to the particular site of the obstruction to the urinary tract. Later the pain is actually localized at the site of the obstruction.

5. Associated somatic pain. This, according to Harvey, is pain in which the disease of the viscus spreads to involve adjacent somatic nerves or to involve the parietal serous surfaces; that is, the parietal pleura or peritoneum which are innervated by somatic pain nerves. This is seen in cases of appendicitis in which the viscus is inflamed; later the overlying peritoneum becomes inflamed, causing neighboring nerves to become involved. Pain is projected along the course of those nerves.

In summary, it might be well to point out that visceral pain is not accurately located by the patient, yet it is one of the most important guides to disease processes. Therefore, the physician in making a diagnosis must remember that the pain may be referred—that it may be a habit reference or a secondary visceral pain or an associated somatic pain. With these in mind he will more nearly arrive at the correct interpretation of the pain. Many examples of this could be cited. However, in the various portions of this chapter the phenomenon of both types of pain will be recorded in connection with the subjects discussed.

The greater omentum is a double layer of peritoneum hanging in apron fashion from the greater curvature of the stomach. As indicated, its importance cannot be overemphasized. In infants it is extremely thin, devoid of fat, and filled with tiny blood vessels. In the adult it becomes filled with fat and is much thicker. Its functions are the functions of the peritoneum greatly amplified, and its movability makes these functions available to all parts of the abdomen. Hertzler studied the migration of the omentum through windows and by x-ray after fastening small shot into it. He believes that the fibrinous exudate at the site of inflammation and the hyperemia of the peritoneum about this area are accompanied by a similar response in the omentum. Thus the omentum becomes a movable tissue filled with leucocytes which are drawn to the field of battle as are other leucocytes, perhaps by chemotaxis. In extremely virulent infections there are few leucocytes in the omentum and no migration occurs. The mesentery is the double layer of peritoneum

polymorphonuclears. This is also very variable, particularly in children. However, even in adults a large proportion of the circulating leucocytes may be within the peritoneal cavity, giving a very low white count. In general, the patient will be ill at ease and worried about his condition. His flexed knees, short breath, distended abdomen, anxious and pinched expression have given rise to the famous "hippocratic facies." The symptoms and signs are due to the underlying pathological conditions (namely, that of a widespread infection together with that of an intestinal obstruction) and therefore they vary with the preponderance of the various components and their effects.

The treatment is based upon ample experimental and clinical experience. Obviously most important is prevention, if possible. This can be done by prompt attention to the cause: appendicitis, gall bladder, perforated ulcer, etc. In case of local, spreading, or even general peritonitis, if the patient's general condition permits, the focus is removed if possible and adequate drainage instituted (although the Penrose or other drains are soon walled in as are other foreign bodies). Much has been written recently on the delayed treatment of spreading peritonitis secondary to perforative appendicitis. Those who favor it invoke the dictum previously quoted in this book: "Wait for localization." Those who oppose it are guided by the rule also given in these pages: "If an acute focus can be removed, spreading of the infection may be avoided and septicemia averted." No hard and fast rule can be given here. Each patient must be individualized. However, there is a happy medium between the extremes, since no operation has merit enough to be used on a patient who cannot stand it. Therefore, the desirable method of procedure is adequate preparation and gentle nontraumatic surgery following this preparation (whether the preparation takes one hour or a week). Lengthy traumatizing procedures must be avoided; they simply add to the shock, as would an extensive scrubbing in a severe burn. In all cases, adequate attention should be given to the fluid balance and blood transfusion used if necessary. This is done before any surgical intervention is attempted. Morphine is given at four-hour intervals until the respirations reach 12 per minute, and no food is taken by mouth, so that the intestines are at rest completely. In addition, the use of the Levine duodenal tube aids greatly in dealing with the ileus. This tube is attached to a suction apparatus (Wangensteen) so that the distended intestines may be decompressed. With this in place, frequent sips of water are given to moisten the throat and test the patency of the tube. Sometimes irrigation of the tube with warm salt solution is necessary. Heat to the abdomen may be helpful as a part of the complex treatment of this disease.

Occasionally, the surgeon will elect to decompress the bowel by direct opening (enterostomy; Witzel's operation; or appendicostomy) under local anesthesia. This is useful where there is, in addition to the

general peritonitis would be comparable to a 100 per cent burn and would be invariably fatal. Fortunately, the extensiveness of peritonitis is not apt to reach this proportion. However, since the peritoneum responds as a unit to infection, should the inflammation involve large areas or persist, the general effects would be similar to an extensive burn.

The large area of inflammation may result in (1) the loss of copious amounts of blood plasma, water, and electrolytes, (2) hemoconcentration, hypoproteinemia, hypochloremia, and reduction of circulating blood volume, (3) stagnant anoxemia as a result of (2), (4) paralytic ileus due to the exudate on the peritoneum and swelling of the bowel wall as in inflammation elsewhere, (5) anoxic anoxemia from the distention because the diaphragm cannot descend and the lungs cannot function properly, (6) anuria due to the preceding changes, (7) pulmonary edema, (8) toxemia, bacteremia, and hemoconcentration which cause the destruction of large numbers of erythrocytes, resulting in persistent anemia which is not detected by hematocrit readings because the circulating blood volume is greatly reduced with a relatively increased amount of plasma lost, giving the picture of hemoconcentration. Secondary effects include azotemia and edema as a result of anuria and alkalosis if vomiting persists.

The general effects vary with the suddenness of the inflammation and the area involved. Thus, a large perforation of the stomach or duodenum from ulcer or the cecum at the base of the appendix from appendicitis or any part of the alimentary canal due to penetrating or perforating wounds may flood the peritoneal cavity, inducing an extensive rapid inflammation, causing profound shock. The insult may be due to chemical mechanical, or bacterial causes with the same effect. If the inflammatory changes are evolved slowly, as in tuberculous peritonitis, general effects are barely perceptible. In between these extremes are the more common varieties of peritonitis which cause milder, but none the less apparent, changes. The symptoms and signs depend upon the extent and therefore vary from pain, tenderness, and rigidity, with slight or no systemic symptoms, to generalized abdominal pain and euphoria just before death. The patient vomits stercoraceous material continually, there is no passage of flatus or feces, and the abdomen is distended and absolutely silent on auscultation. Soon there is marked dehydration, as a result of paralytic ileus.

Symptoms and Signs of Peritonitis.—The fever is high, ranging up to 103° F. and above in adults and up to 105° F. in children. There are great variations in the degree of fever, sometimes ranging up to 106° F., and where there is an overwhelming infection, the temperature may be subnormal. This is particularly true in cases of large perforations of the bowel due to gangrene or due to a large perforated ulcer or in septic abortions. In such cases the temperature may be subnormal and all the symptoms and signs of shock may be present. The leucocyte count is usually high, being about 20 to 25 thousand, with 80 to 90 per cent

albumin-globulin ratio. The serum globulin may be high and the serum albumin low, and yet the total serum protein may be normal or even above normal. However, if the volume of total protein is low, the indications are clear. In addition, blood chlorides may be run whenever indicated. It is our custom to alternate between distilled water with glucose and physiological saline with glucose so that we may avoid hypernatremia. Also the use of multiple vitamins within the fluid at least once a day has, in our opinion, helped to care for the vitamin requirements. It is not our custom to place a cannula in a vein and leave it there except in newborn babies and very small infants, and even here we have found that it is advantageous to use a very fine needle and introduce this needle within the ankle or scalp vein. In all adults, it is our custom to rotate, using a different vein of small caliber to avoid thrombosis of a larger vein. We do not use hypertonic solutions as explained in Chapter 11, and arm veins are preferred so that phlebothrombosis may be avoided in the legs.

Peritonitis is a treacherous disease and even though early complications may be successfully met by the treatment outlined, later complications frequently require secondary operations. Among these may be mentioned late types of obstructions where exploration may be indicated. Although the early types of obstructions may be successfully handled by the Miller-Abbott tube with suction or Witzel enterostomy, a late obstruction may be due to an organized band which may require open operation with exploration of the abdomen.

Pelvic abscess is suspected when the fever becomes intermittent or remittent with chills, and then after the peritonitis has subsided, a persistent diarrhea. This is due to irritation of the sigmoid or rectum by the abscess. Careful rectal or vaginal examination should be done routinely when the progress is not satisfactory. Such an abscess may have to be drained from above or through the cul-de-sac or rectum.

Subphrenic abscess manifests itself also by the symptoms and signs of pus under pressure. In addition, there will be a descent of the liver with an elevation of the diaphragm and an increase in the liver dullness. Fluoroscopic examinations aid greatly in the diagnosis by indicating elevation and fixation of the diaphragm. The treatment is that of abscess elsewhere; namely, wait until localization has occurred and then institute adequate drainage. This is done by resecting a small section of the tenth rib. The pleura is pushed up and the diaphragm is stitched to the chest wall, if not adherent, and drainage is instituted. When the abscess is very large, this may be accomplished through the subcostal region. If the pleura is not adherent, the two layers of the pleura may be sutured together at the costophrenic angle, and after the two layers of pleura have become adherent, drainage may be instituted, thereby avoiding contamination of the pleural cavity.

Idiopathic peritonitis, or primary peritonitis, is caused as a rule by the streptococcus or pneumococcus.

peritonitis, a closed loop of bowel or an obstruction low in the ileum or colon, although these can usually be decompressed by the Miller-Abbott tube.

Congestion at the base of the lungs, with pulmonary edema or complicating patchy pneumonia, is not uncommon in peritonitis. This is due to the bowel distention and sometimes an involvement of the undersurface of the diaphragm. Either cause limits the movements of the diaphragm and increases venous stasis within it, further limiting its motion. In addition, there is stasis in the pulmonary veins. Due to the low plasma content of the blood, the increase in venous pressure, and increase in the negative pressure within the thorax due to dyspnea, fluid exudes into the alveoli. Exudation is increased when large amounts of intravenous fluid are introduced. Respiratory difficulty results and there is cyanosis. This state may be relieved by frequent blood transfusions to increase the osmotic pressure, frequent turning in bed, deep breaths, and the use of oxygen inhalations. The latter are said to aid in the absorption of gas from the bowel.

Attention to the primary cause of the peritonitis takes precedence over all other forms of treatment, and the restoration of water balance and the electrolytes and the replacement of blood volume make this possible. In addition, the use of chemotherapeutic agents and antibiotics to combat the infection offers very much to the management of the disease. The use of penicillin in large doses, namely, 100,000 units intramuscularly every three hours, together with 300,000 units with each intravenous injection, will give the patient approximately a million and a half units a day if 3 liters of fluid are given. In addition, streptomycin up to 2 or 3 Gm. in twenty-four hours, given intramuscularly is advantageous because peritonitis, as we have said, is due not only to cocci, but also to bacilli of the gram-negative group. Sometimes sodium sulfadiazine is given intravenously since the drug cannot be given by mouth. But its possible effects on the kidneys must be remembered. There is no question about the efficacy of chemotherapeutic agents and antibiotics in the treatment of peritonitis, no matter what the cause.

The criteria for the use of physiological saline and glucose, distilled water with glucose, plasma, and whole blood have been evaluated in previous chapters on hemorrhage, shock, and water balance. It may be recalled that a good clinical rule is as follows: If the patient is eliminating an adequate amount of urine with a normal specific gravity and if, in addition, the skin and mucous membranes are moist and the temperature is falling, then the patient is probably receiving adequate amounts of fluid. To substantiate this further, a daily hematocrit and plasma protein may be run by the copper sulfate method. This is an inexpensive and quick method of great accuracy, so that the degree of hemoconcentration and level of plasma protein may be estimated. There is one omission in determining the plasma protein by this method; that is, the

there may also be generalized pain. (2) In an age of less than 3 years, initiation of the illness by a chill is suggestive of the primary peritonitis and yet we have seen pyleophlebitis accompanying appendicitis in children of this age. (3) Leucocytosis is usually higher in the primary form. However, here again, appendicitis simulates it. Pneumonia may closely resemble primary peritonitis, and it may be an accompanying feature. Both may be present at the same time. The x-ray of the chest may be helpful.

Because of the difficulty in diagnosis, exploration is usually indicated; however, not until fluid balance has been restored, transfusion has been given, large doses of penicillin administered. Exploration is usually done under local anesthesia through a small incision. If the surgeon encounters the type of exudate which has been described, he will immediately make a smear, and if a pure culture of streptococcus is encountered, a small Penrose drain will be inserted. There has been a great deal of questioning about the use of this Penrose drain. It has been said that this is superfluous because it is impossible to drain the entire peritoneal cavity, and if it is primary peritonitis, this is unnecessary. Indeed, if one were absolutely sure of the diagnosis, even this small exploration would be superfluous and unnecessary. But even after opening the abdomen, one may be in doubt. It would be wrong to explore too thoroughly such an abdomen, and since trauma accentuates the inflammation, actually the operation would have dire and serious effect. Therefore, it is our practice to introduce two or three small Penrose drains and by so doing, if the diagnosis is an error, drainage about the appendiceal area may prevent further complications. If the diagnosis is correct, drainage of this type does no harm. The care of the patient is the same as in other types of peritonitis with the use of large doses of penicillin given intravenously and intramuscularly. In addition, if the pneumococcus is at fault, sodium sulfadiazine may be helpful.

Mesenteric lymphadenitis is a definite clinical entity. It is usually seen in children. The mesenteric nodes (particularly the lower ileac group) are enlarged and swollen. Sometimes the entire small bowel mesentery is involved. Sections and cultures reveal an inflammation, with polymorphonuclear cells, but no specific organisms have been found. It is probbaly a virus disease related to the upper respiratory infections. The lymphoid tissue in the nose and throat and in the ileum and appendix as well as the lymph nodes is involved. The symptoms are vague. There are diffuse abdominal pain, nausea, and slight elevation of temperature. The leucocyte count is normal or there may be leucopenia. If extensive in older children, a path of tenderness roughly overlying the mesentery of the small bowel may be elicited. The difficulty of distinguishing this disease from appendicitis is obvious, since a swelling of the lymphoid tissue of the appendix is part of the process but not its cause. The condition is benefited by opening the abdomen rather than by the appendectomy which is usually done.

The term primary peritonitis may be questioned since the disease is rarely primary. Another name is metastatic peritonitis, indicating that it reaches the peritoneum from a focus outside the abdominal cavity. The cause of the condition is usually the streptococcus or the pneumococcus, although other organisms may be at fault, such as Friedländer's bacillus.

The etiology is often very obscure. It is thought that the organisms gain entrance in the females through the genital tract by the way of the uterus and tubes. Since the disease occurs in males, this cannot be the only avenue of entrance, and there is no evidence to show that such ascending infection takes place. The gastrointestinal tract may be the source of infection, and the pathological studies have shown severe inflammation of the small bowel, especially the terminal ileum. Pneumococcic peritonitis may result from diaphragmatic invasion by way of the thoracic lymphatics; however, this would imply a descent against the lymphatic current. In most instances the infection gains access to the peritoneum by way of the blood stream. This is true because upper respiratory infections are usually forerunners and bacteria may be found in the blood stream in such cases.

The pathology of the disease is typical of general peritonitis. The general peritoneal cavity is acutely inflamed. When the abdomen is opened, there is a flow of serosanguineous fluid, if the cause is streptococcus, or a flaky exudate if pneumococcus. There is no odor to the pus, and if a swab is taken of the exudate, a pure culture of the streptococcus or pneumococcus is obtained. The visceral and parietal peritonea are involved and no focus is found.

Symptoms and Signs.—The disease occurs about equally in males and females, usually in children. Also usually, but not invariably, it follows upper respiratory infection. Sometimes there is diarrhea. Since the diarrhea in infants and children is so commonly due to gastroenteritis, it offers challenging symptoms to explain. Often the forerunner is referred to as "intestinal flu." The older children will complain of abdominal pain which is diffuse and is not localized, nor does it localize after careful observation. There are high fever and vomiting, which are persistent. The temperature reaches 104 to 105° F., the abdomen is tender, and the pulse is fast. In the older individual there is a great deal of rigidity, but in babies the abdomen may be soft. There is usually some degree of distention, and the abdomen is practically silent, although in children this may vary. The white blood count is extremely high, from 20,000 to 40,000. The red count is increased due to dehydration.

The differential diagnosis lies largely between primary peritonitis and secondary peritonitis due to a perforated appendicitis. It is true that in perforated appendicitis, there are distinguishing features of the disease, such as the following: (1) In appendicitis there is maximal pain on the right side, while in primary peritonitis there is pain and tenderness generally, but this does not offer much help in early appendicitis;

appendix, with a large hole near its base, and outpouring of fecal matter, or acute pancreatitis; occasionally one sees a picture which clinically mimics intestinal obstruction or coronary occlusion.

The cause of the condition is usually leakage following surgery or following acute cholecystitis, subsequently causing gangrene of the gall bladder and perforation. This indeed has been the reason advanced for immediate operation in acute cholecystitis. This will be discussed at the end of Chapter 22. It is not always possible to demonstrate a gross defect in the biliary system in bile peritonitis. We have seen several patients in whom at autopsy no definite perforations could be seen in the biliary tree, yet a generalized biliary peritonitis was present. Both of these had a passive congestion of the liver and the spleen, pulmonary congestion, and cholelithiasis. In most traumatic conditions of the liver, the danger of bile peritonitis is always present.

The treatment of bile peritonitis is, of course, prevention if possible and immediate drainage as soon as the condition is recognized. Recently we have seen two cases with complications who have had gall bladder surgery with closure of the abdomen without drainage. Both had what was thought to be ascites; paracentesis showed the fluid to be bile. Instead of making an incision to drain the abdomen, repeated paracenteses were done, and both recovered. They subsequently developed strictures of the common bile duct which required surgery. Adequate drainage is indicated. Early the problem is one of combating the shock. This requires large quantities of plasma, whole blood, electrolytes, and fluids. The mortality rate is high, and in some sets of statistics it runs up to 65 per cent. In addition to the foregoing treatment, penicillin and streptomycin are given in large doses so that secondary infection may be minimized. A perforated peptic ulcer demands immediate operation, with closure of the perforation, because the chemical peritonitis is rapidly converted (in eight to twelve hours) into a bacterial peritonitis, with a very serious prognosis. Some believe that it is a bacterial peritonitis from the start. Clinically, it has been found that no drainage is necessary if the ulcer is closed within the first eight to twelve hours. If seen after that period, dependent drainage is indicated.

Peritonitis from fatty necrosis is not an emergency. The fat necrosis causes small nodules of soap to form, but these do no harm. If the diagnosis is uncertain, the surgeon will perform an exploratory operation. Should this condition be encountered, he may drain the gall bladder and the lesser peritoneal cavity. (See Chapter 22.)

Tumors and Cysts in the Omentum and Mesentery

Tumors are usually secondary to carcinoma of the stomach, colon, or pelvic organs. Cysts are often congenital and may be diagnosed by the fact that they present a movable tumor mass which is tympanic, due to the fact that cysts are usually in the mesentery, and therefore the bowel will be anterior to them.

Tuberculous peritonitis is often secondary to tuberculosis elsewhere and usually originates in the Fallopian tubes of the female or the appendix in the male. The exudative type is of slow evolution and is seen in young people, with the formation of excessive peritoneal fluid (ascites). The peritoneum is studded with thousands of small grayish-white tubercules. Simple laparotomy is often curative. Should the tubes or appendix be involved, they are removed. The proliferative type (dry) presents areas of caseation and results in fistulous formations if molested. (See Chapter 8.)

Gonorrheal peritonitis (see Chapter 22) is secondary to gonorrheal salpingitis and is rarely more than a pelvic peritonitis. The treatment consists of rest in bed, hot douches, heat to the abdomen, and large doses of penicillin and sulfadiazine. Surgery is withheld unless an abscess develops in the cul-de-sac, in which case it is drained through the vagina. Sometimes a chronic tubo-ovarian abscess must be removed.

Chemical peritonitis may be caused by a perforated peptic ulcer, which permits the hydrochloric acid of the stomach to irritate the peritoneum (this is discussed later in this chapter), or by acute hemorrhagic pancreatitis, in which activated trypsin causes a necrosis of the pancreas and steapsin (which needs no activation) is poured forth and digests the fat, causing fatty necrosis to occur (see Chapter 22).

A third type of chemical peritonitis is that produced by bile. Free bile in the peritoneal cavity may produce serious effects because of: (1) The toxic action of one or more of the products present in bile upon the tissues. This is probably due to the fact that bile salts make the peritoneum less resistant to infection. In clinical practice it is rare to find a bile peritonitis which has not become infected, although bile itself as found in the gall bladder is usually sterile. (2) The infection which is carried into the peritoneal cavity by the bile or subsequently developing through contamination. (3) The production of a condition like surgical shock, caused by the outpouring of large amounts of plasma into the abdomen through the permeable dilated capillaries and venules. The same effect may be produced by concentrated glucose introduced into the peritoneal cavity. Here the effect is one of an increase in the osmotic pressure within the peritoneal cavity, whereas in bile the effect is more of the nature of an inflammation with exudation. The result, however, is the same, and the picture is very much like that which occurs when shock is produced by other causes.

Clinically bile peritonitis does not often produce the shocklike picture described. In a patient who has recently been operated upon for gall bladder disease or in one who has had an attack of acute cholecystitis, any sudden shocklike picture should be interpreted as a large perforation. It is probably true that it takes a large sudden outpouring of bile to produce the syndrome. The picture may resemble a large perforated peptic ulcer with outpouring of gastric content, or a ruptured

palpated. A very careful examination of the female genital tract in elderly women is always indicated; also, careful examination of the bladder, ureters, and the kidneys.

Benign growths may be palpated at times, but often this is difficult. We have seen recently one patient in whom a lipoma protruded through the femoral canal. This was diagnosed as a femoral hernia and when the surgeon operated, he removed the small portion of the lipoma and found no hernia. This patient was referred to our service and upon exploration this was found to be a retroperitoneal lipoma which weighed eleven pounds. The man's symptoms were not only those of pressure on the femoral vein, but gastrointestinal pains with great discomfort as well.

There may be intestinal obstruction symptoms or peritoneal irritation with exudation or great ascites in the disseminated and malignant types of neoplasms. Due to the low-grade inflammation, adhesions form, giving bizarre symptoms and signs.

If free fluid is present, this should be studied carefully for (1) cells, inflammatory or neoplastic, (2) culture, (3) guinea pig inoculation, (4) direct smear, (5) protein content, which helps distinguish between transudates and exudates. In detecting tumors the fluid is centrifuged and a "button" is made which is examined after staining.

The treatment depends upon the condition which is found. Obviously, extensive secondary carcinomas defy extirpation. Mucocele of the appendix requires appendectomy, and the stump should be turned in carefully with two purse-string sutures, because sometimes the base of the appendix is involved. Certainly, it should not be ligated and left open in the presence of a mucocele. Some have stated that if the primary source is extirpated, the secondary implantation may be devitalized and thereby undergo regression. This has not been our experience. In cystadenocarcinoma of the ovary, even when the ovary is removed intact and before metastases are grossly apparent, the danger of secondary invasion of the peritoneal cavity is always present. However, the primary growths should be removed if this is feasible, especially in the absence of metastases. In pseudomyxoma peritonei the gelatinous material is scooped out of the abdomen and washed out as much as possible. This, of course, is only palliative and usually it does recur.

X-ray treatment is indicated in endothelioma and pseudomyxoma peritonei, although its effect is questionable. In small round-cell sarcoma or in lymphosarcoma, x-ray is beneficial. It is worthy of trial not only from the standpoint of its therapeutic effect, but also sometimes it aids in the diagnosis of the lesion by causing a prompt regression of the large growths.

Retroperitoneal Cysts.—Retroperitoneal cysts are not uncommon. The following is a classification which is fairly inclusive and which takes in most of the cysts that would ordinarily be encountered:

1. Cysts of urogenital origin. This includes cysts of the ureter, duplications of the ureter, perinephric cysts, renal cysts. Most of the fetal-renal elements may be found in various types of cysts. Some of

Neoplasms of the peritoneum may be primary or secondary, benign or malignant. Primary tumors are usually retroperitoneal, whereas secondary growths are ordinarily found within the peritoneal cavity. Benign primary tumors include lipoma, fibroma, neurofibroma, lymphangioma, hemangioma, myxoma, leiomyoma (usually in the omentum), ganglioneuroma, angioendothelioma, and various types of cysts which will be discussed later.

Malignant primary neoplasms are unusual and include sarcoma, fibrosarcoma, adenosarcoma, renal cell carcinoma, epithelioma, teratoma, lymphoma, neuroblastoma, endothelioma, or mesothelioma and undifferentiated neoplasms. More common are the malignant secondary neoplasms which may originate anywhere in the body but usually arise in the organs which are partially or completely covered by peritoneum. Therefore, one thinks of the gastrointestinal tract, pancreas, kidney, adrenal, uterus, and urinary bladder first, although carcinoma of the breast commonly metastasizes to the peritoneum. A rarer form of peritoneal neoplasm is known as pseudomyxoma peritonei (Pean's disease). The cause of this condition is obscure, although it has been known since 1842. It is associated with mucoceles, pseudomucinous cysts, or mucoid carcinomas anywhere in the abdomen. Usually, however, the appendix or ovary is the primary site. Not infrequently it follows a proliferating papillary cystadenoma of the ovary. These papilliferous growths are scattered throughout the abdominal cavity and constitute one of the most common types of secondary carcinoma of the peritoneum. The papillary cystadenocarcinomas infiltrate the omentum and mesentery and spread diffusely over the peritoneum and there forms cysts or pours out into the abdominal cavity a large quantity of gelatinous mucous material. It must be said, therefore, that this constitutes one of the forms of pseudomyxoma peritonei. However, a similar condition grossly may be produced by a secondary invasion of a mucoid carcinoma from other points of origin. Rupture of cysts containing mucin or mucoid material may cause the production of considerable amounts of this substance within the peritoneal cavity.

The diagnosis of peritoneal neoplasms may be difficult. This is particularly true of a generalized carcinomatosis of the abdomen, strange as this statement may sound. We have time and again seen patients with primary carcinoma of the ovaries with metastases through the abdomen, carcinoma of the uterus, primary carcinoma of the omentum, or retroperitoneal carcinoma or sarcoma which extends into the abdomen in which all of the usual forms of investigation are normal. These would include gastrointestinal series, scout films of the abdomen, barium enemas, retrograde pylorography, cystograms, and careful x-ray examination of the bony framework. Cystoscopic and proctoscopic examination may reveal very little from which to make a diagnosis, and many of these unfortunate victims are branded as psychoneurotics. The surgeon should be very cautious in making a diagnosis in patients who have vague pain within the abdomen and in whom various masses can be

primitive cell which shows epithelial elements in its wall. This type of cyst usually occurs in women and occupies a lateral position. (2) Those *derived from the mesodermal or lymphatic elements* and occur in any age group and in either sex.

The symptoms and signs of retroperitoneal cysts are discomfort, pressure, and the presence of a tumor mass. They are usually painless, but the enlargement of the abdomen and general discomfort cause the patient to seek medical attention. In addition, there may be anorexia and pain in the very large-sized growths. *The diagnosis is made by a process of elimination.* Sometimes this is extremely difficult. Pyelography, barium enema, and gastrointestinal studies may fail to reveal the diagnosis which may not be discovered until exploration is done. Cysts which arise in the adrenal, kidney, pancreas, or intestines must be thought of and ruled out in the differential diagnosis. They are, in a sense, retroperitoneal cysts.

The treatment is surgical, and in uncomplicated cysts the entire growth may be enucleated. However, usually they are related to the great vessels or the ureter or the intestine in such a way that their removal is not as simple as may at first be apparent. However, by careful dissection usually they may be removed. Lines of cleavage may be found if there has not been too much infection, and the cyst may be dissected loose. Not infrequently, due to the fact that the walls are thin, they may be ruptured and then enucleated. This would have no effect on the prognosis as a rule.

Intestinal Lipodystrophy

*An extremely rare condition of the mesentery is known as **intestinal lipodystrophy*** or *Whipple's disease.* The pathological aspects of this condition include changes in the mesenteric portion of the small bowel and its mesentery. The latter is thickened, yellow, and hard. The lymph nodes are enlarged and firm, and there are dilations of the lymph sinuses The lacteal vessels may be dilated enough to be seen grossly, indicating interference with lymph return and accounting for the chylous ascites which sometimes occurs. The mucosa of the jejunum and ileum is either normal in appearance or swollen and flecked with deposits of yellowish-white lipoid. In some cases fibrous pericarditis is present. Microscopic examinations show foam cells, extracellular and intracellular fat deposits, and foreign body giant cells, together with fibrosis and lymphocytic infiltration. The cause of this condition is entirely unknown, although Whipple believed that the fat in itself holds some abnormal or toxic substance. Another very popular theory as to its causation is the presence of fat necrosis, and this condition is related to the lipodystrophies that are seen elsewhere in the body.

The clinical picture is that of a patient who seems to be obese and yet seems to have vague masses within the abdomen that can be palpated. There is indigestion, gaseous distention, diarrhea, loss of weight,

these may have tubules and glomeruli in the wall and a ureterlike tubular structure. Some will have renal elements which are difficult to recognize and may even be found in the descending mesocolon. The cysts and, for that matter, solid neoplasms of the retroperitoneal space in relation to the adrenal, kidney, broad ligament, spermatic cord, epididymus, and possibly the testicle, have their origin in the wolffian body remnants. In addition to cysts that are in relation to the wolffian body are those that arise from cells of the genital ridge which lies just lateral to the wolffian body. Cases have been repored of ovarian cysts which lie to the outer side of the colon.

2. Teratomas and dermoid cysts. These, in our experience, have not been uncommon. In fact, retroperitoneal teratomas have been about as common as all of the other retroperitoneal tumors together. These include dermoid cysts and teratomas as well. They are frequently found in close association with the sacrococcygeal teratomas.

3. Lymphatic cysts. Cystic lymphomas have been described in Chapter 18. We have encountered many of these. Cystic hygromas and axillary and inguinal lymphatic cysts are reported in the literature in great numbers. Also cystic retroperitoneal lymphangiomas have been reported. It is now thought that the retroperitoneal lymphatic or mesenteric cysts are related to the cystic hygromas that are due to one of the primitive lymphatic sacs remaining in its primitive fashion. These cysts may have an endothelial lining, although it may be absent and the contents may be purulent or bloody, particularly in those which have been secondarily infected.

4. Jones describes a mesocolic type of cyst in which there is imperfect fusion of the layers of the peritoneum. It is conceivable that this can take place; however, it must be extremely rare. If it were found at all, it probably would be found between the layers of the ascending and descending mesocolon and rarely the transverse mesocolon.

5. Traumatic blood cysts are not difficult to understand, particularly following surgery on the uterus in which some of the endometrium has been inadvertently transplanted. Here there would be a blood cyst due to an endometriosis. Traumatic blood cysts imply trauma plus a hematoma with absorption of the hematoma and cyst formation.

6. Parasitic cysts, particularly the echinococcus cysts.

7. Developmental cysts in the fully formed kidney or pancreas or liver. These are really not retroperitoneal in the sense that we are describing retroperitoneal cysts. These belong to the organ in which the cyst is found.

8. The pseudopancreatic cyst which forms as a result of injury or diseased pancreas and results from a closure of the gastroepiploic foramen with an accumulation of fluid in the lesser peritoneal sac.

In this discussion it can be seen that generally there are two types of cysts: (1) Those which are derived from the ectodermal or perhaps the entodermal elements of the wolffian body or genital ridge, or a more

4. Neoplastic diseases with dissemination of neoplastic tissue over the peritoneal surface such as occurs in proliferating papillary cystadenocarcinoma of the ovary with dissemination, this to be distinguished from occlusion of the portal vein due to metastases in the liver
5. Rarely ascites may occur as a result of fibroma of the ovary and this may be accompanied by pleural effusion as well as by ascites as in Meigs' syndrome. (See Chapter 22.)

C. *Combinations*

Combinations of causes occur in which the obstructive factor and the changes in the osmotic pressure in the blood may play a role. This is commonly observed in late carcinoma where the neoplastic elements in the peritoneal cavity produce a local irritation, and, in addition, there may be cardiac impairment producing ascites from increase in hydrostatic pressure in the veins. The ascitic fluid varies greatly in color and consistency. Usually the fluid is clear and yellowish; in carcinoma it is blood tinged; in chylous ascites it is white or milky. In the young, ascites is most commonly associated with Banti's disease (portal hypertension) or with tuberculosis. In older individuals cirrhosis of the liver and carcinoma are the most common causes.

The treatment of ascites is medical or surgical. Medical treatment consists of the control of the primary cause if possible, and, in addition, the use of diuretics. The surgical treatment most frequently employed is that of paracentesis which may be repeatedly carried out (paracentesis peritonei). There have been attempts, however, to form a more permanent type of drainage of ascitic fluid from the peritoneal cavity such as subcutaneous channels made of glass or metal tubes, anastomosis of the peritoneum to the saphenous veins or the renal pelvis, the use of venous grafts from the peritoneal cavity to the subcutaneous space, cannulas inserted in the peritoneal cavity and brought to the outside, resection of the parietal peritoneum. Also methods have been devised to improve the collateral circulation such as the omentopexy of Talma, anastomosis of the sigmoidal veins to the saphenous veins; the splenic to the left renal vein; the superior mesenteric to the vena cava, or the portal vein to the inferior vena cava. Needless to say, surgery is indicated in those conditions which are due to neoplasms or in which there is great splenomegaly. For further discussion of ascites, see Chapter 22.

GASTROINTESTINAL CANAL

Embryology and Physiology

The mesenteron, or central portion of the alimentary canal, is formed from entoderm and consists at first of a simple tube which ends blindly anteriorly and

and general debility. There is a general tendency toward achlorhydria and fat intolerance. The diagnosis is usually made at operation. The prognosis is unfavorable. The treatment is entirely unsatisfactory and most of the patients die within several months to a year and a half. Surgery is of little avail and usually is done because the diagnosis is uncertain. The use of x-ray therapy is likewise not of much help.

Ascites

Fluid in the peritoneal cavity is known as ascites. This fluid may be a transudate or an exudate and may consist of plasma, serum, the products of exudation or chyle (chylous ascites). Ascites may be produced experimentally in the following ways:

1. Ligation of the common bile duct in dogs will produce ascites and this will increase after a high protein diet.
2. Massive saline infusions provided the kidney output is much less than the amount infused.
3. Constriction of the inferior vena cava above the liver by suture, metal bands, or cellophane bands.
4. Constriction of the pericardium especially around the right auricle by sutures or by bands.

Ascites cannot be produced by occlusion of the portal vein or the vena cava below the diaphragm. However, cirrhosis may be induced by the gradual occlusion of the portal vein and this, in turn, may give rise to at least temporary ascites.

The clinical causes of ascites may be listed under the following headings:

A. *General Causes*
   1. Increase in the hydrostatic pressure in the veins
      a. Cardiovascular disease, renal disease
      b. Constrictive pericarditis
      c. Mediastinal tumor with increase in venous pressure
   2. A decrease in the osmotic pressure
      a. Due to excessive amounts of intravenous fluids
      b. Starvation with a decrease in the osmotic pressure due to hypoproteinemia

B. *Local Causes*
   1. Increase in hydrostatic pressure of the veins due to hepatic disease, portal hypertension from thrombosis of the portal or splenic vein or Banti's disease and splenomegaly
   2. Increase in the hydrostatic pressure of the lymphatics due to new growth such as carcinoma and inflammation such as tuberculosis
   3. Inflammatory diseases such as tuberculous peritonitis or any form of chronic peritonitis

4. Neoplastic diseases with dissemination of neoplastic tissue over the peritoneal surface such as occurs in *proliferating papillary* cystadenocarcinoma of the ovary with dissemination, this to be distinguished from occlusion of the portal vein due to metastases in the liver
5. Rarely ascites may occur as a result of fibroma of the ovary and this may be accompanied by pleural effusion as well as by ascites as in Meigs' syndrome. (See Chapter 22.)

C. *Combinations*

Combinations of causes occur in which the obstructive factor and the changes in the osmotic pressure in the blood may play a role. This is commonly observed in late carcinoma where the neoplastic elements in the peritoneal cavity produce a local irritation, and, in addition, there may be cardiac impairment producing ascites from increase in hydrostatic pressure in the veins. The ascitic fluid varies greatly in color and consistency. Usually the fluid is clear and yellowish; in carcinoma it is blood tinged; in chylous ascites it is white or milky. In the young, ascites is most commonly associated with Banti's disease (portal hypertension) or with tuberculosis. In older individuals cirrhosis of the liver and carcinoma are the most common causes.

The treatment of ascites is medical or surgical. Medical treatment consists of the control of the primary cause if possible, and, in addition, the use of diuretics. The surgical treatment most frequently employed is that of paracentesis which may be repeatedly carried out (paracentesis peritonei). There have been attempts, however, to form a more permanent type of drainage of ascitic fluid from the peritoneal cavity such as subcutaneous channels made of glass or metal tubes, anastomosis of the peritoneum to the saphenous veins or the renal pelvis, the use of venous grafts from the peritoneal cavity to the subcutaneous space, cannulas inserted in the peritoneal cavity and brought to the outside, resection of the parietal peritoneum. Also methods have been devised to improve the collateral circulation such as the omentopexy of Talma, anastomosis of the sigmoidal veins to the saphenous veins; the splenic to the left renal vein; the superior mesenteric to the vena cava, or the portal vein to the inferior vena cava. Needless to say, surgery is indicated in those conditions which are due to neoplasms or in which there is great splenomegaly. For further discussion of ascites, see Chapter 22.

GASTROINTESTINAL CANAL

Embryology and Physiology

The mesenteron, or *central portion* of the alimentary canal, is formed from entoderm and consists at first of a simple tube which ends blindly anteriorly and

Fig. 271.—Diagram illustrating the extrusion, rotation and reinclusion of the midgut.

A. *About fourth-week embryo (5 mm.)*, showing the entodermal canal and its derivatives. (1) Rathke's pouch; (2) tongue, (3) laryngotracheal groove, (4) left lung, (5) stomach; (6) dorsal pancreas, (7) liver; (8) *allantois*, (9) *mesonephric* duct, (10) metanephron, (11) cloaca, (12) allantoic stalk; (13) yolk stalk

B. First stage of rotation, about the fifth week. Sagittal section showing the midgut in the process of extrusion (due to its rapid growth and the growth of the right lobe of the liver). (14) midgut, (15) prearterial mesentery, (16) umbilical orifice, (17) anterior mesogastrium; (18) foregut; (19) aorta, (20) celiac axis, (21) superior mesenteric artery, (22) inferior mesenteric artery, (23) hindgut, (24) postarterial mesentery, (25) vitelline duct and artery.

C. About seventh-week embryo, showing further extrusion of the midgut through the umbilical orifice (15) *prearterial mesentery*, (16) umbilical orifice; (18) foregut, (19) aorta (20) celiac axis, (21) superior mesenteric artery, (22) inferior mesenteric artery; (23) hindgut; (24) postarterial mesentery; (25) vitelline duct and artery, (26) great omentum (dorsal mesogastrium), (27) pressure here by left umbilical vein, (28) ventral mesogastrium.

D. End of extrusion, about ninth week, showing the rotation of the midgut in a counter-clockwise manner. (15) prearterial mesentery; (16) *umbilical orifice*, (18) *foregut*, (20) celiac axis; (21) superior mesenteric artery; (22) inferior mesenteric artery; (23) hindgut; (24) post arterial mesentery; (25) vitelline duct and artery, (27) pressure here by left umbilical vein, (28) *ventral mesogastrium*.

E. Tenth-to-eleventh-week embryo showing the progress of rotation coincident with the return of the midgut to the abdomen. (16) umbilical orifice, (19) aorta; (20) celiac axis, (21) superior mesenteric artery, (25) vitelline duct, (28) ventral mesogastrium, (34) great omentum.

F. Completion of the stage shown in *E*, and further migration of the cecum and colon to the right side (25) vitelline duct; (29) small intestine; (30) mesentery, (31) cecum, (32) duodenum (33) stomach; (34) great omentum, (35) colon, (36) mesocolon, (37) mesoduodenum.

G. Continued migration and descent of the cecum to *the normal position*. (29) *small intestine*, (30) mesentery, (31) cecum; (32) duodenum, (33) stomach, (34) great omentum, (35) colon, (36) mesocolon; (37) mesoduodenum.

H. Completed migration and fusion of the mesentery begun (25) colon, (29) small intestine; (30) mesentery, (31) cecum, (32) duodenum; (33) stomach; (34) great omentum, (36) mesocolon; (37) mesoduodenum.

posteriorly. This tube represents only the mucous membrane. Later it becomes enveloped in a layer of mesoderm, which differentiates into two portions, the outer forming the peritoneal covering and the inner forming the muscle and connective tissue elements. In embryos of thirty to sixty days, the epithelium proliferate rapidly, and the alimentary canal down to the ileocecal may be obliterated by the excess of epithelium (solid stage). Soon vacuoles appear, then coalesce, re-establishing the lumen by the twelfth week. These same phenomena are said to occur in the esophagus, stomach, and colon to a much lesser degree. Should a septum persist, an atresia results, and if partially open stenosis remains, an invagination of ectoderm takes place at the two ends, anteriorly forming the stomadeum, which later becomes the mouth, and posteriorly, the proctodeum, which becomes the anal orifice. As the embryo develops, this tube becomes slightly dilated at the levels of the future stomach and colon. Due to the rapid growth of the liver and gut, there is not enough room for its further development, and at about the fifth week the intestine is extruded through the umbilical opening. Attached to the gut is a duct (the omphalomesenteric duct or vittelined duct) which connects the yolk sac with the midgut, and at its intestinal attachment a small pouch may be left (Meckel's diverticulum) which persists in about 2 per cent of adults, or the duct may fail to close, forming an umbilical fistula. Between the fifth and tenth week the abdominal cavity is large enough to accommodate the intestines and they re-enter, first, the small intestine, then the cecum (to the upper left quadrant, with the ileum entering from the right to left), then the colon. The cecum then migrates to the right upper quadrant and finally to its normal position in the right ileac fossa.

The foregut gives rise to the upper portion of the alimentary canal, part of the oral cavity, the pharynx and its derivatives, the esophagus, the stomach, and the first portion of the duodenum (down to the duodenal papilla and from the duodenum, the liver and pancreas). It is supplied by blood from the celiac axis, and its function is chiefly digestive. It, indeed, is the chemical laboratory of the alimentary canal. The chief digestive fluid of the foregut is the gastric juice, composed of rennin, which coagulates or curdles milk, and hydrochloric acid and pepsin for protein digestion; also inorganic salts, histamine, lipase (traces), and the antianemic factor of Castle.

There are approximately 35,000,000 gastric glands in the fundus and body of the stomach. The chief cells in the neck of the glands secrete mucin, as do the pyloric glands, whereas those in the body of the gland (zymogenic cells) secrete pepsin or its precursor; parietal cells in the gland secrete the hydrochloric acid. Glands about the pylorus and esophagus and in the cardiac end of the stomach secrete chiefly mucin. Gastric lipase is a fat-splitting enzyme which acts only in an acid medium.

If the stomach content has a free HCl value below 20 after a test meal, the condition is called hypochlorhydria, or subacidity. Complete absence of free HCl is called achlorhydria, or anacidity (present in 4 to 10 per cent of normal adults). Complete absence of acid and pepsin is referred to as achylia gastrica. Anacidity is found in pernicious anemia, carcinoma, and chronic gastritis. Hypochlorhydria may be found normally and also in gall bladder disease, Addison's disease, and sprue. Hyperchlorhydria, or hyperacidity, is the condition in which the free acid is above normal (60 to 90), remaining high after the first hour following a test meal. This is not due to the secretion of an excessively acid juice (the maximum acidity is 0.4 to 0.5 per cent HCl). It is due to a hypersecretion (secretion of too much juice) or to a failure of neutralization. This is seen in peptic ulcer, especially if associated with pyloric obstruction.

The stomach absorbs alcohol, some glucose, and water but almost nothing else. It cannot be regarded as an absorptive organ. Mucin secreted by the pyloric and Brunner's glands (in the pyloric antrum and pars superior duodeni) is present to protect the lining of the stomach and duodenum against the corrosive action of the hydrochloric acid.

We have performed experiments to determine this mechanism. Brunner's glands have two secretions—a local protective mucin (glycoprotein) and a systemic hormone, gastrin, which stimulates the local production of mucin as well as the production of gastrin, which in turn assures the necessary hydrochloric acid for this stimulation, thereby perpetuating the cycle. In addition, mucin is secreted by pyloric, fundic, and cardiac glands (dissolved mucin) and by the goblet cells of the gastric mucosa (surface mucin). Mucin has a pH of 7.0 to 7.5. Its antipeptic action is due to mucoitin sulfuric acid. The secretion of the cardia is alkaline and consists mostly of mucus; that of the fundus (and corpus) is acid and contains pepsin and mucus; that of the pylorus is alkaline and contains no acid but much mucus and is important but not essential to the humoral phase of gastric secretion.

The columnar surface epithelial cells are thought to produce the so-called visible mucus. These cells are found lining the entire stomach. The "mucous chief cell" is found principally in the cardiac and pyloric portions and are said to give rise to "dissolved mucin." Mucus is composed of carbohydrates, protein, mucoitin sulfuric acid, hydrochloric acid, leucocytes, lymphocytes, and desquamated epithelium. The regulation of the secretion of mucus is through nervous, mechanical, and chemical stimuli.

Vagal stimulation which is weak produces mucus which is alkaline; when strong, it is acid. Brunner's glands are activated by vagal stimulation. Vagotomy decreases mucus production. Stimulation of the sympathetics (splanchnics) causes mucus production.

Chemical stimulation. High acid usually calls forth more mucus even in atropinized animals. Histamine stimulates parietal cells but inhibits the production of pepsin and mucus. Adrenaline simulates sympathetic stimulation in that it increases the spontaneous secretion of alkaline or neutral mucus. Secretin stimulates Brunner's gland. Acetylcholine produces a secretion of very thick mucous fluid which possesses a high peptic power but is only slightly acid. When histamin and acetylcholine are used, a secretion richer in pepsin and mucus and lower in acidity is produced than when histamin alone is employed.

Local mechanical irritation provokes the secretion of mucus.

Gastric mucus serves to lower gastric acidity, inhibits pepsin, and acts as a mechanical protection for the mucous membrane when irritated; however, the lowering of gastric acidity by alkaline mucus is most effective when the secretion of gastric juice is at low ebb. This is accomplished by neutralization and adsorption, and therefore it is most prominent at the beginning of a meal (cephalic phase) and at the end of a meal when much of the acid has been used in the digestion of a meal. Thus it serves to protect at such times when there is no food to take up the hydrochloric acid and would have its greatest protective influence at the beginning and end of a meal, between meals, and at night.

The normal rate of secretion varies between 30 and 117 c.c. per hour, and it is more or less continuous. This has been called the interdigestive secretion and is said to be an important factor in the causation of ulcer, particularly during the night when the stomach is empty. The total volume of gastric juice is 2 to 3 liters per day (interdigestive and digestive juices). (See Chapter 11.)

The digestive secretion is divided into three phases: (1) The psychic (cephalic). This phase is extremely important and gives rise to a strong psychic juice. Secretory fibers for the gastric glands are found in the vagus and splanchnic nerves. Insulin provokes gastric secretion by the hypoglycemic stimulation of the vagal center. This test is now used to determine whether the vagi have been completely severed after vagotomy. The thought, sight, smell, or taste of food stimulates psychic juice. Resentment, hostility, aggressivenes, and anxiety produce hypersecretion and hypermobility and increased congestion of the gastric mucosa—even superficial ulceration (Wolf and Wolff); Sadness, discouragement, and self reproach produce hyposecretion

posteriorly. This tube represents only the mucous membrane. Later it becomes enveloped in a layer of mesoderm, which differentiates into two portions, the outer forming the peritoneal covering and the inner forming the muscle and connective tissue elements. In embryos of thirty to sixty days, the epithelium proliferate rapidly, and the alimentary canal down to the ileocecal may be obliterated by the excess of epithelium (solid stage). Chemical stimulation. High acid usually calls forth more mucus even in atropinized animals. Histamine stimulates parietal cells but inhibits the production of pepsin and mucus. Adrenaline simulates sympathetic stimulation in that it increases the spontaneous secretion of alkaline or neutral mucus. Secretin stimulates Brunner's gland. Acetylcholine produces a secretion of very thick mucous fluid which possesses a high peptic power but is only slightly acid. When histamin and acetylcholine are used, a secretion richer in pepsin and mucus and lower in acidity is produced than when histamin alone is employed.

Local mechanical irritation provokes the secretion of mucus.

Gastric mucus serves to lower gastric acidity, inhibits pepsin, and acts as a mechanical protection for the mucous membrane when irritated; however, the lowering of gastric acidity by alkaline mucus is most effective when the secretion of gastric juice is at low ebb. This is accomplished by neutralization and adsorption, and therefore it is most prominent at the beginning of a meal (cephalic phase) and at the end of a meal when much of the acid has been used in the digestion of a meal. Thus it serves to protect at such times when there is no food to take up the hydrochloric acid and would have its greatest protective influence at the beginning and end of a meal, between meals, and at night.

The normal rate of secretion varies between 30 and 117 c.c. per hour, and it is more or less continuous. This has been called the interdigestive secretion and is said to be an important factor in the causation of ulcer, particularly during the night when the stomach is empty. The total volume of gastric juice is 2 to 3 liters per day (interdigestive and digestive juices). (See Chapter 11.)

The digestive secretion is divided into three phases: (1) The psychic (cephalic). This phase is extremely important and gives rise to a strong psychic juice. Secretory fibers for the gastric glands are found in the vagus and splanchnic nerves. Insulin provokes *gastric secretion by the hypoglycemic stimulation of the vagal center.* This test is now used to determine whether the vagi have been completely severed after vagotomy. The thought, sight, smell, or taste of food stimulates psychic juice. Resentment, hostility, aggressivenes, and anxiety produce hypersecretion and hypermobility and increased congestion of the gastric mucosa—even superficial ulceration (Wolf and Wolff); Sadness, discouragement, and self reproach produce hyposecretion

and pallor of the gastric mucosa. (2) Gastric phase stimulated by (a) the mechanical distention of the stomach and (b) chemical excitatory stimuli. The latter may be in the food or may arise as products of digestion; they may act directly as secretogogues or indirectly through the liberation of a gastric hormone. Histamine is the best known and most effective secretory chemical stimulus. Others are peptones, meat, extracts, alcohol, liver extracts, and pyloric mucosa (Kamarov). (3) Intestinal phase which is provoked by secretogogues in the intestines. Serious distention inhibits gastric secretion; injury to intestinal mucus stimulates it, probably due to histamine release.

Gastric secretion is inhibited by (1) Chemical or hormonal factors: (a) Acid in the stomach or intestine and ulcer which has not been produced in the experimental animal by acid alone; we have shown that acid does stimulate the mucous cells and there is an increased amount of mucin; (b) enterogastrone which is released by the presence of fat in the intestine; (c) dextrose which may inhibit gastric secretion, particularly in the hypoglycemic state; (d) an inhibitory substance found in the urine (urogastrone). (2) Nervous inhibitory factors: (a) through the vagi and splanchnic; mental states inhibit gastric secretion; (b) distention of the intestine. Gastric juice secretion is affected by many factors not as yet fully understood such as internal secretion (thyroid and parathyroid) and vitamins, especially B complex. In hyperparathyroidism and hypercalcemia gastric secretion is inhibited, whereas in hypocalcemia it is increased. Deficiency of the vitamins A and B decreases secretion as do other food and water and salt deficiencies. Tobacco does not stimulate secretion; morphine does. Vagotomy decreases secretion but has no effect on the secretory response of the stomach to histamine or caffeine; however, it does abolish the stimulating effect of insulin hypoglycemia. X-rays, fever, anemia, and anoxemia decrease secretion.

As digestion proceeds, psychic, gastric, and intestinal phases of secretion cause the rise and fall of the volume of gastric secretion. Then, too, such factors as enterogastrone, acid inhibition, and gastric emptying time affect the volume. The acid volume is affected by (1) food which combines with acid and ''sops'' it up, (2) alkaline secretions of the stomach (mucus and mucoid secretion) and bile and pancreatic juice, (3) and the products of peptic digestion which inhibit secretion.

Motor Activity of the Stomach.—The metabolic requirements of the body are made known to man by the sensation of hunger. This sensation in turn is probably due to hunger contractions of the stomach. Animals appear to experience hunger after gastrectomy or denervation. This shows that in addition to stomach contractions a central mechanism may play a role.

As food enters the stomach, it is held in the fundus and body (the hopper) where it undergoes little changes except some liquefaction. Periodically some of the food is forced into the pylorus (the grinder), where it is mixed and ground, and passed toward the sphincter by peristaltic waves, starting near the incisura and cardia. Fluids usually begin to leave the stomach within a few minutes. Solids take a longer time. If the material is irritating to the duodenum, still more time is required.

Gastric evacuation occurs chiefly as a result of antral activity, or the difference in pressure between the antrum and bulb rather than the activity of the pyloric sphincter. If the antral wave is so strong as to occlude the sphincter completely, most of the material returns to the body of the stomach. Peristaltic waves begin in the incisura during most of the digestion, but as the stomach becomes empty, the waves originate higher. The pylorus responds to approaching waves of peristalsis much as does the adjacent part of the pars pylorica, and the relaxation of the pylorus alone is not followed by the passage of food. This takes place only when the pylorus and the duodenum are relaxed at the same time. Stretching of the stomach hastens evacuation. The antrum (mostly) and the sphincter and bulb (to some extent) are inhibited by great distention of the duodenum, or by fats, hydrochloric acid, protein-split products,

sugars, and intravenous hypertonic solutions. Inhibition of the region of the sphincter results from the enterogastric reflex and enterogastrone.

Gastric motility tends to be inhibited by vagotomy and augmented by splanchnicectomy. On theoretical grounds, excessive activity of the sympathetics might lead to spasm of the cardia, atony of the fundus and body, spasms of the pyloric sphincter, and a decreased motility of the intestines. No changes in secretion of gastric juice will result, but there should be local and general vasoconstriction. Afferent sensory nerve fibers run with the sympathetics and, therefore, if they are divided, there should result atony or relaxation of the cardia and pylorus and increase in tonus and motility of the stomach; in addition, partial anesthesia.

The vagus mechanism is theoretically antagonistic to the sympathetics, and if there is excessive activity of the efferent vagus fibers, there should be a relaxation of the cardia and pylorus, increased motility and tonus of the stomach, and an increased secretion of gastric juice. Afferent pain fibers probably do not run in the vagus. Division of the vagus should cause spasm of the cardia and pylorus, atony of the stomach, decreased secretion of gastric juice, and no anesthesia.

In addition to these extrinsic nervous mechanisms, there is an intrinsic or local automatism throughout the gastrointestinal tract. Experiments by Cannon and others have shown that complete denervation does not prevent normal function, and moreover that new fibers soon find their way into the denervated organ from many adjacent sources. If the entire autonomic nervous system is interrupted, the experimental animal loses its homeostatic adaptabilities for a while, then gradually regains them.

By nervous control through the sympathetics and parasympathetics (see Chapter 18) food is not only digested but also propelled by peristaltic waves into the intestines below. The entire gastrointestinal tract is laid down around the inner layer (mucosa). External to this is the muscularis mucosa; then the tough submucous coat, made so by its fibrous tissue; then the muscularis; and, externally, the serosa (visceral peritoneum). The secretory functions are carried out through gastric glands (in the stomach) and intestinal glands (in the intestines), aided by the pancreatic juice.

Mid-gut.—The mid gut gives rise to the intestine from the second portion of the duodenum to the middle of the transverse colon. It is nourished by the superior mesenteric artery and its function is chiefly absorptive. The small intestine is covered with villi—about 20 to 40 to the square millimeter. Each villus has a lymph vessel (lacteal), an arteriole, a capillary plexus, and several venules. Between the villi are the crypts of Lieberkuhn. The cells are columnar and may become transformed into goblet cells which secrete the protective mucus. There are four types of cells in the crypts: columnar and goblet cells, whose functions are protective; argentaffine cells, which may be endocrine elements or producers of intestinal ferments; and cells of Paneth, which probably supply the intestinal juice.

Intestinal Absorption.—Absorption takes place through the intestinal villi, of which there are about 5,000,000 in the human intestine. Amino acids and glucose are absorbed by the capillaries Of the digested fat, 60 per cent passes into the lacteals; the fate of the remaining 40 per cent is uncertain.

The physiological causes of intestinal absorption have been explained in different ways:

1. Differences in concentrations and therefore of diffusion pressures between crystalloids in the blood and in the intestinal lumen.

2. Increased hydrostatic pressure in the intestine due to peristaltic movements. (In intestinal obstruction this pressure may cause absorption by forcing fluid directly through the distended bowel wall into the peritoneal cavity.)

3. The colloid osmotic pressure in the capillaries of the villus (caused by the plasma proteins) which is two to three times greater than the hydrostatic pressure in these vessels and so brings about absorption.

In the mid-gut the partially digested meal is changed further by the pancreatic juice poured into the duodenum at the ampulla of Vater (through the pancreatic and accessory pancreatic ducts of Wirsung and Santorini) and contains trypsin for protein digestion, amylase for carbohydrates, and lipase for fats.

There is also some rennin in pancreatic juice, some maltase, and possibly erepsin. The secretion of pancreatic juice is both under hormonal (secretin, prosecretin) and nervous (vagus) control. Pancreatic juice is alkaline in reaction and contains electrolytes essential to life. Total loss of the juice by fistula results in death due to dehydration and loss of electrolytes. In experimental animals life may be prolonged by Ringer's solution and normal saline for a few weeks.

Bile from the common bile duct also enters the duodenum at the ampulla and aids in the digestion of fats and perhaps stimulates the motor function of the intestines. The digestive ferments in the intestinal juices are (1) various peptidases (erepsin), (2) sucrose, maltose, and lactose for the digestion of the disaccharides cane sugar, malt sugar, and milk sugar, (3) lipase, and (4) some amylase.

Hind-gut.—The hind-gut gives rise to the remainder of the colon and to the rectum but not to the anus. It is nourished by the inferior mesenteric artery, and its function is chiefly excretory, although absorption of water and salts occurs.

At birth only the terminal part of the pelvic colon lies in the pelvis. This is due to the small size of the pelvic cavity. Furthermore, the iliac colon lies in the left iliac region, but the sigmoid flexure (pelvic colon) usually lies on the right side and passes over the right portion of the brim to enter the pelvis. The small pelvis in the linear type adult apparently does not prevent the complete descent of the pelvic colon commonly seen in the lateral type.

Anatomical and Physiological Considerations of the Large Intestine

The large intestine is equal to about one-fifth of the entire intestinal canal and measures five to five and one-half feet. Its breadth is greatest at the cecum, and from this, with the exception of a dilatation at the rectum, it gradually decreases to the anus. At the cecum it measures, when distended about three inches in diameter; beyond this it gradually diminishes and measures only one and one half inches, or less, in the descending, iliac, and pelvic divisions of the colon. The iliac colon has no mesentery, whereas the pelvic colon has a well developed one. This permits a wide range of movement. It usually crosses the pelvis from right to left, then bends backward and returns along the posterior wall of the pelvis to the median line. The layers of the large bowel are like those of the small; namely, mucosa, muscularis, submucosa, circular muscle, longitudinal muscle, and serosa. The large intestine, with the exception of the rectum and vermiform process, may be easily distinguished by the three longitudinal bands, or taeniae coli, and the appendices epiploicae. The longitudinal fibers of the muscular coat do not form a complete layer continuous all around the bowel but are broken up into these three bands which are about one fourth inch (6 mm.) wide. They begin at the base of the appendix and extend along the surface of the gut at nearly equal distances until the rectum is reached, where they form a continuous layer of longitudinal muscle fibers. Since the taeniae are one-sixth shorter than the intestine to which they belong, the bowel is thrown into sacculations.

Three rows of saccules are thus produced along the length of the bowel between the longitudinal bands. If the taeniae are dissected off, or their contractile power is reduced under anesthesia or post mortem, the sacculation is largely lost. On the inside of the bowel the saccules give rise to pouches (haustra) separated by crescentic folds (plicae semilunaris coli) which correspond to the creases on the outside separating the saccules.

The taeniae lie on the anterior, posterolateral, and posteromedial side of the gut. The appendices epiploicae lie chiefly on either side of the anterior longitudinal band. Here diverticula are frequently encountered. On the transverse colon the arrangement

appears differently, but if it is turned up on the abdomen, the bands are in the same position. However, as seen within the abdomen, the anterior taenia becomes the posteroinferior (taenia libera) and the posterolateral becomes the anterior (taenia omentalis), whereas the posteromedial becomes the superior (taenia mesocolica). The posterolateral taenia of the iliac colon passes below to the front of the pelvic colon and rectum and unites with the anterior taenia to form a broad band which occupies nearly the whole width of the bowel. The posteromedial taenia spreads out in a similar manner on the back, so that the lower portion of the pelvic colon has almost a complete longitudinal layer, except a narrow margin on each side. Here the circular muscles come to the surface, and sacculations, although small, are present. These disappear as the rectum is approached, and the longitudinal muscles are thicker.

The blood vessels of the large bowel enter from the mesentery along the mesenteric side of the lateral and medial posterior taeniae and also some small vessels between them. Since the longitudinal muscle is incomplete, the vessels lie rather superficially between the posterior and anterior longitudinal bands beneath the serosa. This accounts for the enormous distention which is possible in the large intestine without complete interference of the blood supply, as compared with the relatively small amount of distention tolerated in the small bowel where the vessels are covered by both circular and longitudinal muscles.

Diverticula are frequently found where the blood and lymph vessels enter or leave the bowel, for it is here that the circular muscle is defective and the area of least resistance is created. Since the veins are larger than the arteries and are easily distended by passive congestion, this opening rather than the arterial is probably at fault at the onset, although there is no proof of this.

Motor Activity of Large and Small Intestines.—The large bowel is innervated by the sympathetics and parasympathetics (craniosacrals). The former is inhibitory and the latter stimulative, while the sphincters (ileocolic, internal, and external anal) are contrarily innervated; that is, the motor nerve to the sphincters is through the sympathetics, and the parasympathetics are inhibitory. Therefore, stimulation of the parasympathetics increases bowel tone and causes relaxation of the sphincters, whereas stimulation of the sympathetics inhibits intestinal activity and causes a contraction of sphincters (reciprocal innervation or contrary innervation), although the external anal sphincter is also under voluntary control.

Due to this dual mechanism and also to the rhythmical property of intestinal muscle itself, certain movements are seen in the large bowel. There is little movement in the cecum and the fecal mass is propelled by (a) passive overflowing of the cecum and (b) slow ill-defined contractions. Although some antiperistaltic waves have been seen in lower animals, this has not been observed in man.

The rest of the large bowel, unlike the small, does not show antiperistaltic, segmenting, or to-and-fro pendulum like movements. Even peristalsis is ill-defined. There is contraction of the circular muscle showing the sacculations and, in the transverse colon, some weak movements and alternate shortenings and elongations. By far the most important motor action of the large bowel is the mass peristalsis which sweeps the contents for some distance. This corresponds to the "rush" wave of the small intestine. It is said to occur not more than two to three times in twenty-four hours, and the subject is normally unaware of it. Sometimes it is initiated after eating (gastrocolic reflex) and, no doubt, psychic influences affect this.

The wave usually begins in the hepatic flexure and the colon loses its haustral markings. The fecal mass is moved into the pelvic colon, which acts as a storehouse, and then the haustral markings reappear. The ascending, transverse, and descending colon are usually empty, except when transferring feces, and the pelvic colon fills from below, upward. It is evacuated through the rectum and anus by defecation. The rectum is also empty except preceding and during the act of defecation.

When the fecal mass fills and distends the rectum between 40 and 50 mm. Hg, the defecation reflex occurs. This is as follows:

1. Strong peristaltic contraction of the colon.

2. Shortening of longitudinal bands which are indirectly fixed to the rectococcygeus muscle.

3. Relaxation of sphincters.

4. Voluntary contraction of abdominal muscles and fixation of diaphragm in inspiration, causing a rise in intra-abdominal pressure. This depresses the ascending, transverse, and splenic flexure of the colon. The fixed cecum becomes globular, and the intrarectal pressure, which is normally 20 mm. Hg, may rise to 100 to 200 mm. Hg during straining. The levatores ani, transversi perinei, and coccygeus muscles prevent prolapse, and the former actually pull against the descending force.

Leading from the intestine are lymphatics and lymph nodes, which lie in the mesentery, close to the arteries and veins. The portal vein carries the absorbed food products to the liver to be stored as glycogen or to be detoxified, whereas the lymphatics (lacteals) carry their emulsified fat to the blood by way of the thoracic duct. The situation of lymph nodes is important to the surgeon because of their frequent involvement in carcinoma.

The entire gastrointestinal canal is in a state of continual motion (peristalsis), carried on by the muscular layers of the bowel, with stronger waves at the upper and weaker at the lower end of the small bowel. In the small intestine there are waves producing a to-and-fro churning action and "rush" waves going straight downward; there are reverse waves in the ascending colon, forward waves in the transverse and descending colon, and strong waves in the sigmoid, which are felt as a desire to defecate.

Many other conditions affect the peristaltic movements and the progress of the fecal stream to the small and large intestine. The valvula coli (ileocecal valve) has been the subject of much study, and many theories have been advanced as to its structure and function. These are (1) that the ileum is separated from the cecum by sphincter muscle and (2) that the cecum is separated from the ileum by a valve. Probably both of these theories are correct. The ileocecal valve attains development late in fetal life and often does not develop completely until after birth. Consequently, there is a great variation in its structure and also in its function as a result of its structural differences. Perhaps the adequacy or inadequacy of the ileocecal valve function is best explained on the basis of arrested development. As a rule, when fully developed, the valve is represented by two transverse folds lying above and below its orifice and constituting the two segments of the valve. These are known as labii and resemble a small intussusception. These labii are formed of an infolding of all coats of the gut except the peritoneum and the longitudinal muscle layers and are covered by the mucosa of the ileum and cecum on their respective surfaces. The two valve segments are elevated and slightly approximated when the cecum distends. The more distended the cecum becomes, the tighter will be this approximation. The cecum must become distended for the valve to function. The valve is very strong and is almost as thick as the intestinal wall. Therefore, it would be able to withstand more pressure than the cecal wall itself. The importance of the ileocecal valve is seen in the distention of the large intestine caused by obstruction distal to the ileocecal valve. The use of the Levine tube or the Miller-Abbott tube, as is well known, will decompress the small intestine but not beyond the ileocecal valve, where decompression must be done by cecostomy or transverse colostomy. However, in children where the valve is not always fully developed, this does not necessarily hold true. A Miller Abbott tube will very often decompress the large bowel as well as the small intestine. A good rule to follow, then, is that in the case of obstruction below the ileocecal valve, some form of decompression other than the Miller-Abbott tube should be used in order to avoid the possibility of a perforation of the cecum. This is usually a cecostomy or transverse colostomy, depending on the site of large bowel obstruction.

Other practical observations concerning intestinal motility before and after operation and its relation to postoperative distention have been described. The contrary type of motility between the small and large bowel has been noted when the small bowel is vigorously contracting and the colon is inactive. Conversely, when the colon contracts, the small intestine appears to be inhibited. Those drugs including the opiates, physostigmine, Prostigmine methyl sulfate, and the derivatives which stimulate the motility of the small bowel appear to inhibit the motility of the colon. Posterior pituitary gland solutions and Pitressin produce powerful contraction of the colon but diminish the motility of the small bowel. In addition, Pitressin has a restrictive effect on smooth muscle and therefore is not used postoperatively because of the danger of coronary occlusion and other types of vascular occlusions which might occur within the abdomen or the extremities. Postoperative distention may be due to the action of morphine on the colon. The effects of heat and cold on the bowel are variable. It has been said that cold increases peristalsis and tonus of the stomach and bowel when applied externally and that cold causes a sharp rise in the gastric acidity. When applied internally by drinking ice water, the reverse effect is produced. Heat applied externally decreases tonus and peristalsis and when applied internally by drinking hot water, increases tonus and peristalsis. This has been discussed previously. (See Chapter 5.) However, these results are not invariable because the state of tonus and motility of the gastrointestinal canal is constantly varying, and the effect of cold on gastric motility may be dependent on the state of tonus at the time that the temperature has been lowered. Perhaps the comfort of the patient should determine whether or not hot or cold applications are best. However, there is enough experimental evidence to show that the effects of heat upon the blood supply to the bowel is that of dilation, and since it conceivably does tend to tone down peristalsis or activity, it would be useful in the treatment of an inflammatory disease of the abdominal cavity. Furthermore, usually the patient is more comfortable with heat than with cold, although after a while, cold so completely freezes the part that it becomes more or less insensitive to pain.

Gaseous Distention.—The causes of gaseous distention of the gastrointestinal tract has been the subject of long and arduous investigation. The gas in the intestine is there for the following reasons: (1) aerophagy or swallowing of air, (2) air sucking or air suction, (3) fermentation, and contrary to popular opinion, it is probably least important, (4) gas from the blood, and (5) the gas which is in the intestinal tract does not move forward due to some failure in the motility. In the normal adult, scout films of the abdomen usually reveal very little gas in the small bowel. Most of it is in the colon. This may be due to the greater ability of the small bowel to absorb gases or to pass them on into the colon. Some of the gas in the intestine is probably excreted from the blood. In children, however, this is not true, particularly in the infant. Here the small bowel often contains much gas. The gas which is ordinarily found in the flatus usually contains very little carbon dioxide or oxygen because these gases are easily and rapidly absorbed from the bowel and thrown out through the lungs. In herbiverous animals large amounts of gas are constantly being taken up by the food as it passes through the wall of the stomach and the cecum. Therefore, any condition which interferes with the return of venous blood from the intestine is likely to produce gaseous distention. Pneumonia, which interferes with the passage of gas from the lung, produces gaseous distention. This is also true of cardiac inadequacy or cardiac failure. Here, however, not only is gas not returned to the heart and thereby to the lungs for excretion, but due to the passive congestion there is diminished peristalsis so that gas is not carried forward. All other gases such as methane, carbon disulfide, in addition to carbon dioxide and oxygen, are absorbed, but nitrogen is poorly absorbed. Since four-fifths of ordinary air is nitrogen, the inhalation of pure oxygen may displace the nitrogen, thereby relieving intestinal distention.

Belching has been described and discussed previously in the chapter. Bloating has such a great and enormous variety of causes that many of them are intangible or

not discernible. Also, many patients complain of a false sense of flatus, and examination fails to reveal any abdominal distention. Constipation gives this feeling and yet it is not due to gas but rather to the mechanical distention of the rectum which gives the false sensation. However, constipation may act in the form of an obstruction so that gas may actually be trapped and there may be a great amount of gaseous distention. Therefore, flatus or flatulence, as it has been called, may be innocent or it may be extremely serious as it is seen postoperatively or in intestinal obstruction. For example, the causes may be as follows: the eating of certain foods which irritate the mucosa of the bowel and interfere with passage of gas through it or into the blood, food allergy and food overeating, anxiety or pain, cholecystitis, cold and upper respiratory infections, diarrhea in which the large bowel is constantly being emptied, and due to the contrary impulse, if there be such a thing, the small bowel is distended. The same picture is true of patient with the so-called irritable or sensitive colon. Along this same line, hemorrhoids or fissures or any other inflammation about the anus may produce an obstructive accumulation of gas. This may be due to a reflex spasm of the sphincter muscles, and in this way gas may be formed. Also the presence of a mild peritoneal infection should be considered; also, rarely, the cause of gas is due to intestinal parasites. The surgeon is particularly interested in the obstructive phases which may be the cause of flatulence. Before passing on to this consideration, it should be mentioned that vitamin deficiency has produced various gas patterns, some of which can be discerned by the expert roentgenologist who is familiar with this type of deficiency. This is particularly true of vitamin B deficiency.

Since most of the gas present in the gastrointestinal tract reaches the canal by air swallowing or by air suction, surgeons have resorted to the Levine tube or the Miller-Abbott tube to decrease pre and postoperative distention. In fact, many surgeons use the tube routinely following surgery.

Thus we see that the gastrointerocolic canal is a very complex system which makes life possible through its enzymes, which in turn are secreted because of nervous and hormonal influences; among the latter are "gastrin" to stimulate gastric secretion, prosecretin and secretin to stimulate pancreatic secretion, cholecystokinin to stimulate gall bladder evacuation, enterogastrone to inhibit gastric secretion, hydrocrinin to stimulate intestinal secretion, enterocrinin to stimulate the intestinal glands, duodenin to aid in carbohydrate metabolism and also to stimulate the islands of Langerhans. Also through these secretions digestion is maintained. The absorption of the digestive food products is made possible through their simplification and rapid absorption through the forces of selective absorption as well as osmosis dialysis. Last, we have seen that the bacteria in the large intestines are able to synthesize the vitamin K, and it has been thought by some that it may even help in the synthesis of thiamine, riboflavin, pyridoxine, pantothenic acids, and nicotinic acid.

STOMACH AND DUODENUM

Diseases of the Stomach and Duodenum

Diseases of the stomach and duodenum are either functional or organic. Perhaps functional disease paves the way for organic, especially in the case of peptic ulcer.

Congenital Anomalies of the Stomach and Duodenum

Congenital anomalies of the stomach and duodenum may be divided into (a) duplications, (b) diverticula, (3) atresias, (d) stenosis, (e) nonrotation and malrotation.

Duplications.—Duplications of the stomach and duodenum are rare. Several theories have been put forth as to the origin of these conditions. The most probable of the theories advanced has been that of Lewis and Thyng who found diverticula in various parts of the fetal alimentary tract of the pig, rabbit, cat, sheep, and man. They found that the outpocketings are most often seen in the ileum, and this corresponds to the greater frequency of duplications in this part of the alimentary canal. The duplications in these parts have been given many names in the past. They were formerly described as enterogenous cysts, enteric cysts, ileum duplex, giant diverticula, occlusion cysts, or duplications of the alimentary tract. It is perhaps best that we use the term duplications because this in reality is what they are. The duplications are found anywhere along the gastrointestinal tract, and since this discussion is limited to the stomach and duodenum, we shall discuss at this point only duplications of the two portions mentioned.

The abnormality which is present gives rise to the large sac filled with clear, colorless, mucoid substance which has been secreted by its own membrane. Very often this secretion is entrapped under a very high pressure and may induce necrosis and even sloughing of the lining membrane. At times the fluid becomes hemorrhagic. This may be due to local ulceration. If there is an opening into the bowel, duplication contents are similar to those of the intestinal canal. Sometimes the duplication has a separate blood supply; usually, however, the blood supply is the same as the organ which is duplicated. Therefore, it very often becomes necessary to remove both the duplication and the original normal structure. Duplications look very much like mesenteric cysts; however, the latter are lymphatic in origin. They have a thin wall and they can usually be shelled out from the adjacent viscera and from the mesentery, as a rule. The duplication has a thick, muscular wall and, as has been said, is usually very densely attached to the parent structure.

The symptoms and signs of duplication may vary; usually, however, they may be classed under three categories: (1) Those that resemble partial obstruction of the bowel; in addition, a mass can be felt; (2) those in which there may be pain due to the enormous amount of fluid present; (3) those which may press upon mesenteric blood vessels and produce necrosis, sloughing, and bleeding in the adjacent intestine. In the latter instance, of course, there is usually an opening which has been present or a new one which has been made, due to necrosis. Duplications of the stomach cause symptoms of epigastric fullness and discomfort. However, the majority of duplications cause colic and pain, vomiting, visible peristalsis, and all the other symptoms and signs of intestinal obstruction, partial or complete.

The diagnosis is made by a study of the symptoms and signs, and the fact that the condition is present in a child, a barium enema and barium meal give valuable information. Since the cystic structure in the intestines has a common wall at one point and usually the two cannot be

separated from one another without injuring the bowel and also since the arteries and veins of the contiguous portion of the alimentary tract usually course over the surface of the cyst, attempts to resect the cyst alone will be fraught with danger unless the blood vessels are interrupted; if they are, gangrene of the normal component occurs. Because of these conditions, operation usually consists of resection of the duplication as well as the parent organ. However, in the case of duplication of the stomach, Ladd elected to open the cyst and resect it and marsupialize the remaining portion. In some cases of duplication of the rectum and even duplication of the colon, it is possible to remove the cyst without removing the attached bowel. In practically every case that we have seen, the attachment was so close that the bowel wall was injured and had to be repaired.

Diverticula.—Diverticula may occur anywhere along the gastrointestinal tract as well as in the pharynx and esophagus. Diverticula also appear in the lower bowel, and the most common type is Meckel's diverticulum which will be discussed later. Diverticula of the stomach and duodenum also occur and may give rise to many symptoms. Diverticula of the stomach and duodenum may be classified as true or false. The true diverticula are those that contain all of the coats of the normal bowel. The false diverticula are those that occur as a result of inflammation or ulceration with the formation of a pouch which is made up of part of the coat of the bowel.

The symptoms and signs of diverticula in the stomach and duodenum are usually due to inflammation in the diverticulum. The changes within the diverticulum due to this inflammation may actually cause gangrene or perforation and peritonitis. If the diverticulum is inflamed without any of the results mentioned, the symptoms may be those of peptic ulcer in the stomach or duodenum. The diverticulum is diagnosed by careful x-ray examination with barium meal.

The treatment of the diverticulum consists of its removal. Several methods are available to the surgeon. Some authorities have recommended that the diverticulum be turned in. Since the penetrating vessels that surround it are tied, the sac will ultimately slough or cause its obliteration. It is better, however, to remove the diverticulum and close the opening. Cysts of the duodenum, as they have been called, are usually diverticula. The cysts may be enucleated or completely excised with the removal of the parent portion of the alimentary canal. The latter is difficult in the duodenum and would require, if near the ampulla of Vater, transplantation of the common bile duct. In most cases, however, it may be removed safely and the edges sutured. Should the bowel require resection, a posterior gastroenterostomy may be done or continuity established by anastomosis of the divided ends.

Atresias.—In our previous discussion concerning the embryology of the fore-gut, we have seen that the intestine goes through a so-called solid

phase. This is also true of the duodenum, and it is probably occasionally true of the stomach. The atresias of the intestine will be discussed later in the chapter. At this time we should point out that the atresias may be in the form of a diaphragm or a veil which completely blocks the lumen, or in the intestine it may end in an absolutely blind end with no continuity of the bowel except perhaps a very thin fibrous strand which may join the two ends together. The condition of atresia is distinguished from that of stenosis; the latter type implies a partial type of obstruction and will be discussed next.

The stomach is originally a straight tube which enlarges on its posterior side faster than on its anterior surface. As a result, this dorsal enlargement sags and becomes the greater curvature. The organ then rotates on its axis to the right; the right side becomes the posterior, and the left side becomes the anterior surface of the stomach. In the same way the anterior wall becomes the lesser curvature, and, as has been stated, the posterior surface becomes the greater curvature. This explains the innervation of the anterior surface by the left vagus and the posterior by the right vagus nerve.

Originally the stomach is laid down around the mesenteron, which is mucous membrane; then the mesenchymal elements surround this, and, last, the mesothelium covers it. It is easy to understand, therefore, that any one of the layers of the stomach may be involved in a congenital deformity. First, obstructions of the stomach in young children are usually encountered in the pylorus. This lesion is known as congenital hypertrophic pyloric stenosis. It is easily identified by its characteristic clinical symptoms and signs. Second, the pylorus may be narrowed without hypertrophy, a state which is infrequently encountered because it rarely gives sufficient symptoms in the child to warrant operation. Third, the stomach may be occluded by hands or adhesions in the outer layers. Last, the stomach is rarely obstructed by intrinsic or extrinsic tumors or cysts.

We have seen two cases of obstruction in the stomach due to a prepyloric membrane. Touroff and Sussman reported a case which resembles ours and which they state is the first to be reported in an infant. The literature reveals only two or three cases comparable to ours.

The history of our first case shows that the child apparently had no symptoms until three weeks before admission, and, therefore, the lesion was not related to a hypertrophic pyloric stenosis which usually is seen in about the sixth or eighth week of life. It is inconceivable that this diaphragm could have grown to its present size and thickness in three weeks; therefore, the lesion has probably been present since birth or shortly thereafter. Complete obstruction occurred while the child was in the hospital. The boy's vomitus contained no bile. There was little distention, and there were infrequent bowel movements of the starvation type; however, these contained bile. We concluded from this observation that the obstruction was above the ampulla and that the gastrointestinal tract

below the site of the occlusion was clear. *At operation, the diaphragm* was found to be approximately an eighth of an inch thick, and it was covered with mucous membrane on each side. The pylorus was patent and no other defects could be demonstrated. Accordingly, the diaphragm was divided down to its lumen which barely admitted the tip of a hemostat. The *incision* was made longitudinally and was closed transversely in the manner of Heineke-Mikulicz's pyloroplasty. The diagram illustrates the type of operative procedure. The child made an uneventful recovery and *his check-up films demonstrate that he has been entirely relieved* of his obstruction.

Atresias of the duodenum have been encountered more frequntly. Usually *the atresia is due to a persisting membrane or veil rather than a*

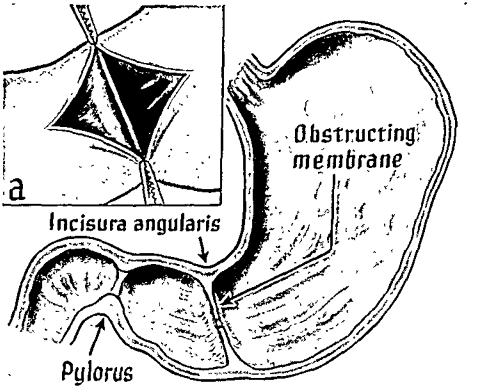

Fig. 272.—Diagram illustrating a very rare condition—prepyloric membranous obstruction. This was in a white boy 2 years of age who came to the hospital complaining of persistent vomiting. In the week prior to our examination he had had no bowel movements and enemata had been ineffectual. X-ray examination *showed* a greatly dilated stomach, due chiefly to gas but also to a large volume of fluid and food. Peristaltic waves were weak and ineffective. Two hours after the barium meal all of it was retained in the stomach and twelve hours after *ingestion there* was about 20 per cent retention. At operation the rare condition known as prepyloric membranous obstruction was encountered. Although this is not a complete obstruction, it was sufficient to produce *the symptoms and signs of a pyloric stenosis* from which it must be differentiated in the early weeks of life. However, at 2 years of age the diagnosis of *some* other anomaly must be entertained.

The cause of this obstruction is said to be due to the fact that in embryos thirty to sixty days vacuoles appear in the walls of the gastrointestinal tract, and *epithelial* septa completely block the lumen for a short period. Sometimes these septa persist and an obstruction results, but such membranes are rarely found in the stomach. There have been only two or three such cases reported so far as we are aware. *The* diagram illustrates the condition which was found and the manner in which it was corrected. *a.* Much of the membrane was removed through a longitudinal opening in the stomach and then the stomach was *closed in a transverse manner. The* child made an uneventful recovery. (After Berman and Ballinger: Quart. Bull. Indiana Univ. M. Center 4: 14, 1942.)

blind end which is seen in the lower ileum. The condition manifests itself by *the usual signs and symptoms of obstruction*; however, the vomitus is different than in the prepyloric or pyloric obstruction in that it contains bile. Distal to the obstruction is a small bowel which contains no gas and which has only within its lumen a few shreds of mucous cells which have been cast off. Proximal to the obstruction the bowel is greatly distended and sometimes reaches 3 to 4 cm. in diameter. Because of this great distention, necrosis and perforation may occur. The *meconium in intestinal atresia* has been of great value in suspecting the diagnosis, and this will be discussed later in dealing with obstruction lower down. However, it might be said here that in a normal child, meconium is composed of dead cells from the intestinal lining, various secretions from the stomach, intestines, liver, and pancreas, and material from the amniotic fluid which the baby is said to swallow in utero.

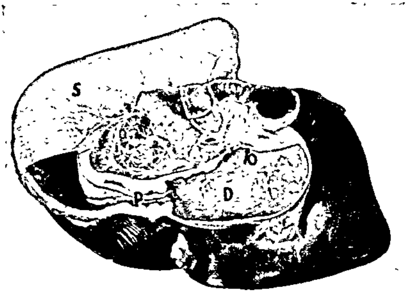

Fig. 273.—Congenital obstruction of the duodenum (second portion) due to atresia. *S*, stomach; *P*, pylorus; *D*, duodenum; *O*, obstruction. Forty-eight-hour-old infant. Death occurred before operation could be done.

Among the constituents of amniotic fluid is vernix caseosa and squamous epithelial cells, which are sloughed from the skin. The meconium of the normal baby, therefore, contains cornified epithelial cells which passed through the intestinal wall. In an atresia, of course, the intestine or colon will not allow them to pass beyond the obstructed point. Therefore, Barger has called attention to the fact that a specimen of meconium may be examined and a smear made on a glass slide. If this is washed with ether, then stained with Sterling's gentian violet, and then decolorized with acid alcohol, the decoloration removes the dye from all of the specimen except the cornified epithelil cells. In any newborn child with

intestinal obstruction, the absence of cornified epithelial cells in the meconium is a presumptive evidence of the atresia. However, the vomiting which contains bile, x-ray showing the pattern of distended bowel, and other clinical signs, such as distention above, will usually be sufficient to point to the correct diagnosis and, moreover, to the site of obstruction. Abdominal distention is present in a baby even though the obstruction is high. However, in duodenal obstruction this distention will be limited to the epigastrium, whereas in the obstruction lower down, the distention is very great, involving the whole abdomen. It has been our custom not to give barium by rectum if an obstruction low down is suspected. The barium enema will give valuable information in making the diagnosis and in excluding such anomalies as malrotation low down and diaphragmatic hernia. The presence of fluid within the abdominal cavity may be suspected from the x-ray films, particularly in babies, because of the separation of the bowel loops.

The treatment for atresia is prompt surgical intervention. The newborn stands operation well if a Levine tube is placed in the stomach and the baby's fluid balance is taken care of. The atresia usually requires resection, and this should be done under general anesthesia. The method of surgical treatment usually consists of division of the bowel and lateral anastomosis. If the bowel is obstructed by a membrane, this may be divided. However, in our experience, this has been extremely rare. If an atresia is single rather than multiple, the prognosis is fairly good. In the duodenum atresias are best treated by doing a duodenojejunostomy or an extremely high posterior gastrojejunostomy. The duodenojejunostomy is usually retrocolic as is also the gastrojejunostomy. Ileostomy is not tolerated by the newborn at all. If the ileostomy is done close to the ileocecal valve, there is a chance providing secondary operation is done within two or three days.

Stenosis.—The term stenosis is used to imply an incomplete obstruction, and this, too, may be due to a persistence of a vein such as we previously described. Stenosis of the bowel are not uncommon in the duodenum.

The symptoms and signs in early cases are, therefore, those of a partial obstruction, and there will be vomiting which will be persistent, some abdominal distention, loss of weight, and diminished number and size of stools. The vomitus is colored green because it is below the ampulla of Vater. However, occasionally the obstruction may be above the ampulla of Vater, and in these cases the stenosis resembles pyloric stenosis which will be discussed subsequently. In the older babies the symptoms and signs will be those of partial obstruction. The baby has difficulty in getting along with his diet. There is more or less persistent vomiting and failure to gain weight; dehydration takes place, and in most instances the baby has a progressively downhill course. However, some children may live on for long periods of time, not gaining and yet not losing,

simply because a small amount of food gets through the partial obstruction. In children, large peristaltic waves are easily detected, and in the duodenum the distention may be very great. X-ray examination, of course, aids greatly in making the diagnosis, although even here sometimes it is difficult, unless the obstruction is in the second portion of the duodenum, to distinguish between this lesion and that of pyloric obstruction.

The treatment is surgery, and the operation should be an anastomosis between the obstruction and an unobstructed portion of the bowel. In the case of the duodenum it will be a duodenojejunostomy unless it is very high. In such cases a posterior gastroenterostomy is indicated.

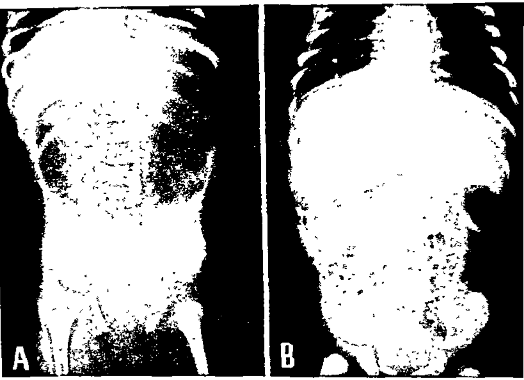

Fig. 274.—Congenital stenoses of duodenum. This was the case of a child, 6 weeks of age, who came to the hospital vomiting everything taken. *A*. X-ray photograph which clearly demonstrates the enormous dilation of the stomach and the first portion of the duodenum. This child was operated upon and the condition was found to be a stenosis of the duodenum at the junction of the first and second portion due to fibrosis of the wall of the duodenum The first portion of the duodenum and the jejunum were brought together with a side-to-side anastomosis anterior to the transverse colon. This child made an uneventful recovery. *B*. Postoperative films showing gas throughout the alimentary canal. (Case referred by Dr. William Browning.)

Nonrotation and Malrotation of the Intestine.—Although this subject belongs more properly to the midgut, we shall discuss it at this time since errors in rotation frequently produce obstructions to the duodenum, due to adventitious bands or adhesions.

Since the mid-gut shows the most complex developmental arrangement, congenital anomalies are most common in this region. The mid-

gut in its earliest development is a convex loop with its end attached to the duodenocolic isthmus and supported throughout its length by a common dorsal mesentery. In this mesentery runs the superior mesenteric artery. Until the end of the third week the mid-gut communicates with the yolk sac through the vitello-intestinal duct, but after this date the duct should normally close. Should it not do so or should its attachment persist, an anomaly commonly known as persistent vitello-intestinal duct and Meckel's diverticulum may occur. During the fifth week, as a result of the rapid growth of the midgut, it is extruded as a partly herniated loop through the umbilical orifice so that the liver may have room to enlarge. Between the fifth and tenth weeks, while the loop is herniated, rotation begins, and it is in this stage that variations may occur.

The intestine in this stage appears as a loop with a pointed dome, to which is attached the vitelline duct. There is also a lower projection which is to form the ileocecal juncture. This is seen as a sagittal protrusion. Rotation proceeds in a counterclockwise manner, and by the end of the tenth week a return of the extruded loop is begun back into the abdomen.

Since all the intestine cannot return at the same moment, it is supposed that the portion of the mid-gut which forms the duodenum and jejunum returns first and then the cecum and ileum follow. The last portion of the ileum to return carries the superior mesenteric artery with it, and its return is followed by the cecum and adjoining colon. Since this is true, it is apparent that the duodenum will cross behind the superior mesenteric vessels near their origin, whereas the colon will cross the same point anteriorly. Upon entering the abdomen, the ascending colon first lies upward and toward the left and has the ileum entering it from the right. Then it begins its rotation toward the right and downward so that it may come to lie in its normal position. After the tenth week there is some progress of rotation, and this continues to the time of birth and even later. Finally the mesentery becomes fused and is attached to the posterior abdominal wall.

In summary we may state that this process of development of the mid-gut to allow for its own rapid growth as well as the growth of the liver is fraught with danger and may be conveniently divided into three stages: the first stage, from the fifth to the tenth week, while the loop is herniated; the second stage, during the tenth and eleventh weeks, while the loop is rotating and going back into the abdomen; and the third stage, from the eleventh week until birth or even later, while the loop becomes fixed in its normal position and the mesenteries fuse. Dott has summarized the dangers of these stages as follows: During the first stage extroversion of the cloaca may occur. This implies that not only rotation is interfered with but that development of the mid-gut and hind-gut is imperfect. This anomaly is therefore incompatible with life and not of surgical importance.

During the second stage we find most of the errors which are encountered in surgery. These are listed by Dott as:

1. Nonrotations of the mid-gut loop in which the small intestine lies chiefly to the right of the midline and the cecum lies in the left ileac fossa or in the pelvis and is reversed so that the ileum enters it from the right. The ascending colon passes upward and to the left. The importance of this is that adhesions may adventitiously produce obstruction, and the small intestines and the proximal half of the colon remain suspended by a narrow pedicle (the duodenocolic isthmus).

2. Reversed rotation of the mid-gut loop. Instead of a counterclockwise rotation, as we have previously described, there may be a clockwise rotation through an extent of about 90 degrees. This would put the transverse colon behind the mesenteric artery and the duodenum in front. The intestine would otherwise be in a normal position except that its anterior and posterior surfaces would be reversed. The importance of this is the possible obstruction of the transverse colon.

3. Malrotation of the mid-gut loop. A variation of disorders may occur as a result of this error. For example, the small intestine may pass in front of the vessels to lie on the right side. This puts the cecum into a high position in the region of the pylorus so that the duodenum and ileum lie close together.

On the other hand, the small intestine may remain entirely on the right side of the artery where again the cecum and ascending colon are prevented from reaching the right ileac region and, of course, this would retain a long primitive mesentery. The practical importance of these arrangements is the liability to volvulus.

Based upon this study, Fraser has listed the congenital errors of the mid-gut as follows:

1. Congenital atresia
2. Congenital diverticula or fistula
3. Errors of rotation (congenital volvulus)
   a. Extroversion of cloaca
   b. (1) Nonrotation of midgut loop
      (2) Malrotation of mid-gut loop
   c. Local displacements

Causes of Errors.—Although no one can definitely state the causes of these errors, many explanations have been advanced. The following causes of errors in rotation have been suggested:

1. Errors occur at the site of embryological events such as obstruction where the anus (proctodeum) and hind-gut meet or where the mouth (stomodeum) and fore-gut meet or where the vitello-intestinal duct enters the mid-gut.

2. Vascular defects due to pressure on the arterial blood supply, such as duodenal obstruction from anomaly of mesenteric vessels.

3. Defective rotation as described by Dott. *Variations in size of the umbilical orifice may account for errors in rotation.*

4. Prentiss states that in embryos of *thirty to sixty days vacuoles* appear in the wall of the duodenum. *These epithelial septa completely* block the lumen. The remainder of *the small intestine remains open, although* vacuoles form in its epithelium. *Sometimes this impervious duodenum* of the embryo may persist as a *congenital anomaly. Simpson* speaks of this as the segmental *arrest of development during certain* known periods of embryological *sequence of events, such as tenth week* of fetal life, when the duodenum *and certain other portions of the intestinal* tract are practically solid *from proliferation of the lining epithelium* too rapidly for the increase in diameter of the gut.

5. Fetal disease (peritonitis) *or faulty development of the sympathetic* nervous system according to Davis and Poynter.

6. Hale has produced anomalies *in pigs experimentally* by withholding vitamin A in the mother's diet at certain periods of gestation.

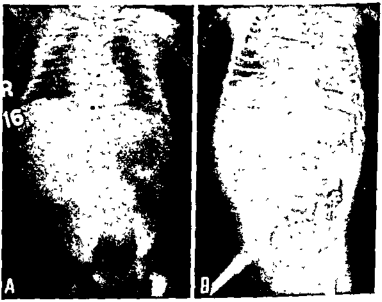

Fig. 275.—Malrotation. X-ray photographs of an infant, 5 days old, who had vomited since birth.

A. Scout film before surgery. The gas pattern is all on the left side; the stomach and duodenum are dilated. *B.* Lipiodol given by *mouth before operation.* Most of it is returned in the stomach. Note dilated duodenum. Only a small amount trickles through into loops of small bowel.

There had been an occasional passage of meconium. There was much distention and peristaltic waves could be easily detected going in various directions across the upper abdomen. Preoperative diagnosis was malrotation with obstruction of the duodenum due to *bands.* At *operation upon opening the abdomen* the ascending and transverse colon presented. There was great distention of the duodenum and stomach. *An obstruction was found in the second portion of* the duodenum due to direct pressure from the bands which connected the undescended mid-line cecum to the lateral wall of the abdominal cavity. The ileum entered the cecum from right to left. The duodenal obstruction was evidently due to the bands and also to the cecum which immediately overlay the third portion of the duodenum. The peritoneum was incised and the bands were divided, permitting the cecum to be transferred to the left side. After this was accomplished, the obstruction was released. The anatomical arrangement following operation was as follows: the duodenum descended in a straight line into the jejunum and was not covered by the posterior peritoneum. The ileum entered the cecum from right to left. The cecum was on the left side of the abdomen and the colon ascended on the left, and then by sharp curve it came down as the descending colon and sigmoid. After operation the child was entirely relieved of his symptoms. (Case referred by Dr. S. Kauffman.)

Method of Diagnosis.—The diagnosis of congenital anomalies of the small intestine is not always a simple matter. The clinical signs of obstruction may be variable and although vomiting, distention, absence of stools, and borborygmus are the cardinal signs, these may not be apparent early. For example, high obstruction is accompanied by early vomiting and little or no distention, and stools occur until the bowel below the obstruction is empty, whereas in low obstruction, vomiting is very late, and distention and absolute constipation early. Then, too, multiple lesions may be present. Careful roentgen ray examination by the barium enema, together with examination and manipulation of the abdomen under the fluoroscope, and shifting gas pockets, as described by us, aid greatly in locating the site of the lesion.

Farber emphasizes the value of studying the epithelial cells in the meconium. He states that the presence of such cells aids in the differential diagnosis by ruling out obstruction. Farber states that the absence of cornified cells in smears of meconium is proof of congenital atresia of the alimentary canal. Meckel's diverticulum without a patent omphalomesenteric duct may defy preoperative diagnosis.

Ladd has described two types of malrotation which are most commonly encountered. (1) Obstruction of descending duodenum with incomplete rotation of the cecum. One finds this organ just below the distal half of the stomach and bands of reflected peritoneum running from it or the ascending colon to the right posterolateral part of the abdominal wall. These bands run across the descending portion of the duodenum and obstruct it. Sometimes the cecum has proceeded farther, but as yet has incompletely rotated so that it lies directly over the duodenum. (2) Volvulus of the mid-gut. The mesentery of the small intestine lacks its normal fixation so that it has only a short rudimentary attachment just below the origin of the superior mesenteric artery.. When the intestine from the duodenojejunal juncture to the transverse colon is thus supported by an incompletely anchored mesentery, there may be a volvulus of the entire midgut. This rotation takes place in a clockwise *direction. Volvulus and an obstruction of the duodenum may be present* at the same time. Consequently it is well to speak of these two conditions together. With these lesions, of course, there will be great distention or dilation of the duodenum. If there is volvulus of the mid-gut, then the jejunum and ileum will be collapsed at first because duodenal contents cannot enter this obstructed segment. Later, however, there may be some gas in the obstructed portion of the bowel, due to local bacterial growth. The chief symptom of this condition is vomiting. The vomitus contains bile, but it is early and persistent. Distention is not very great because only the duodenum and stomach are dilated. It is, therefore, limited to the epigastrium. Dehydration takes place very rapidly, and fever which is probably due to dehydration occurs. In older children there is abdominal pain, nausea, vomiting, and symptoms and signs of partial obstruction. Hence, in these older children there is ab-

dominal distention, poor absorption of food, and intolerance to certain substances. The diagnosis of celiac disease may be erroneously made. However, the complaints which have been enumerated may be brought about by twisting of the mid-gut in a way that the terminal ileum is temporarily or partially obstructed. It is, therefore, important to examine by x-ray all the individuals who have so-called celiac disease. The scant film of the abdomen reveals the distended loop which usually helps in making the diagnosis. A barium meal should not be given as a rule. Barium enema may be used, and it will give a great deal of information, since the cecum is mobile and may be placed in an abnormal position. This is sufficient to make a diagnosis. In partial obstructions, barium by mouth may be administered if weak; however, this too may convert an incomplete into a complete obstruction.

The treatment for malrotations and nonrotations is surgical. There will be two types of lesions which will be encountered, according to Ladd. (1) When the ascending and transverse colon present and there is a duodenal obstruction. Here the obstruction of the duodenum results from direct pressure from the overlying cecum or by peritoneal bands which cross over the colon or cecum. This duodenal obstruction is relieved by an operation which was devised by Ladd several years ago. The operation is as follows: The posterior parietal peritoneum is incised just to the right of the cecum which permits clearing of the anterior surface of the duodenum. The cecum is transferred to the left side, and all pressure is thereby taken off the duodenum. No attempt is made to restore the normal anatomical position of the cecum. (2) A mid-gut volvulus; on opening the abdomen, the bluish-colored small intestine will present. The cecum and ascending colon cannot be found and often it appears as though loops of small bowel are herniating through the mesentery of another portion of the intestine. The only way to deal with this situation is to remove the whole mid-gut from the abdomen and place it on warm sponges; then the volvulus can be recognized. It has usually taken place in a clockwise direction and may go through an arc of 360 degrees. The volvulus is reduced by turning the mass in a counter-clockwise direction. As soon as this is done, the normal color returns to the intestine, but this may mislead the surgeon into believing that the operation has been completed. However, the cecum and ascending colon which now lie on the right upper quadrant must be free to transfer to the left just as in the previous instance. This can be rapidly done by incising the peritoneum to the right of the ascending colon. After this is slit, the duodenum will be seen coursing downward in the right paravertebral gutter joining the jejunum. The cecum and colon will lie to the left side of the abdomen. One last congenital anomaly should be mentioned; namely, that of a mobile cecum. Occasionally this produces symptoms because it lacks a normal posterior attachment. If there is a normal oblique attachment to the mesentery, then the mobile cecum can be tacked down posteriorly. If, in addition, the mesentery does not have

a normal posterior attachment, then it is technically easier, safer, and quicker to slit the peritoneum at the right of the hepatic flexure so that the entire right half of the colon shifts over into the left side of the abdomen. We have seen a congenital volvulus of the duodenal jejunal juncture which was treated by rotating the obstructed loop in a counter clockwise direction. We have also seen a malrotation or reverse rotation showing the superior mesenteric artery in front of the transverse colon and the duodenum in front of the arteries. We have also seen a very rare condition in which the transverse colon was behind the superior mesenteric artery, but so was the duodenum.

Congenital Hypertrophic Pyloric Stenosis

Characteristically this disease occurs in infants in the fourth to the sixth week of life. Although the cause of the condition is not known, it usually is in the male child, usually in the firstborn. There is no racial distribution, and heredity does play a role. The condition manifests itself as a pyloric tumor at birth, and although it cannot be felt at that time, the presence of such a tumor is generally agreed upon. It has been known to occur in premature infants and in stillbirths. We have operated upon one child who was born six weeks prematurely. The symptoms and signs of the lesion occurred when he was two weeks premature and we operated upon him successfully while he was at two weeks prematurity. Therefore, in reviewing the pathogenesis of the lesion, we may say that it is congenital. The other important pathogenic factors are work hypertrophy, pylorospasm, and a combination of pylorospasm and work hypertrophy. The pyloric tumor, together with edema of the mucous membrane from the mechanical irritation that has occurred, explains the clinical picture.

The onset of symptoms, usually in the second to fifth week of life, is that of vomiting without bile. This vomiting is not constant, although it is continual. The pathology is as follows: The pyloric sphincter becomes greatly hypertrophied and spindle shaped and fades off into the stomach side *but ends abruptly on the duodenal end.* Microscopically the important finding is the tremendous hypertrophy of the circular, smooth muscle layer, together with an actual increase in the smooth muscle fibers. Sections of the mucosal layer reveal edema and slight leucocytic infiltrations. The symptoms and signs are dehydration, vomiting, weight loss, scanty stools, alkalosis, if the vomiting continues, and peristaltic waves. The waves pass from left to right and are best seen immediately after feeding. Sometimes, while watching such a wave, it ends abruptly and the child vomits forcibly. One must be cautious in making a diagnosis on waves alone, since a normal infant may show small waves which pass across the abdomen. However, if the waves are large and if they can be easily seen, then there can be little doubt that this finding is pathognomonic. Palpation of a tumor is, of course, diagnostic. Usually it is best to attempt this palpation either immediately

after vomiting or after some sedative has been administered. The palpation of a tumor is said to be possible in over 98 per cent of the cases. This has not been our experience, although it can be palpated in a great number of cases, certainly much over half. The laboratory finings are not of much help. However, they may act as a guide in preparing the child for surgery if there is a hemoconcentration and if the serum protein is low. Therefore, it is our custom to do a regular blood count, and, in addition, a determination of the plasma protein and hematocrit by the copper sulfate method. This is now routine. X-ray examination is not of great help. If there is a pyloric obstruction, the baby may regurgitate and aspirate some of the barium. If there is not a pyloric obstruction, there may be sufficient spasm to mislead even the most experienced roentgenologist. However, the x-ray features of diagnostic value are gastric dilation, intermittent hyperperistalsis, greatly elongated pyloric canal, which is very small in diameter, delayed gastric emptying time. The differential diagnosis lies between pylorospasm, infectious vomiting, improper feeding, and intracranial injury; also achalasia of the esophagus. The condition has been described as persistent vomiting with no other signs of pyloric stenosis. It can be diagnosed by x-ray films which show the gastric cardia in a state of continuous relaxation with frequent regurgitation of the barium which has been given. Babies with this difficulty respond well to a therapeutic test of thickened feedings while they are kept in an upright position. Extrinsic obstructions such as malrotation volvulus and intrinsic intestinal obstructions or atresias must also be considered. Differential diagnosis in the latter group is difficult at times. Usually, however, in the extrinsic types of obstructions, the vomitus will be bile stained, since the obstruction is at a lower level. The same is usually true of malrotation, but a duodenal stenosis may be very confusing, particularly if it is above the ampulla, and sometimes this diagnosis cannot be made before operation. (See Figs. 280 and 289.)

The treatment for congenital hypertrophic pyloric stenosis is very satisfactory and consists of an operation which is designed to divide the hypertrophied sphincter muscle. (Fredet-Ramstedt pylorotomy.) The babies are usually prepared by subcutaneous saline and, if necessary, intravenous administration of blood or plasma, or both. It has been our experience that it is very easy to overhydrate these infants and, therefore, we are cautious to give only approximately 10 c.c. per pound of body weight. We also give vitamins C and K preoperatively. Usually we pass a small catheter down into the stomach, wash out the stomach, and leave the catheter in place until the conclusion of the operation, when it is removed. We have done all of our operations under local anesthesia, although it is possible to do them under general anesthesia, and some surgeons prefer this. We do not use barbiturates, or morphine, preoperatively; instead we prefer to give 1/500 grain of atropine sulfate and nothing more. We use 1/2 of 1 per cent procaine solution for local

infiltration without Adrenalin. We use a right paramedian incision, split the rectus muscle, and then divide the transversalis transversely. The pylorus is delivered, and a small longitudinal incision is made through the serosa. This is about one-half to three-fourths of an inch in length. The muscle is split with a hemostat, and the mucous membrane is allowed to bulge. The dangerous part of this procedure is the inadvertent injury or penetration of the duodenal mucous membrane. This can be avoided if care is taken on this side of the incision. Should this occur, the mucous membrane is sutured and the omentum is sewed down over the leak. Hemorrhage may occur if the transpyloric vessels are cut. These sometimes require ligation.

Functional Disorders of the Stomach and Duodenum

Functional disorders of the stomach are common. Indeed, the stomach has been called the "barometer of the body." Bad news, pain, worry, or excitement, may induce vomiting. Indiscretions in diet or alcohol may cause the same, or an inflammation (gastritis). However, by far the most common disorder (so-called "nervous indigestion") is intimately related to dysfunction of the autonomic nervous system, which produces spasm (pylorospasm, cardiospasm) or secretory disorders achlorhydria and hyperchlorhydria). The treatment, after ruling out organic disease, consists in dietary measures, sedatives, and antispasmodics, together with rest and freedom from adverse psychic disturbances.

Acute dilatation of the stomach is a very serious condition in which this organ becomes greatly distended with fluid and gas. Its walls are atonic, and the more they become distended with fluid, the more atonic they become. The patient regurgitates dark, foul fluid continually. This results in hypochloremia, alkalosis, dehydration, and often tetany. It is seen usually after operation but often following a severe injury, or even after extreme overeating. Sometimes it is seen in pneumonia. The cause of the loss of gastric tone is a reflex nervous mechanism. The treatment is by Levine tube and suction (Wangensteen). The prognosis may be serious.

Vomiting is brought about by contraction of the abdominal wall, descent of the diaphragm, reduction of gastric tone, and relaxation of the cardiac sphincter and the esophagus. The glottis is closed and respirations are inhibited. In intestinal obstruction, antiperistaltic waves originate in the small intestine. These force the vomitus through the stomach, which does not manifest such waves.

In 1813 Magendie removed the stomach of an experimental animal and substituted a bladder filled with fluid; injection of an emetic was followed by evacuation of its contents. If the abdominal muscles are paralyzed by curare, vomiting does not occur. In human beings the stomach plays a small but minor role in the act. The author demonstrated this in studying the mechanism of perforated peptic ulcer.

Vomiting is controlled by a center in the medulla, and the afferent fibers to this center may come from almost every region of the body. Stimulation of the fauces, the pharynx, the mucosa of the stomach, or other abdominal viscera, pain from the special sense (eyestrain, tinnitus, vertigo, etc.), and even emotional states, such as fear, sorrow, joy, and excitement, may result in vomiting. Last, the center itself may be stimulated by such drugs as apomorphine, producing emesis. There is also a reflex vagus stimulation probably by way of the carotid sinus, and the heart is slowed or even momentarily stopped. Even nausea causes a slowing of the pulse, and on this basis simple paroxysmal tachycardia has been treated with ipecac. It has been thought that this reflex slowing of the heart is a conservative mechanism, preventing the blood in the large abdominal veins from being forced into the right heart, causing right-sided failure, and if not, pulmonary edema.

Heartburn has been described previously. Many patients with ulcer have it, but not when the ulcer is active and they have hunger pain. The degree of stomach acidity is unimportant and heartburn occurs with achlorhydria. Alcohol, tobacco, eating too fast or too much, or certain foods may cause it. It is probably due to regurgitation into a sensitized esophagus and partly to reverse waves of peristalsis coming up from the stomach.

Smoking produces heartburn and nervous indigestion, and according to some it may play a role in the recurrence of peptic ulcer. It is said to inhibit or depress hunger motility, and often secretion as well. In some smokers, saliva is increased; in others, it is not. All evidence, experimental and clinical, does show that occasionally there is gastric retention and increase in acidity. It is perhaps the type of individual rather than the smoking, or the peculiar temperament which impels a man to smoke one cigarette after another that gives rise to nervous indigestion or ulcer.

Caffeine stimulates gastric secretion and acid and may cause "nervous indigestion" and may be related to the chronicity of peptic ulcer. In large doses it may produce ulcer in cats. Coffee in moderation shows no abnormal effects in man.

Alcohol is known to increase the secretion of gastric juice of high acidity. It may be a cause for so-called nervous indigestion, gastritis, and even peptic ulcer.

Injuries to the Stomach and Duodenum

Foreign Bodies.—Injuries to the stomach may occur from within by chemical agents (ingestion of acids or alkalis) or mechanical agents (glass, sharp instruments, pins, etc.) or from without by penetrating, perforating, or nonpenetrating wounds.

1. *Injuries from within* are caused by swallowing the irritating or obstructing material inadvertently or intentionally. The latter may be inadvertent in that the patient is not aware that the harmless substance

over a long period of time may be injurious. In this category belong the bezoars (phytobezoars, plant) and trichobezoar (hair balls) which may fill the entire stomach, causing serious symptoms. Lastly, parasites (ascaris and taenia), gallstones which erode through usually into the duodenum, and sequestra from bone may be called endogenous in origin. We have recently seen a mercury tip tube swallowed, and no doubt this is true of Levine and Miller-Abbott tubes, especially when they become knotted.

Chemical substances that are strong acids or alkalis will burn the mouth and esophagus before reaching the stomach and duodenum and will have "spent themselves" so that ordinarily they do not burn the

Fig. 276.—Corrosive gastritis. The x-ray photograph is that of a child (D. P.) 18 months old who drank some "plumber's soldering fluid" or flux made from hydrochloric acid, zinc scraps, and tallow. This child presented few symptoms except restlessness and anorexia for about ten days; then vomiting occurred and it became progressively worse Finally, there was a complete obstruction which is readily seen in the x-ray photograph. It will be noted that the lower two-thirds of the stomach are occluded except for a very fine line (arrow). This child was treated ultimately by a high anterior gastroenterostomy. At the time of operation the interior of the stomach was inspected and found to be a mass of soft, bleeding granulation tissue The gastrojejunostomy was done above the area of obstruction and the child made a smooth recovery. Recent follow-up shows the child to be in normal condition. (Case referred by Dr M. Winter.)

gastric mucosa. Weaker acids and corrosives burn the stomach and duodenum. In the latter group are zinc compounds, ammonia compounds, acetic acid, etc. We have seen a case of corrosive gastritis that illustrates the problem. A child 18 months old drank some plumber's "soldering fluid" or flux made from hydrochloric acid, zinc scraps, and tallow. The child presented few symptoms except restlessness and

anorexia for about ten days. Then vomiting occurred which became progressively worse. Finally there was complete obstruction which was demonstrated by x-ray as involving the lower two-thirds of the stomach. A high anterior gastroenterostomy was done and the child made a smooth recovery.

Mechanical objects usually pass through the pylorus even if sharp. However, the large ones (bezoars) will be retained. Gallstones will pass down to the ileocecal valve or even to the rectum where lodgment may occur. Sharp instruments or needles may leave the stomach and wander into other viscera or the abdominal wall.

The diagnosis is made by the history, which may be misleading in that the foreign body was aspirated and not swallowed, or in the case of children or dements it may have been lost or inserted into the rectum or vagina. The x-ray examination with barium for radiolucent objects and without barium for others is indispensable.

Treatment is usually nonsurgical. Practically all small foreign bodies will pass through the pylorus, including open safety pins, needles, and straight pins. For the latter group we have given mashed potatoes mixed with long fiber cotton, assuming that this would envelop the sharp end. On a few occasions we have had to remove the open safety pin or a large foreign body (phyto- and trichobezoars) through a gastrotomy. The incision is made longitudinally and closed transversely.

2. *Injuries from without* are not always easy to diagnose. Penetrating and perforating wounds may be traced fairly accurately and the injury may be suspected. However, in perforations without external wounds the diagnosis may be more difficult. Traumatic retroperitoneal rupture of the duodenum has been reported, and we have seen two cases. We have encountered four cases of ruptured stomach without external wound: one in which a chronic peptic ulcer was present and the blow on the abdomen in an auto accident caused the perforation; two were due to fractured ribs which had penetrated the abdomen and stomach; and one without apparent cause except the external trauma. Most of our cases presented the perforation in the jejunum just beyond the ligament of Treitz and on the mesenteric border.

Diagnosis is made from the history and symptoms which consist of a rigid abdomen, absence of bowel sounds, pain in the left shoulder usually, and vomiting and constipation. X-ray examination in the upright and lateral decubitus positions shows free air in the majority of cases.

Treatment consists of immediate operation after the patient has been treated for shock. In all stomach injuries the lesser peritoneal cavity should be opened through the gastrocolic omentum so that the posterior wall of the stomach as well as the pancreas, may be inspected. Postoperative care includes Levine tube with suction chemotherapy, attention to water balance, and blood volume replacement.

Inflammation of the Stomach and Duodenum

Inflammations of the stomach and doudenum may be due to chemical, thermal, mechanical, and bacterial causes and to the little understood factors which cause it to become ulcerated. In addition, gastric inflammations are associated with *Bacillus coli* systemic disease such as pernicious anemia, tuberculosis, and syphilis as well as local neoplastic disease.

The stomach and first part of the duodeneum in healthy adults are usually sterile except after a meal, yet inflammations due to bacterial causes occur. Nonspecific types are acute, and chronic *acute gastritis*, which may be mild and are caused by any of the agents previously mentioned as well as by bacteria after the ingestion of grossly contaminated food. A form known as phlegmonous gastritis (acute suppurative cellulitis of the stomach; gastric erysipelas) is a rare highly fatal disease. It is caused by alcoholic injury to the wall of the stomach and subsequent infection by streptococci, *Bacillus coli*, and other organisms. It is perhaps comparable to gangrenous stomatitis and is the soil rather than the seed. It may be produced in dogs not by bacteria alone or bacteria and ground glass but by alcohol, then streptococci.

The process begins in the mucosa and quickly spreads throughout the thickness of the gastric wall. Occasionally the duodenum is involved. Suppurative peritonitis ensues in over one-third of the cases. The symptoms are persistent vomiting, severe pain, abdominal tenderness, and rigidity. Diagnosis is difficult, and in an alcoholic, perforated ulcer is often thought of. The true nature of the disease is discovered at operation. The prognosis is very grave and surgery offers little. Chemotherapy and antibiotics should be given. Rarely a case survives after gastrectomy.

Chronic gastritis is a vague entity which has been regarded as a complication of organic disease (ulcer, carcinoma) by some and as a forerunner of these diseases by others. The superficial types, as seen through the gastroscope, show some hyperemia; the atrophic variety is seen in pernicious anemia and corresponds to the smooth pale tongue and the pale atrophied vaginal and rectal mucous membrane often seen in the disease. Hypertrophic and postoperative varieties have also been described. Diagnosis can be made by fluoroscopy and gastroscopy; however, an organic lesion must be ruled out in every case.

Syphilitic gastritis occurs in the secondary and tertiary stages of the disease. In the latter, gross deformities occur as a result of infiltration of the submucosa. The diagnosis should be suspected when a young individual with stomach complaints is found to have a funnel deformity of the stomach resembling that of diffuse scirrhous carcinoma but much more pliable when examined with a barium meal and fluoroscopy. In addition, the stigmas of syphilis are present. At operation, resection is done and the true morbid anatomy discovered by microscopic examination of the excised tissue.

Tuberculosis of the stomach is uncommon and occurs as an ulcer in the pyloric region and fundus. Infection is probably hematogenous or lymphogennous rather than mucosal. Vomiting, emanation, and diarrhea are the most frequent symptoms. The diagnosis is difficult especially in children and cannot be made with certainty by any method. In adults surgery is indicated and biopsy should be done.

Duodenitis is frequently reported in x-ray studies. It probably follows somewhat the same pattern as gastritis.

Peptic Ulcer

The exact cause of the ulcers which form on the lesser curvature of the stomach or in the first portion of the duodenum is unknown, and various theories have been advanced to explain them. In fact, the term gastroduodenal ulcer is probably a misnomer, since ulcers of the stomach are in many ways different from those of the duodenum. The latter gives a slightly different clinical picture (discomfort appears later after the meal) and a greater tendency to perforation, and, if hemorrhage occurs, the position of the ulcer is posterior. The former has a greater tendency to bleed and obstruct, but, most important, the possibility of carcinoma is from 10 to 14 per cent, although this figure includes those gastric ulcers which were ulcerating carcinomas from the start. The positions are so variable that one is not justified in speaking of a single area as being ulcer bearing, although the magenstrasse of the lesser curvature is the most common site. Ulcers may be high up on the posterior wall, in the cardia, but rarely along the greater curvature (where carcinoma is more common) and in the duodenum down to the ampulla. Ulcer of the duodenum is far more common and is present in acute or chronic form in 5 to 10 per cent of the adult male population. They may be single or multiple. Among the causes which have been postulated are mechanical causes (trauma, vascular lesions, spasm of the pylorus). Some mechanical factors (trauma) are mentioned under miscellaneous causes. Often many causes are at work simultaneously. Secretory causes (an alteration in the gastric juice or in the normal resistance to it in the mucous membrane). Ulcers are usually encountered with high gastric acidity. Is this cause or effect? Acid is an inhibitory agent and stimulates the formation of mucin. The mere occurrence of a high acidity does not mean that a peptic ulcer will develop any more than the presence of streptococci in the throat means a streptococcic pharyngitis. In the latter case, the local immunity of the individual, if unimpaired, prevents this from occurring. In the former case, the protective mucin and neutralizing pancreatic juice also protect the tissue. The occurrence of an ulcer may be attributed to some breakdown of the protective mechanism. Mucin is protective in that it presents a slippery surface to irritants, it combines with and neutralizes the acid; when acid is secreted in large amounts, the mucus precipitates and forms an insoluble tough coat. In the duodenal cap there is less mucus, and it is

brushed aside by the chyme, leaving the mucosa unprotected. This was the basis for the author's experiments with duodenogastric intussception. These findings explain the fact that ulcers may occur with low acidity or achlorhydria and may not occur with high acidity or, having formed, may heal in the presence of hyperchlorhydria. It is surprising how little acid is required to produce a peptic ulcer in the absence of mucosal protection. This is exemplified in peptic ulcer in Meckel's diverticulum.

The first part of the duodenum is an acid area with an average pH of 5.6 in the fasting state and of 5 after an Ewald meal, but free acid is usually not present; and neurogenic causes (a constitutional susceptibility to the disease in certain individuals) in which ulcers occur run a natural course irrespective of treatment. However, complications may require treatment. The increase of ulcer in civilian population during the London blitz and in soldiers after the fall of Dunkirk illustrate the role of neurogenic causes. Gastric ulcers increased in members more than duodenal.

Miscellaneous Factors.—Infections in the sinuses, teeth, tonsils, appendix, prostate, and cervix uteri formerly regarded as silent and symptomless foci apparently play no role in the causation of ulcer (see Chapter 4).

Acute peptic ulcer may follow various injuries, namely, burns, Curling's ulcer, intracranial and spinal, fractures of long bones, and abdominal wall. It is also seen after operations such as thyroidectomy for thyrotoxicosis, intracranial operations, resection of the colon for carcinoma, cholecystectomy, pneumonectomy, drainage of lung abscess, spinal fusion. Last, it is sometimes seen in diabetic coma.

Dietary effects have been mentioned under the physiology earlier in this chapter. It is very doubtful if any dietary indiscretion not excluding alcohol is per se the cause of an acute or chronic ulcer. Perhaps the constant consumption of alcohol may play a role in susceptible individuals.

Experimental Studies.—

The injection of histamine in beeswax permits gradual liberation of histamine and the production of a sustained hyperchlorhydria with the formation of ulcer. Histamine inhibits the production of mucus and pepsin. Vagotomy inhibits the production of acid and also mucus. Vagotomy does not protect the experimental animal from histamine-induced ulcers.

Virtually all organs and tissues sewn experimentally into the gastric wall, including the stomach itself, except gastric epithelium, ultimately undergo digestion and fibrosis. Any tissue implanted which becomes covered by gastric epithelium is safe from further digestion. Jejunal transplants sutured into the stomach tend to inhibit ulcer, but when histamine in beeswax is injected, ulcer develops. Some authors have reported that there is an inhibition of gastric secretion following the sulface implantation of a portion of the jejunum as a pedicle graft. Other experimenters have not been able to verify these findings. Also, in the Mann Williamson dogs, ulcer develops after jejunal transplants. Most of the recent articles concerning the causation of ulcer have placed a major emphasis on gastric acidity. But ulcer does not develop in all cases of hyperacidity, and it may heal in the presence of hyperacidity, both in experimental animals and in man. Frequently pylorospasm has been invoked as a possible

cause of ulcer, and this in turn has been said to be due to an increase in hydrochloric acid. All experimental evidence to date shows that hydrochloric acid in the duodenum of the normal dog with concentration equal to or exceeding that of the stomach does not produce pylorospasm. In fact, the predominant effect is inhibition of the entire region of the sphincter.

Trauma is certainly not essential to the formation of ulcer. An isolated segment of the duodenum, jejunum, ileum, or the colon of the dog may be successfully implanted into a defect in the stomach; if the transplant has its blood supply, it will remain grossly intact and of normal appearance for about a year. In a somewhat similar manner the spleen, the kidney, and the pancreas of a dog may be mobilized and sutured into a defect in the gastric wall. If this is done with care not to injure the blood supply of the transplant, it will remain undigested for many weeks. The fibrous capsule of the sutured organ may be first removed so that the gastric juice has direct access to the parenchyma causing the tissue to be partly digested away, but in time an epithelial covering of gastric mucous membrane will grow out and finally cover the transplant.

Pure gastric juice has the capacity to destroy and digest all living tissues, including the wall of the stomach itself. Pure fundus secretion can be obtained by constructing in the dog the Heidenhain or Pavlow accessory stomach pouch or one of the more recent modifications. When tissues are implanted into the stomach wall of the isolated Pavlow or Heidenhain accessory stomach or in the total isolated stomach, the transplant promptly becomes excavated by the digestive action of the gastric juice. Death from hemorrhage takes place within a few days.

The exclusion of bile in the upper intestinal tract may be followed by duodenal ulcer in the experimental animal. This has also been proved in man. On the other hand, certain kinds of external biliary fistula may divert the bile from the duodenum for many months without causing ulceration. Exclusion of the pancreatic juice similarly may be followed by ulcers, but not invariably so. Recently, with the development of the operation of pancreatectomy, according to the Whipple technique, very few ulcers have been reported, although it must be said that at the time that this operation is done, partial gastrectomy is done also. If the duodenal juice is excluded from the intestine by operation which removes the duodenum and also prevents bile and pancreatic juices from entering the bowel, ulcer does not develop. It is perhaps correct to assume that the absence of pancreatic juice, bile, and duodenal juice or possibly any one of these juices from the upper intestine may cause an ulcer of the duodenum. The protection afforded by these secretions is said to be due to the neutralization of the hydrochloric acid. The effective substance is probably sodium bicarbonate; since it is in greater concentration in the pancreatic juice, it makes this secretion most important.

It is probably not so much an increase in the acidity but rather an increase in the amount of secretion or rather a hypersecretion of the normal juice with deficient neutralization that plays a role in the causation of ulcer. On the basis of this information it is assumed that the patient with ulcer secretes more gastric juice in response to food than does the normal person; also, and what is more important, he secretes more gastric juice when there is no obvious stimulant.

Recent studies have shown that patients with ulcer do not secrete any more gastric juice at night than do normal patients. However, if hydrochloric acid is the chief factor in ulcer distress, and delayed healing, it is essential that more attention be focused on the nocturnal phase of gastric secretion, regardless of how the patient feels during the night and regardless of the volume of gastric juice and the concentration of hydrochloric acid. While ulcer patients may not secrete more gastric juice or hydrochloric acid than the normal person, ulcer patients retain more of the juice and acid in their stomachs at any one time. During the night, therefore, the hydrochloric acid of the stomach may undo in part what neutralization accomplishes during the day, and during the night there is no food in the stomach, or liquids. The latter have a diluting effect.

The meal solids perform the neutralizing effect because of their acid absorbing power. Feedings during the night are therefore essential or night secretion should be reduced. While the foregoing findings were true in extensive tests, many observers have not verified these findings, stating that there is no increase in the amount of secretion during the night.

Chronic peptic ulcer does not occur in patients with complete and persistent achlorhydria. It would seem that the paramount importance of acid seems inescapable. Pepsin greatly facilitates this process, but it alone will not destroy the mucosa. Although evidence is lacking for the findings of chronic ulcer in the presence of achlorhydria, yet various cases have been reported in which at least transient achlorhydria was present. Furthermore, many cases are known to occur where the acid content is extremely low.

An attempt to produce ulcer experimentally by ligation of gastric vessels was unsuccessful in most animals; however, in rats this may be accomplished. Infarcts do occur which do form ulcers, but these usually heal spontaneously.

Acute ulcers have been observed in experimental burns. The ulcers are thought to occur as a result of mucosal congestion with associated increase in the susceptibility of the mucosa to slight trauma in the first stage in the pathogenesis of experimental ulcers. Burns may be complicated by shock and infection; it is the shock rather than the infection which is presumably the cause of the mucosal congestion. The detailed pathological evidence demonstrates that the final stage of duodenal or gastric ulceration in these dogs is a corrosive and not a local infectious process.

The over-all picture as to the probable cause of gastric ulcer has been summarized in four words: hypermotility, hypertonicity, hyperperistalsis, hypersecretion. It should be emphasized that many observers regard gastric and duodenal ulcer as distinct entities. This is certainly true as regards their respective potentialities with regard to cancer which is common on the gastric side and almost nonexistent on the duodenal side.

The incidence of ulcer was definitely increased during the London blitz and after the fall of Dunkirk. Peptic ulcer has been said to be a constitutional disease, running a natural course, irrespective of treatment. Complications, of course, require active treatment. It has also been called a psychosomatic disease, and the evidence for this is good.

Recent studies of duodenal ulcer have been made to correlate the psychosomatic changes with the activity of the ulcer. A distinctive pattern is said to be present not only in the duodenum, but in the digestive tract as a whole and also in the constitutional behavior of the patient. This pattern is said to be characterized by hypersensitivity, hyperirritability, hyperactivity, which involves the affected duodenum, the digestive tract as a whole, and the personality.

It has been previously observed that patients with an ulcer have a decrease in gastric mucus, and we have demonstrated to our satisfaction that it is the mucin which has the greatest protective value against the erosion by gastric juice in the experimental animal. However, in a recent series of tests, the mucin content in human peptic ulcer and gastritis was within normal limits. This was shown to be true in human beings as well as in experimental animals. This is contrary to the previous conception that a lowered mucin content exists in peptic ulcer and is of importance in its pathogenesis. No other clear evidence can be found of any difference between the mucin content in the gastric juice of healthy individuals and that of individuals suffering from various gastric disorders. It is well to say in this connection that the gastric acids in this particular group of patients was within normal limits. There was no reason for the mucin to be greatly increased; that is, because there was no calling forth of the mucin by an increase in the hydrochloric acid. In this study the average mucin content of the gastric juice varied from 0.15 to 1.5 per cent, the average being about 0.5 per cent.

Recently the effects of vagotomy have been studied by many surgeons after the pioneer work of reviving this operation by Dragstedt and co-workers. The exact cause

for the striking relief which patients derive from vagotomy is not entirely known. There may be several explanations: (1) the effect of the anesthesia that has been used in the patient during the operation, (2) the interruption of sensory pathways, although the sense of pain can be interpreted, as proved by the introduction of hydrochloric acid, which the patient feels, (3) the absence of free hydrochloric acid, (4) the decrease or absence of the peristaltic activity of the stomach.

Peptic ulcer may occur beyond the first portion of the duodenum; although this is unusual, it occurs regularly enough so that the surgeon must be on his guard unless he misses one of these ulcers. The most frequent site is the medial aspect of the superior duodenal angle, slightly within the initial portion of the descending duodenum, this being the area beyond the bulbar vertex, including the supra-ampullary region. The lesions are less frequently found as one approaches the ampulla, and they are exceedingly rare beyond this area.

Intensive experimentation has been done in an effort to evaluate the various types of operations for ulcer. *Gastrojejunostomy* is said not to offer much protection against the formation of ulcer induced by the injection of histamine in beeswax to expedite its occurrence. Our experiments show that it is one of the very best ways to prevent ulcer induced by histamine in beeswax. *Gastric resection* or antral excision in which the gastrojejunostomy of the Billroth II type is done does not protect animals against development of ulcers. The operation fails to reduce gastric acidity adequately and must be considered unsatisfactory. *Extensive gastric resection*, which controls the gastric acidity, ensures against recurrent ulcers, and leaves a residual pouch large enough to provide adequate gastric capacity, would appear to be the most satisfactory operation. Following the anastomosis of the first portion of the jejunum and an inversion of the lesser curvature according to the Hoffmeister pattern, the experimental animal is completely protected against ulcer. This is especially true if a short afferent loop has been used. The Finsterer *antral exclusion* without excision of the antral mucous membrane is followed by erosions of the gastric pouch. If the mucosa is excised and a three-fourths resection is done, animals do not get ulcer. Antral resection plus total intragastric regurgitation is found to enhance the possibility of jejunal ulcer rather than to protect against ulcer. *Fundusectomy*, with *gastrojejunostomy*, appears to furnish satisfactory protection against the development of jejunal ulcer, although this procedure offers less protection than gastrectomy as previously described. *Hemigastrectomy* does not furnish adequate protection. *Devine exclusion* with total intragastric regurgitation is unsatisfactory. *Resection* or *segmental* resection is not *conclusive*. The clinical limitations of such an operation are obvious. Vagotomy does not protect the animal against ulcer produced by histamine.

Summary.—Extensive three-fourths resection, including the antrum or at least the antral mucosa, and anastomosis with a short proximal afferent loop and small stoma is the operation of choice from the experimental angle, although if histamine in beeswax is used, posterior gastroenterostomy is equally efficacious in dogs as shown by us (J. F. Boyd and the author).

In a review of the bacteriology of peptic ulcer which was carried out to determine whether or not infection played a part in the causation of peptic ulcer, it was found that in most cases bacteria was isolated in carcinoma in nine out of ten cases, whereas in only sixteen in forty cases could any bacteria be isolated in benign ulcers.

Experimentally the use of omentum to close perforations of the stomach where no other tissue is available has been found to be satisfactory.

Recent studies on the bacterial flora in the abdomen following perforations of peptic ulcers show that practically all perforated ulcers have bacterial contamination in the peritoneal cavity soon after the perforation of the ulcer. Gastric acidity is low at the time of perforation, if not shortly before, and bacteria are to be found in gastric contents. The role of the chemical peritonitis is to favor the bacterial peritonitis which causes death. The time element, of course, plays a role, but this is thought to be

due to the extensiveness of the infection rather than to the secondary invasion by bacteria. Gastric juice poured into the peritoneal cavity is not lethal. It is true, however, that the mixtures of bile and pancreatic juice are occasionally lethal.

After a rather complete review of the literature on methods of closure of the duodenal stump in gastrectomy or pylorectomy, we are convinced that it is not the method of closure which leads to leaks but rather an interference with blood supply. Recent extensive dissections on the cadaver have shown that the blood supply of the duodenum is a very important factor in leakage after gastrectomy from the duodenal stump, adequate circulation must be preserved. The arteries of the duodenum are really end arteries, and there is a lack of intramural or marginal anastomosis. This finding is important to demonstrate the fact that due to the poor anastomosis of the duodenal vessels, inversion of the duodenum to the point of pancreatic attachment so that collateral circulation may provide nourishment is necessary.

Summary of Etiological Factors.—After carefully reviewing the enormous volume of clinical and experimental studies of peptic ulcer, one is struck by the fact that here is a disease which is, in most instances, the result of a failure of compensatory mechanisms properly to protect the wall of the stomach or of these mechanisms having been tried to the "breaking point" by gross indiscretion. In other words, "it takes two to make a bargain"—the "insult" and the failure of nature adequately to protect or repair the injury after it has occurred. There is no doubt that the "antigen" is mediated through excessive acid and the "antibody" or protection is the mucin which is at least part of the protective mechanism employed by nature in all of the mucous membranes of the body. Behind this unbalance lies the abstruse effect of a constitutional factor difficult to define and vaguely described as psychosomatic in origin. It is perhaps true that it is not the drink but the drinker, not the tobacco but the smoker. These problems may be solved some day by early training in environmental adjustments, although peptic ulcer is not too rare in children between the ages of 2 and 7 years. A prophylactic training of the central nervous system, so that it may take the ordinary adversities of life with the same equanimity as the autonomic nervous system takes the task of making its adjustments through compensatory mechanisms, may be a means of decreasing peptic ulcer as well as other psychosomatic diseases.

Pathology.—Peptic ulcers may be acute with much inflammatory reaction. These are usually but not invariably superficial and have little fibrous tissue around them (erosions of Dieulafoy) in contradistinction to the chronic fibrous (callus) ulcer which corresponds to ulcers elsewhere (see Chapter 6) which have developed granulation tissue but have not been covered with epithelium as in varicose ulcer. The granulation tissue changes to scar tissue, leaving a pale, hard, cicatrized bed over which epithelium will not grow. In addition, there is venous and lymph stasis with local anoxemia. Add to this its firmness, and it becomes evident that the edges cannot collapse or fold over and heal. This chronic ulcer is more apt to be on the posterior side. Also, like ulcers elsewhere, this fibrous bed may break down and ulcerate more, leading to erosion

into a blood vessel or adjacent organ as the pancreas. Ulcers may occur anywhere in the stomach, but over 60 per cent occur on the lesser curvature within 6 cm. of the pylorus. On the duodenal side there is greater

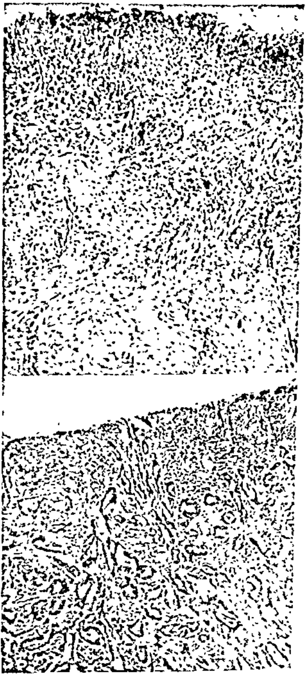

Fig. 277.—*A.* Low-power photomicrograph of a gastric ulcer. Due to the high acidity, the mucosa has been digested away. *B.* Malignant gastric ulcer. No free acid is present and therefore there has been no mucosal digestion; only slight erosion of the mucosa due to the growth. Note extension of the carcinoma into the submucosa.

variability, but the most common site is within 1 cm. of the pyloric ring (40 per cent) without about equal distribution between the anterior and posterior walls. In about 7 to 10 per cent there are both gastric and

duodenal ulcers. Necropsy statistics show gastric and duodenal ulcers to occur in about the same ratio; however, clinically duodenal ulcers are seen 10 to 1.

Complications of ulcer are hemorrhage, perforation, obstruction, and, on the stomach side, carcinoma. *Hemorrhage* occurs in both gastric and duodenal ulcer in some degree in over 30 per cent. It is said that hemorrhage is a more common complication of gastric than duodenal ulcer. Our experience does not bear this out, particularly in gross hemorrhage, which is more often duodenal due to a posterior ulcer eroding into the gastroduodenal or superior pancreatic duodenal arteries.

Hematemesis (vomiting of blood) may occur from various causes. A common error is to regard the bleeding from ruptured esophageal varices (due to cirrhosis of the liver) as a bleeding peptic ulcer. The former occurs without previous gastric symptoms; the latter may also occur without gastric symptoms, but this is rare. Parenthetically another common mistake is to interpret the gastric crises of tabes as evidence of organic disease of the stomach. In tabes there is severe pain but no vomiting. Diseases which may cause gastric hemorrhage are (1) trauma to the stomach by mechanical or chemical agents, (2) peptic ulcer, (3) benign or malignant neoplasms, (4) ulcerations associated with nephritis and severe toxemias, which may also produce gastritis with hemorrhage, (5) hepatic diseases (Laennec's cirrhosis, biliary cirrhosis, Banti's disease, hemolytic jaundice, anemia, phlebitis of the spleen or pylephlebitis, severe jaundice), (6) infectious diseases (yellow fever, pneumococcic infections, septicemias, scarlet fever), (7) blood dyscrasias (pernicious anemia, leucemia, purpura, hemophilia) or altered blood chemistry (phosphorus and arsenic poisoning, uremia, severe icterus, and cholemia), (8) heart disease with passive congestion, (9) tabes with gastric ulceration, (10) miscellaneous causes, some of which are vague and probably inaccurately diagnosed, such as vicarious menstruation and nervous disorders, (11) hereditary hemorrhagic telangiectasia. Gastric hemorrhage in the newborn is seen in severe icterus, infections, and toxemia; however, peptic ulcer in the newborn has been reported.

Perforation of the *acute* variety occurs in about 5 per cent of the ulcers of the stomach and duodenum. Slow or chronic perforations and subacute (forme fruste) types occur in 25 to 28 per cent of the chronic ulcers. Chronic perforations may have a thick fibrous wall and resemble a diverticulum on the x-ray. Perforations into the pancreas are not uncommon and may evoke considerable reaction in the pancreas, producing in some cases a low-grade parenchymatous pancreatitis. Acute perforations are said to occur more frequently on the gastric side; however, we have found the duodenum the more common site; perhaps this is due to greater number of duodenal ulcers encountered. Acute perforations are usually anterior and therefore they cause a chemical peritonitis which is soon converted into a bacterial infection because acids are low at the

time of perforation and food is contaminated. The amount of food which enters the peritoneal cavity and the length of time it is permitted to remain determine the extent of the bacterial invasion.

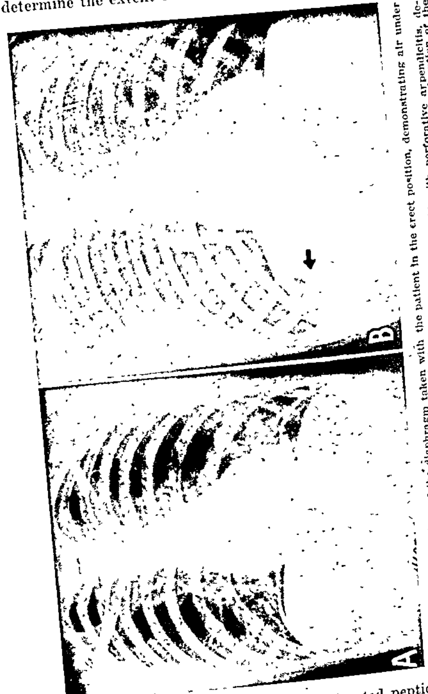

Fig. 278.—*A*, Flat plate of the diaphragm taken with the patient in the erect position, demonstrating air under the diaphragm, the result of a perforated peptic ulcer. *B*, Subphrenic abscess with air in the abscess cavity. The patient, a child with perforative appendicitis, developed a subphrenic abscess, which was aspirated, permitting air to enter the space. Note the elevation of the diaphragm on this side.

The differential diagnosis between perforated peptic ulcer and appendicitis is not always easy because the irritating gastric fluid gravitates downward and to the right, due to the position of the mesentery. A careful history, the boardlike rigidity, and the free air demonstrable by x-ray will in most instances clear up the diagnosis. Some acute perforations heal over or seal themselves by attachment to the gall bladder or omentum.

Hemorrhage and perforation do not often occur together. Such cases have been reported but as a rule acute perforations do not occur in bleeding ulcers and bleeding does not occur in acute perforating ulcers. This is not true of the chronic variety where perforation occurs on the posterior wall in a slow manner.

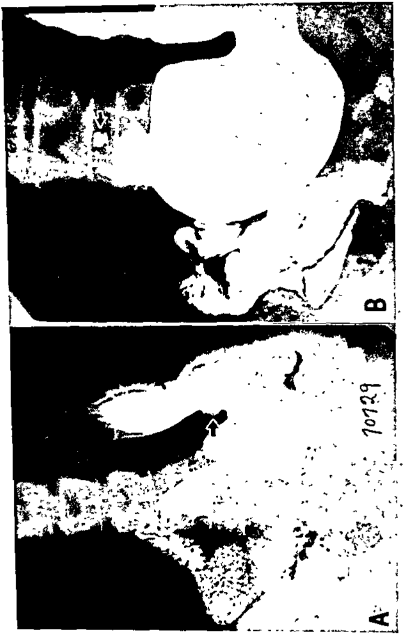

Fig. 279.—*A*. Gastric ulcer on the lesser curvature just above the incisura. Arrow points to crater. *B*. Duodenal ulcer with obstruction due to scarring and spasm. Arrow points to crater. Note the huge dilatation of the stomach.

Obstruction may occur at the pylorus (pyloric stenosis) and less commonly higher up in the stomach as an hourglass contraction. The obstruction is the result of fibrosis caused by the healed or healing ulcer. This scar may be very thick and as it contracts stenosis occurs. This incomplete obstruction causes a hypertrophy of the stomach wall. As the

pylorus becomes more and more occluded, the stomach wall gradually dilates and becomes thin and atonic.

Carcinoma secondary to ulcer occurs in about 5 to 10 per cent of *gastric ulcers.* This is seen mostly in those ulcers which have a fairly low acid and are on the greater curvature. The fact that 3 to 5 per cent of all cancers of the stomach start out with a diagnosis of ulcer does not prove the relationship, because such ulcers may be ulcerating carcinomas from the start. This relationship of cancer and ulcer is not seen on the duodenal side, although cancer of the duodenum exclusive of ampullary carcinoma does occur in the presence of ulcer scars.

Most ulcers heal with a soft scar or slight puckering, and these are commonly encountered at operation, even after severe hemorrhage which occurred only two to three weeks before surgery. Many ulcers go through stages of quiescence and exacerbation, much like varicose ulcers which are treated by bed rest until they heal and which form again when the patient is back at work.

Symptoms and Signs.—Peptic ulcer is a disease of young adults, usually males, but during World War II the incidence rose greatly in females. Since then the male predominance is again evident. Is this another evidence of "stress and strain" as a cause? Children from birth to 7 years of age have ulcers more of the acute type. We have seen two with hemorrhage following spinal fusions and one with perforation without apparent cause. Between 7 and 15 years the ulcer resembles more the chronic type.

Pain or *gnawing* sensation which appears shortly after eating (gastric ulcer) or about two hours after (duodenal ulcer) and which is usually relieved by food is the most constant symptom. This has led to the "pain-food-relief" triad used in describing ulcer pain. Alkalis also give relief.

Pain in ulcer may be due to an increased sensitivity of the nerve endings which changes the distress of normal hunger contraction to severe hunger pains; peristalsis, or local spasm, occurring at the site of the ulcer in muscle of changed sensitivity; and, perhaps most important, chemical irritation by the hydrochloric acid.

Pathways of pain are probably by way of the visceral splanchnic nerves; however, the varying shifts of pain into different regions is due to involvement of other organs, and the parietal peritoneum and mesentery which in turn send their impulses over cerebrospinal nerve twigs (spinal-sensory-somatic pathway). Therefore, the referred pain will be over the course of the spinal nerve involved. Perforating posterior duodenal ulcers produce referred pain to the right upper quadrant and right side of back, whereas perforating gastric ulcers produce pain in the left upper quadrant and left side of back. Perforating lesions involving the diaphragm are painful, and the pain is referred to the shoulder. This is explained by the assumption that the painful impulses reach the spinal cord over the phrenic nerve which arises from the fourth cervical seg-

ment (also to some extent from the third and fifth cervical); after going through the thorax, it supplies motor fibers to the diaphragm and sensory fibers to the diaphragmatic pleura as well as the peritoneum lining the undersurface of the diaphragm. Since the supraclavicular, suprascapular, and supra-acromial nerves arise in the same spinal cord segment, pain is referred to the shoulder. This same mechanism explains the shoulder pain in a perforated ulcer with air and acid chyme under the diaphragm, also any diaphragmatic irritation.

The pain of ulcer is not a pain in the sense that morphine is required. It is an uneasiness relieved by pressure in the epigastrium momentarily. The pain is not constant. It varies with seasons, time of day, degree of work, mental strain, preoccupation, lack of rapport. Night pain is uncommon unless there is obstruction or carcinoma. The diagnosis is made from the symptoms but is confirmed by a barium meal fluoroscopic examination.

Hemorrhage relieves all symptoms of ulcer for a while. If large and from the stomach, there is apt to be hematemesis as well as "coffee ground" vomitus and tarry stools; if from the duodenum, no evidence of bleeding is seen until the black tarry stool appears. Only 75 c.c. of blood are required to produce a tarry stool, and the test for occult blood will be present for three to four days afterward.

An increase in blood urea nitrogen occurs following alimentary absorption of large amounts of digested protein. This condition occurs clinically most often in patients with bleeding peptic ulcer. In either, symptoms of shock appear early, but they are transient and mild, consisting of simple fainting. Within six to eight hours blood changes begin to occur due to hemodilution. In milder types of bleeding no symptoms occur. It is astounding to see patients walk into the office with blood counts of 1 to 2 million and hemoglobin as low as 5 Gm. The diagnosis is made from the anamnesis and symptoms and signs. Other causes of bleeding must be ruled out.

Acute perforation is usually sudden and dramatic. The pain is excruciating, but there is no shock early unless a very large hole is present and a full stomach has flooded the peritoneal cavity. Vomiting is usually absent. The pain at first is in the epigastrium but may be in the upper right quadrant and right shoulder. Later (two to three hours) the pain may be in the right lower quadrant. This is thought to be due to the direction of the small bowel mesentery which guides the gastric contents into this area. This often makes the differential diagnosis between acute perforated appendicitis and ruptured ulcer difficult. Usually the pain is so severe that it is mimicked by only a few other calamities. One of these is acute hemorrhagic pancreatitis which occurs usually in very heavy men after they have eaten a large meal or drunk much alcohol and have exerted themselves by strenuous work, yet the identical circumstances may surround a perforated ulcer, and if the

perforation is in the lesser peritoneal sac, the picture is almost identical. Mesenteric thrombosis resembles a ruptured ulcer insofar as pain is concerned, and, if high up, may cause bright red bleeding resembling a bleeding ulcer. Usually the vomitus is dark, and there may be blood in the stools if the inferior mesenteric is occluded. A scout film of the abdomen may reveal gas under the diaphragm in the upright position and on the lateral wall of the abdomen if the x-ray is taken in the lateral decubitus position. Gas in the stomach is decreased, but even so the magenblase prevents a clear delineation of free air which is better observed over the liver. Formes frustes types and chronic perforation cause pain which is milder and is referred to various sites, depending on the location of the perforation.

Obstruction causes continual pain and fullness with eructation of sour fetid material. Later, vomiting occurs which may be prodigious. Sometimes food eaten twenty-four to forty-eight hours previously is vomited. Fluoroscope examination with barium shows gastric retention above the level of the perforation.

Carcinoma in an ulcer of the stomach is to be suspected in middle-aged or older people who complain of loss of appetite, strength, and weight. They have low or absent acidity (though this is not invariable) and an anemia which persists, and their pain is present in the morning on arising and is not relieved by food but may be aggravated by it. Barium meal and fluoroscopy help materially, but in carcinomas which grow centrifugally, the x-ray findings are notoriously misleading. Ulcer patients have a good appetite, higher than normal acidity (not invariable), and normal blood count (unless there has been persistent bleeding).

Treatment.—The treatment is usually nonsurgical and consists of a bland diet with frequent feeding, especially milk and cream. Cream and milk tend to inhibit gastric secretion, cause the expulsion of bile from the gall bladder (in the case of cream), and stimulate pancreatic secretion. They thus reduce acidity by direct action, and also by indirect action by neutralization of the acid. Also by the fact that fat in the intestine releases enterogastrone which inhibits gastric secretion. The rationale for this is that these foods act much as a sponge, sopping up the free hydrochloric acid and thereby preventing it from eroding the mucous membrane. Often alkaline powders, such as calcium carbonate, magnesium oxide, and bicarbonate of soda, are used. Frequently the latter has been tried by the patient before consulting a physician. Sodium bicarbonate, if used to excess, causes a state of alkalosis, with gastric tetany, and it has an irritant action on the gastric mucous membrane.

Other forms of medical treatment include dietary measures first introduced by Celsus (about 10 A.D.), who advocated "a soft smooth diet without acid or acrid substances and light wine to be not too hot or too

cold." Liberal diets adequate in minerals, vitamins, and protein are best. Timing is important, and the bland meal, together with 10 A.M., 3 P.M., and 10 P.M. feedings, is designed to sop up excess acid. The continuous milk and cream drip is designed to accomplish the same purpose. Diets should not include condiments and roughage. Duodenal feeding through the Einhorn tube has been employed to put the stomach at rest. Amino acids have been advocated because these mixtures are antacid and easily assimilable so that hypoproteinemia may be combated. Alkalis and adsorbers are advised by some, condemned by others. Among these are calcium carbonate, the aluminum compounds such as aluminum hydroxide gel, and magnesium oxide.

"Enterogastrone" has been used intramuscularly by day in the treatment of recurrent ulcer. Other drugs such as atropine are used to cut down vagus stimulation, hypermotility, hypertonicity, and hypersecretion, and phenobarbital for sedation.

Recurrences are common (80 to 85 per cent) after medical treatment, but surgery is indicated only in the intractable types, especially on the posterior side; persistent gastric ulcer or one or more of the complications, namely, hemorrhage, perforation, obstruction, chronicity and intractability due to erosion into the pancreas or chronic perforation with diverticulum-like protrusion, chronic gastric ulcers which may be carcinomas, and very large ulcers.

Surgical treatment is designed to relieve pain, reduce the acid, or produce anacidity, provide for neutralization of the remaining acid by reflux of alkaline juices and mucin, relieve obstruction, and remove the ulcer on the gastric side and also duodenal side if possible. To accomplish these objectives, almost every conceivable operation has been tried. These may be divided into the following groups:

1. Pyloroplasties: Heineke-Mikulicz, Horsley's, Finney.

2. Gastrojejunostomy and gastroduodenostomy with stomach intact anterior to transverse colon or posterior. Devine exclusion. Fensterer antral exclusion with excision of antral mucosa and without excision of this mucosa which is supposed to contain the hormone which stimulates gastric secretion.

3. Combinations of 1 and 2. Duodenogastric intussusception with posterior gastrojejunostomy, Devine and Fensterer exclusions. (See Fig. 280.)

4. Removal of portions of the stomach. Pylorectomy, antrumectomy, partial gastrectomy, subtotal gastrectomy, fundusectomy, sleeve resection, or segmental gastrectomy. (See Fig. 281.)

The operations in 4 are subdivided according to the manner in which the continuity of the intestinal canal is re-established. (1) In sleeve resections the stomach itself is sutured—gastrogastrostomy; (2) in all others, the stomach is anastomosed to the duodenum in accordance with Billroth I gastroduodenostomy (Billroth I, Kocher, Schoemaker, Von Haberer-Finney, Horsley, von Haberer) or to the jejunum like a

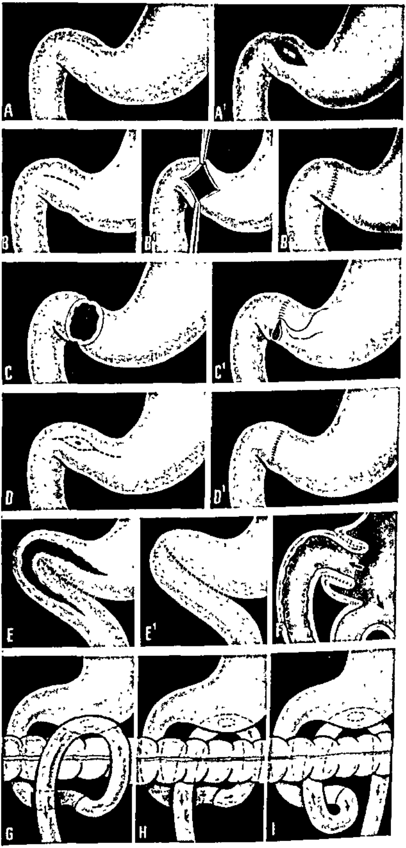

Fig. 280.—See opposite page for legend.

Billroth II gastrojejunostomy (Billroth II, von Eiselsberg, Polya, Hofmeister-Finsterer, Moynihan, Polya-Balfour or anterior Polya) (see Fig. 282).

5. Denervation by parasympathectomy or vagotomy, supradiaphragmatic and infradiaphragmatic, transthoracic vagotomy, or transabdominal vagotomy, respectively. (See Fig. 283.)

Denervation with gastroenterostomy or resection. Sympathetic denervation by left splanchnicectomy and celiac ganglionectomy or bilateral splanchnicectomy. Combined vagotomy and splanchnicectomy.

The merits and demerits of the various operations have been discussed in volumes of writings, and the results have been investigated experimentally and clinically. There is no operation which guarantees against recurrence, and even the most radical, consisting of a resection of 75 per cent of the stomach with short afferent loop, is followed by recurrences. Less radical subtotal resections have a recurrence rate of 5 to 10 per cent. At present, in our opinion, the following conclusions may be drawn concerning the *indications* and *reasons* for the particular operation selected and *complications* which may follow its use:

1. Pyloroplasty is used only rarely in the treatment of ulcer. In older individuals with low acid and obstruction due to a fibrosed *duodenal* ulcer which is "burned out" or inactive, a pyloroplasty of the Finney type is indicated. This is especially true in badly debilitated

---

Fig. 280.—Operations upon the stomach without resection. Stomach operations are very numerous and are done in so many different ways that in this and the succeeding diagrams of various types of operations only the more commonly practiced varieties will be illustrated.

In general, operations upon the stomach are divided into three large classes: first, those which are done upon the outlet and the inlet of the stomach without removing any portion thereof; second, operations upon the stomach with removal of a part or all of the organ; and third, those operations which are done outside the stomach and which deal with the nervous innervation of the stomach. In this figure the diagrams represent various types of surgical procedures upon the pylorus and the body of the stomach without resection. *A*, Rammstedt-Fredet. This operation consists of incising down to the mucous coat in a longitudinal manner, then spreading the muscle which is hypertrophied as a rule and allowing the mucous membrane to bulge as shown in A^1. *B*, Heineke-Mikulicz pyloroplasty. This consists of dividing the pylorus longitudinally and suturing it transversely as shown in B^1 and B^2. *C*, The Judd pyloroplasty which consists of removing the anterior third of the pylorus and then suturing it transversely as shown in C^1. *D*, Horsley-Judd types of pyloroplasty. The Horsley type is a variation of the Judd variety and consists of excising the ulcer at the pylorus, carrying the incision in a longitudinal fashion proximally and distally, and then closing the pylorus in a transverse manner as depicted in D^1. *E*, Finney gastroduodenostomy or Finney pyloroplasty. This operation consists of suturing the duodenum to the greater curvature of the stomach, and then by a horseshoe incision the stomach and duodenum are brought together as shown in E^1. This creates a wide opening from stomach to the duodenum and is useful in certain types of pyloric stenosis from ulcer where the risk of doing more radical procedures is too great or technically too difficult. *F*, Duodenogastric intussusception with posterior gastrojejunostomy. This operation is useful in those patients in whom more extensive procedures are dangerous, and yet gastrojejunostomy is risky because of the danger of jejunal ulcer or marginal ulcer. By this method Brunner's glands are brought up into the pyloric antrum, thereby tending to cause an increase in gastric mucin. This factor offers some protection to the stoma of the gastrojejunostomy against jejunal or marginal ulcer. The operation has also been useful in perforations where after covering the perforation the opening from the stomach to the duodenum has been so narrowed that it is feared that obstruction will ensue. *G*, Gastrojejunostomy. This is the anterior form and consists of bringing the jejunum to the anterior portion of the stomach as close to the greater curvature as possible and in front of the transverse colon. It was first done by Wolfer in 1881. The posterior gastrojejunostomy or, as it is sometimes called, gastroenterostomy was first done by Courvoisier in 1883. This type operation is very useful in all forms of benign obstruction. However, the danger is a recurrent ulceration at the site of the anastomosis so that the operation is not commonly employed today. *H*, Posterior gastrojejunostomy antiperistaltic; that is, from left to right. *I*, Posterior gastrojejunostomy isoperistaltic; that is, from right to left.

patients without a great amount of extrinsic adhesions and fixation. It is a simple safe operation with few complications but offers no protection against a recurrent ulcer.

2. A simple posterior gastroenterostomy is indicated under conditions outlined in 1 where great scarring of the pylorus prevents its use in anastomosis readily. The Devine exclusion operation has a place in massive hemorrhage in patients over 50 years of age, although it is apt to be followed by secondary hemorrhage unless a second operation may be done later. The chief complication is recurrent ulcer or jejunal ulcer. Not infrequently a gastrojejunocolic fistula may form, causing diarrhea, vomiting, pain, loss of weight, and even death from starvation and dehydration. The treatment of this complication requires excision of the ulcer and reestablishment of the normal preoperative status. If the patient can stand more or if pyloric obstruction makes further surgery mandatory, gastric resection is done at the same time. This may be deferred for a second stage by doing an enterostomy for feeding when

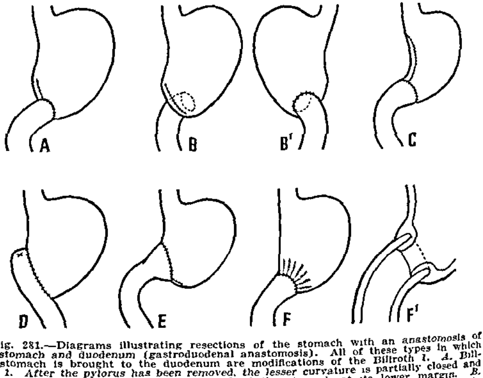

Fig. 281.—Diagrams illustrating resections of the stomach with an *anastomosis* of the *stomach* and duodenum (gastroduodenal anastomosis). All of these types in which the stomach is brought to the duodenum are modifications of the Billroth I. *A.* Billroth I. *After the pylorus has been removed, the lesser* curvature is partially closed and the duodenum is sutured to the open end of the stomach at its lower margin. *B.* Kocher. In this case the distal end *of the stomach is* closed and the duodenum is brought up to the posterior margin of the closed stomach. *B*[1]. Posterior view showing the end of the duodenum anastomosed to the stomach. *C.* Schoemaker. In this instance the lesser curvature of the stomach is sutured and brought down to the same size as the duodenum and then an end-to-end anastomosis *is done. D.* Von Haberer-Finney type. In this operation the side of the duodenum is brought up to the end of the stomach so that the entire end of the stomach is open. *E. Horsley.* The Horsley type of gastroduodenal anastomosis uses the lesser curvature end of the stomach to suture to the duodenum and closes the greater curvature end. *F. Van Haberer.* A *modification of the* operation shown in *D.* The stomach is, so to speak, narrowed or puckered so that it fits the end of the duodenum. A modification of *this has* been done by some *in the following* way. *The* duodenum is split longitudinally and its ends are flared open so that the opening will be large enough to fit the open end of *the stomach.* *F*[1]. Another *modification of von Haberer gastroduodenostomy.* The stomach wall is folded over on the invaginated duodenum.

obstruction demands this. Rarely, parts of the jejunum and transverse colon must be removed and anastomosed.

Finsterer exclusion with mucosa intact is useful where there is great inflammatory reaction and inversion of the duodenal stump is difficult. This may be followed by recurrence, and therefore at a second stage the remaining antrum and ulcer with duodenal cuff may be removed.

The greatest danger of complication in duodenal closure and gastrojejunostomy lies in leakage from the duodenal stump. This may be due to anomalies in the blood supply (gastroduodenal, supraduodenal right gastric, right gastroepiploic, and superior pancreatico-duodenal) which may cause necrosis when principal branches are tied. Often it is necessary to bury the duodenal stump in the pancreas or close it with an attached omental graft or a free graft of the omentum.

The Finsterer operation with mucosal excision gives better results and is useful in a densely adherent pylorus or a poor-risk patient. The results are as good, when combined with adequate stomach resection, as any other type of operation.

3. Combinations of 1 and 2. Poor risk patients who are confirmed "ulcer formers," as evidenced by previous perforated ulcers, recurrence on dietary management, and after vagotomy, may be benefited by duodenogastric intussusception combined with posterior gastroenterostomy. This combination has been used by us with encouraging results. Its value lies in the fact that it moves the pylorus and first portion of the duodenum into the pyloric antrum. The ulcer-bearing area (the pyloric end of the stomach and the pars superior duodenum) is thereby transplanted into a new and more highly acid environment. The effects of this may be hypothetically explained in the light of modern gastric physiology: Acids are reduced because enterogastrone may be released in greater abundance, thereby reducing gastric secretion; the acid in the duodenum is greatly increased, thereby further reducing gastric secretion; and, above all, the transplanted mucin glands (Brunner's and pyloric glands) are stimulated, producing prodigious amounts of mucin. The objections to the operation as follows: the pyloric mucosa is left intact so that it may presumably stimulate secretion and the invagination is apt to delay emptying time. To offset the latter, the operation is combined with posterior gastroenterostomy so that the gastroenteric stoma is continuously bathed with mucin.

4. Of all the resections the most popular is a two-thirds to three-fourths gastrectomy with a Polya type anastomosis, using a short duodenojejunal loop. Wherever possible, the duodenal ulcer is included in the resection. If the ulcer is too close to the ampulla, it is left in situ, and if this cannot be accomplished because of dense adhesions, a two-thirds gastrectomy is done; the pylorus is left but its mucosa is removed. If the inflammatory reaction is too great for mucosal excision, the pylorus is left intact. Later it may be removed. Some have even

patients without a great amount of extrinsic adhesions and fixation. It is a simple safe operation with few complications but offers no protection against a recurrent ulcer.

2. A simple posterior gastroenterostomy is indicated under conditions outlined in 1 where great scarring of the pylorus prevents its use in anastomosis readily. The Devine exclusion operation has a place in massive hemorrhage in patients over 50 years of age, although it is apt to be followed by secondary hemorrhage unless a second operation may be done later. The chief complication is recurrent ulcer or jejunal ulcer. Not infrequently a gastrojejunocolic fistula may form, causing diarrhea, vomiting, pain, loss of weight, and even death from starvation and dehydration. The treatment of this complication requires excision of the ulcer and reestablishment of the normal preoperative status. If the patient can stand more or if pyloric obstruction makes further surgery mandatory, gastric resection is done at the same time. This may be deferred for a second stage by doing an enterostomy for feeding when

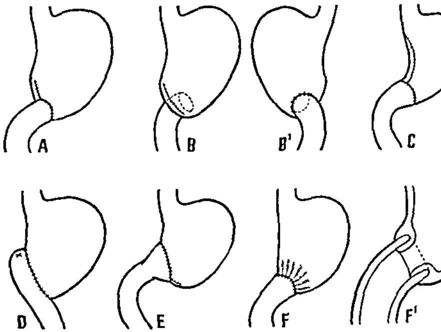

Fig. 281.—Diagrams illustrating resections of the stomach with an anastomosis of the stomach and duodenum (gastroduodenal anastomosis). All of these types in which the stomach is brought to the duodenum are modifications of the Billroth I. *A*. Billroth I. After the pylorus has been removed, the lesser curvature is partially closed and the duodenum is sutured to the open end of the stomach at its lower margin. *B*. Kocher. In this case the distal end of the stomach is closed and the duodenum is brought up to the posterior margin of the closed stomach. *B*¹. Posterior view showing the end of the duodenum anastomosed to the stomach. *C*. Schoemaker. In this instance the lesser curvature of the stomach is sutured and brought down to the same size as the duodenum and then an end-to-end anastomosis is done. *D*. Von Haberer-Finney type. In this operation the side of the duodenum is brought up to the end of the stomach so that the entire end of the stomach is open. *E*. Horsley. The Horsley type of gastroduodenal anastomosis uses the lesser curvature end of the stomach to suture to the duodenum and closes the greater curvature end. *F*. Van Haberer. A modification of the operation shown in *D*. The stomach is, so to speak, narrowed or puckered so that it fits the end of the duodenum. A modification of this has been done by some in the following way: The duodenum is split longitudinally and its ends are flared open so that the opening will be large enough to fit the open end of the stomach. *F*¹. Another modification of von Haberer gastroduodenostomy. The stomach wall is folded over on the invaginated duodenum.

advised two-thirds gastrectomy for high ulcers as a palliative measure since acids are greatly reduced. Here a transthoracic resection of the cardia would be more apropos. Statistics on the mortality of radical gastrectomy vary from 2 to 10 per cent.

Complications which may follow subtotal gastrectomy are (1) recurrent ulcer or gastritis, (2) dumping syndrome, (3) inability to regain weight, (4) anemia, (5) hyperglycemic and hypoglycemic syndromes, (6) rarely, duodenal fistula. From 20 to 30 per cent of all gastrectomized patients have some complaints.

Recurrent ulcer occurs in about 5 per cent; however, this figure varies greatly in different groups of statistics. Some patients complain of ulcerlike symptoms with occasional bleeding. These cases are acute ulcers or *small erosions* with *gastritis*. More than half of our patients fail to gain weight, regardless of rest or diet. Anemia is transient and readily controlled but is persistent in a very small group. Duodenal fistula is the result of leakage from the inverted duodenum as a rule. Unfortunately many fatalities are due to this leakage since drainage is not usually employed. The treatment of fistula is directed chiefly to the replacement of electrolytes lost. The fistula will usually close if the normal channel is open (see Chapter 5).

The Dumping Syndrome.—Gastrectomy was formerly done so that the stoma between the stomach and the jejunum was left so wide that large quantities of gastric material were suddenly dumped into the jejunum which was not capatious enough to hold it. This resulted in a syndrome which consisted chiefly of abdominal distention, cramplike pains, constipation, and rarely diarrhea. In addition, there were vague *symptoms of a sense of goneness, nausea, and fainting. This has largely* been corrected by modifying the Polya operation with the Hoffmeister technique, which consists of closing the lesser curvature portion of the stomach and anastomosing the jejunum to the greater curvature half.

III. *Open end of stomach. C.* Kronlein-Balfour. This is isoperistaltic, antecolic, and end-to-side. The entire end of the stomach is anastomosed to the side of the jejunum. *C*[1], Moynihan II. This is an antiperistaltic, antecolic end-to-side gastrojejunostomy, in other words, the jejunum is brought up anterior to the transverse colon, the entire end of the stomach is sutured to the side of the jejunum, but the flow of the current is from greater to lesser curvature, thereby creating an antiperistaltic effect. *C*[2], Reichel-Polya. This is an isoperistaltic (that is, from lesser to greater curvature), retrocolic, end-to-side gastrojejunostomy. This is one of the most common varieties employed today following a subtotal gastrectomy.

IV. The stomach is not resected. These operations are known as the exclusion operations. *D.* The stomach is divided, the distal portion is turned in, the proximal portion is brought up to the jejunum, usually according to the Reichel-Polya or Kronlein-Balfour type of end-to-side anastomosis. However, any of the varieties of anastomosis of gastrojejunostomy may be practiced. The exclusion operation is rarely done except in those cases where the inflammatory process is too acute and the patient too sick to permit any further type of surgery. Later the antrum may be resected. A modification of this is the one advocated by Finsterer in which, in addition to excluding the antrum, he takes out the mucous membrane of the antral portion which is supposed to secrete the acid-producing hormone. These have been known as the Devine exclusion and the Finsterer antral exclusion with and without resection of the antral mucosa. *E.* The Roux type. This is also known as the "En-y" type of anastomosis. Here the jejunum is severed, the distal limb is sutured to the cut end of the stoma of the stomach or to the side of the stomach as in Billroth 2, and the proximal limb is sutured to the side of the distal jejunum. This operation is useful where there is an insufficient amount of bowel to bring up to the stomach or where this is technically not possible because of dense adhesions. This type of anastomosis avoids viscious circles and dumping syndromes which have been described in connection with other types of operations.

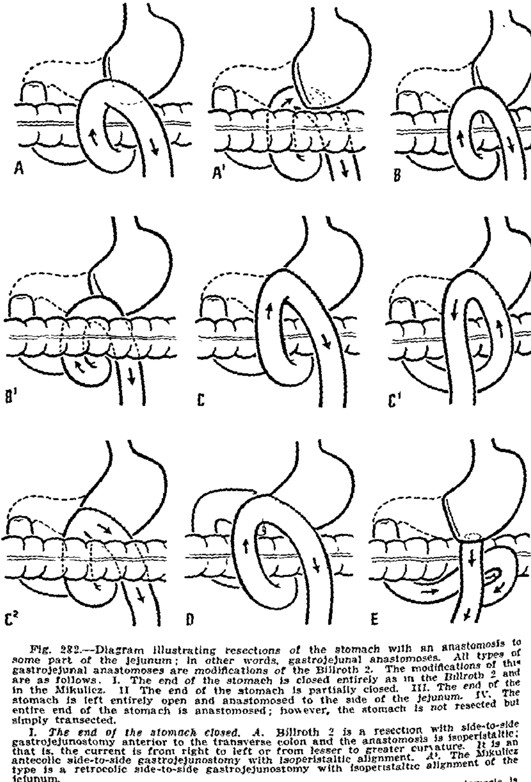

Fig. 282.—Diagram illustrating resections of the stomach with an anastomosis to some part of the jejunum; in other words, gastrojejunal anastomoses. All types of gastrojejunal anastomoses are modifications of the Billroth 2. The modifications of this are as follows. I. The end of the stomach is closed entirely as in the Billroth 2 and in the Mikulicz. II The end of the stomach is partially closed. III. The end of the stomach is left entirely open and anastomosed to the side of the jejunum. IV. The entire end of the stomach is anastomosed; however, the stomach is not resected but simply transected.

I. *The end of the stomach closed.* A. Billroth 2 is a resection with side-to-side gastrojejunostomy anterior to the transverse colon and the anastomosis is isoperistaltic; that is, the current is from right to left or from lesser to greater curvature. It is an antecolic side-to-side gastrojejunostomy with isoperistaltic alignment. A¹. The Mikulicz type is a retrocolic side-to-side gastrojejunostomy with isoperistaltic alignment of the jejunum.

II. *Partially closed end of the stomach.* B. Von Eiselsberg. The anastomosis is antecolic end-to-side, isoperistaltic, but the superior portion of the stomach is closed for a greater part of its surface, thereby creating a small stoma. This allows resection of a greater portion of the lesser curvature and decreases the size of the stoma, thereby tending to avoid the so-called dumping syndrome. B¹. Hoffmeister-Finsterer. This is a retrocolic, end-to-side gastrojejunostomy and is isoperistaltic; that is, from lesser to greater curvature just as the von Eiselsberg's type.

(Continued on opposite page)

follows gastroenterostomy operations. In the hypoglycemic phase, Evansen, whose work was a pioneer study in this field, shows that blood sugars will fall to 65 mm. or less.

Vagotomy Treatment of Gastroduodenal Ulcer.—Recently, due to the studies of Dragstedt and co-workers, the operation of vagotomy has been reintroduced. Dragstedt isolated the stomach in dogs and introduced a gold-plated cannula, leaving the blood supply intact as well as the vagus innervation. Such stomachs are found to secrete an average of 100 c.c. of gastric juice with a free hydrochloric acid concentration of .35 to .42 per cent in twenty-four hours. The total secretion for a month was collected, and then the vagus nerves were divided in the chest just above the diaphragm. The volume of gastric juice immediately declined to an average of 410 c.c., with a free acidity of 0.11 to 0.32 per cent, and this effect persisted for at least sixty days. The operation was found to have no effect on the secretory responses of the stomach to histamine or caffeine, but it abolished the stimulating effect of insulin hypoglycemia. Following this experimental work, Dragstedt began doing the operation of vagotomy through the transthoracic route. The vagus was divided and the proximal ends were tied and buried in the mediastinal pleura so that the two ends could not reunite. Later the operation was performed through an abdominal approach so that conditions in the abdomen could be carefully investigated.

Dragstedt has employed the insulin test to determine if all of the vagus secretory fibers to the stomach were interrupted. The insulin test is as follows: After aspirating the fasting contents of the stomach with a Luer syringe, a sample of blood is taken for the determination of fasting glucose; then 15 units of insulin are injected intravenously and the time of the injection noted. If severe symptoms of hypoglycemia develop, sterile glucose solution is given intravenously. For two hours after injection the stomach contents are aspirated every fifteen minutes and the volume, time of aspiration, and presence of mucus or bile are recorded. A sample is kept for acidity titration. Usually the minimum blood sugar value is reached within thirty minutes. If all of the vagus fibers have been cut, there will be no rise in acidity. This test is usually performed two weeks after the operation. Theoretically, if gastric secretion is decreased, so is mucin. Even though acid has been reduced by vagotomy, we are not sure that this is the entire factor in the causation of ulcer and, if it is, at the same time we are reducing the normal protecting mechanism of the gastric mucous membrane, mucin, so that what little acid remains may do harm.

Clinical Evaluation of Vagotomy.—The results of vagotomy according to Dragstedt have been very good. There are, however, certain complications which are inherently present in the operation. The first is a decrease in the motility of the stomach to such a degree that not infrequently a posterior gastroenterostomy has to be done in order to permit

In addition to the dumping syndrome, another group of symptoms may occur consisting of the following: mild or severe sensations of warmth, sweating, dizziness, faintness, palpitation, nausea, and abdominal pain. In extreme instances there may be syncope or convulsions.

The first group of symptoms occur shortly after the ingestion of food; the other after a latent period of one hour or longer. Rarely the two groups of symptoms may appear in the same individual. It is thought now that both types are related to the rate of absorption of sugar from the small intestine into the blood stream. When the large volume of the stomach content suddenly pours into the unprepared jejunum, a transient hyperglycemia results. This elevated blood sugar is tolerated well by many patients. In a few, however, some symptoms arise. In a study of these patients it has been found that symptoms sometimes precede the rise of blood sugar which does occur as a result of the abnormally quick absorption. Previously it has been thought that the early symptoms following the ingestion of food were due to the dumping syndrome. However, experimental work with balloons showed that this is not the entire explanation. Whatever the exact mechanism, there is in most instances an increased gastric motility and an abnormally rapid delivery of food into the jejunum, usually aided by a short circuit around the duodenum. There is further a failure of normal dilution of hypertonic solutions of sugar in the stomach because of the first two factors mentioned.

Fourth, there is an abnormally rapid absorption of sugar from the jejunum as a result of hypertonic solutions and a larger delivery of food than normal. Fifth, possible effects of distention of the jejunum by direct irritation of the mucosa by undiluted food and the susceptibility of the individual patient. It is perhaps correct to assume that the hyperglycemia phase does not play an important role in the causation of postgastrectomy symptoms which occur two to three hours after eating. Hypoglycemia may account for some of the symptoms which occur in the early morning before the intake of food. The hypoglycemic phase can be partially abolished by the use of atropine and by frequent feedings, especially if atropine is given before bedtime.

Apparently the vagus plays no role in these postgastrectomy symptoms. The entire syndrome is due to a very large absorption of sugar in a very short period of time. Patients often have a blood sugar of 250 to 400 mg. per 100 c.c. of blood. This calls forth a large amount of insulin. The most likely explanation for the syndrome just described is that of a hypoglycemia, not unlike that produced by too much insulin.

The treatment for this syndrome is simple. Patients usually learn the trick of eating solids at the beginning of the meal, so that they will leave slowly, and of restricting their sugar intake. Frequent feedings also help the condition by keeping up a constant level of blood sugar. The foregoing symptoms are not limited to postgastrectomy but also

Fig. 283.—Vagotomy. Operations recently attempted to ameliorate gastric and duodenal ulcer have been directed against the nerve supply of the stomach. Denervations of the stomach are not new but have recently been revived. At present the operation of vagotomy offers great promise. This may be done through an abdominal approach and requires the division of both anterior and posterior vagus nerves. In addition, some type of anastomosis is done to provide for the emptying of the stomach which becomes atonic. For this purpose a posterior gastrojejunostomy is usually employed. The transabdominal approach further offers the surgeon the opportunity to investigate the local condition and decide on what operation is best suited for the particular state of affairs. The transthoracic type of vagotomy is, perhaps, better insofar as it can remove more completely the vagus nerve and its branches. However, gastric atony may ensue. For this, the drug urocholine is sometimes employed. In general if an operation has previously been performed on the stomach and there is a recurrence of the ulcer, transthoracic vagotomy may be a useful procedure. If no previous surgery has been attempted, the transabdominal approach is to be preferred.

Bilateral splanchnicectomy has also been suggested for the treatment of peptic ulcer. The combined vagotomy and left splanchnic interruption has also been tried.

A. Vagotomy through a transabdominal approach. The left lateral hepatic ligament is divided to permit retraction of the left lobe of the liver. The peritoneum over the esophagus is divided transversely and the esophagus is gently pulled downward with the aid of a piece of umbilical tape.

B. Division and excision of a portion of the left splanchnic and celiac ganglion through an incision in the gastrohepatic ligament.

sympathetics and, therefore, if they are divided, there should result a decrease in painful stimuli which may originate in the stomach. As we have pointed out under the subject of motor activity of the stomach, this operation on theoretical grounds could be effective because division of the splanchnics together with the removal of the celiac ganglion, particularly the left, might result in increased mobility or relaxation of the cardia and pylorus and relief from pain. The contention that "no acid, no ulcer" would seem to contraindicate the operation because division of the splanchnics definitely does not decrease the volume or the degree of acidity of the gastric juice. The left splanchnic and left celiac ganglion form the gastric and esophageal plexuses and, therefore, it is probably true that only the left nerve and ganglion need be excised.

The advocates of complete denervation believe that both vagotomy and splanchnicectomy and celiac ganglionectomy would result in an ideal state so far as the production of ulcer is concerned. Here again we would have the decrease in gastric juice together with the obviation of the bad effects of vagotomy. The combined procedure has been done in too few cases up to the present to evaluate the operation clinically. However, in those which we have observed the results were comparable to those of vagotomy, and in one case a recurrence took place. Here, again, complete denervation of the stomach is probably temporary. The intrinsic nervous mechanism of the stomach ultimately reasserts itself. These operations must await further study before they can be definitely evaluated.

The Treatment of Complications of Gastroduodenal Ulcer.—(1) For a long time the dictum of treating *hemorrhage* from gastric or duodenal ulcer was to sit by the bedside and observe the patient in shock, hoping that the factors involved in the natural arrest of hemorrhage would take place and that the patient would soon perform a spontaneous arrest. In addition, small transfusions were given with the idea that with a large one, it would increase the blood volume to such a degree that hemorrhage would recur. The same was said concerning intravenous fluids of all types. This dictum is good insofar as it takes care of the loss of blood volume and the electrolytes. However, it is probably erroneous in some ways. First of all, there was a great difference of opinion at that time as to whether or not any feeding should be given. One school of thought was that the patient should get nothing by mouth at all; another advocated the use of antacids, but no food; and a third used bland feedings to sop up the gastric juice. These three schools of thought were frequently arguing the merits and demerits of their respective methods of management. We can easily understand that food might dislodge a clot within a vessel. Our experience and that of other observers has shown that hemorrhage is not always spontaneously arrested in bleeding gastric or duodenal ulcers.

Studies of large series of bleeding ulcers show that a mortality of approximately 6 to 8 per cent, irrespective of age, takes place. In the

evacuation of the food, although urocholine is useful in treating this complication. In some patients there is diarrhea; however, this is not persistent. Practically all patients say they are relieved from pain caused by the ulcer. Recently, Dragstedt has used the transabdominal approach because it is difficult to know exactly the conditions within the stomach and duodenum. For example, the degree of obstruction, the degree of penetration in the posterior wall, the epigastric and periduodenal adhesions all had to be determined by x-ray and this was not entirely satisfactory. By doing the operation through the abdomen, if other operations are necessary in addition to vagotomy, they may be done at the same time. There is much to be said in favor of this operation. However, the work is too recent to evaluate it correctly, and hypothetically it may be assumed that whereas the section of vagus nerves will give temporary relief, the intrinsic nervous mechanism of the stomach will certainly reassert itself within a definite period of time, the length of which is not yet known. If the motor function of the vagus returns through reinnervation or through the intrinsic motor fibers within the stomach, then surely the secretory fibers will also become reinnervated, either through local channels or those closely related. However, much remains to be seen because the operation in its newer phase is relatively recent, and the final results cannot be estimated yet. There is a place, however, where vagotomy seems to be definitely indicated, and that is in patients who have had a gastrectomy and have had gastrojejunal ulcer or recurrence of ulceration. Here the local factors are known. The stoma is open, the stomach has been resected, and now there is a recurrent ulcer. In such patients a transthoracic vagotomy would certainly be indicated. If the night secretion on the empty stomach is an important factor in the causation of ulcer and the recurrence of ulcer, vagotomy would have a definite place. This seems to be the case in many instances. However, one wonders whether or not large doses of atropine might not accomplish the same thing. In our experience, this has not been true. Even with enormous doses of atropine, motility is decreased but little, and secretions are only slightly reduced. One last point should be made, and that is that the operation probably has no place in the treatment of *gastric* ulcer in which the problem of carcinoma is always present. For this type of ulcer certainly if vagotomy is used, resection should be done at the same time. Factors in favor of the operation are its relative ease of performance and its low mortality rate.

Clinical Evaluation of Splanchnicectomy and Celiac Ganglionectomy.—The operation of denervation of the sympathetics has recently been advocated based upon the fact that excessive activity of the sympathetics might conceivably lead to spasm of the cardia, atony of the fundus and body, and spasm of the pylorus sphincter. Apparently no change in secretion of gastric juice will result, but there should be vasoconstriction of the stomach. Apparently sensory nerve fibers run with the

follows; failure to improve promptly under a strict regimen of bed rest, moderate doses of morphine, milk and cream, 4 ounces, every two hours by mouth, adequate blood transfusions. If, under these conditions, there is recurrence of hemorrhage while the patient is on this strict regimen, then operation will save a life, and it should be done within twenty-four to forty-eight hours from the onset of the bleeding. The mortality in this group of patients will be lower than in those who are left without surgery. Although the most conservative operation which is possible and consistent with the condition of the patient should be done, yet simple ligations of vessels transduodenally or ligation of the gastroduodenal artery has not been found to be effective in arresting the hemorrhage permanently. Hemorrhage may occur from the inferior pancreaticoduodenal or even anomalous vessels. The operation of gastrectomy should be done if at all possible. If not, it should be done as soon as feasible.

Our greatest disappointments have been in patients who have been bleeding for ten days to two weeks or longer, having spurts of severe bleeding and then amelioration with recurrence of bleeding, treated by repeated blood transfusions. These patients stand surgery poorly. (See Chapter 13.) This is due to the fact that irreversible changes take place in tissue cells due to anemic anoxemia which definitely impede their reparative powers so that complications are frequent. Sutures will not hold, and infections due to leakage in the peritoneal cavity may occur. Therefore, it is best to perform the operations for arrestment of hemorrhage early or, if it has been decided that this is not indicated in the older group, then perhaps a feeding jejunostomy would be the treatment of choice, hoping for spontaneous arrest of the bleeding. In those patients who are on the borderline between acceptable risks for gastric surgery and treatment by palliation only, a simple operation should be done such as transduodenal suture of the bleeding ulcer or the use of Gelfoam sewn in place over the bleeding site simply as a temporary measure. A secondary operation should be done later, when the patient has had a chance to recover.

The Treatment of Perforation.—We have seen that ulcers will perforate anteriorly into the peritoneal cavity or posteriorly into the pancreas. We have also noted that the symptoms in these two lesions is entirely different. Rivers has recently suggested that perforation into the pancreas may be diagnosed by the symptoms and signs. He speaks of a clear-cut pattern of the visceral syndrome being distorted by the addition or the substitution of the somatic syndrome. The symptoms become more severe and frequently require more heavy use of opiates; relief obtained by the ingestion of food or alkalis is completely lacking, and there are periods of freedom from symptoms, with changes in location and extension of pain. The pain is usually through to the back in a fixed area over the upper lumbar vertebrae, but it may radiate in various directions in the

older group the mortality is much higher, ranging up to 20 per cent, and in those who have an initial severe hemorrhage, the mortality rate may even reach 30 per cent. Patients under 45 years of age with severe hemorrhage usually recover. Furthermore, in younger people, several hemorrhages may occur without any mortality. In older people a second hemorrhage may be fatal. In striking contrast to these statistics has been a recent study concerning the mortality rate of patients treated by gastric resection who are actively bleeding. The mortality rate has been reduced to a total of approximately 22 per cent. Among patients past

Fig. 284.—X-ray after barium meal showing great dilatation of the duodenum and stomach. This patient had a duodenal ulcer with extremely high acidity. Posterior gastroenterostomy had previously been performed. Incomplete obstruction resulted at the point of anastomosis. At operation a jejunal ulcer was found. The anastomosis was abolished and partial gastrectomy was done.

45 years of age with severe hemorrhage, the mortality rate was 42 per cent, and among those under 45 who had resection, the mortality rate was 30 per cent. According to these studies, patients under 45 years of age do not need surgery, as a rule, because the mortality is practically nil with conservative treatment. It is also true that patients past 45 years of age may have repeated hemorrhages without a fatality. It has been our rule to try to differentiate between patients with fatal and nonfatal types of hemorrhage, and the most consistent criteria have been as

stomach kept empty for a period of seven to ten days. Feedings are allowed, but the suction is started again in two to three hours after the feeding. Adequate fluid balance is maintained by intravenous injection, and plasma and blood volume is maintained by transfusion of plasma and whole blood. After the stomach has been lavaged and prepared in this manner, operation is performed. Usually this will consist in a subtotal gastrectomy. However, as has been pointed out, the indications for different types of procedures, such as duodenogastric intussusception, pyloroplasty, gastroenterostomy, may have their indications.

Carcinoma of the Stomach as a Complication.—Carcinoma of the stomach as a complication of ulcer is not usually determined until the time of operation. One statement should be made in connection with this complication at this time. The surgeon may hold the lesion in his hand and yet not be able to differentiate correctly between a chronic ulcer and a carcinoma or an ulcerating carcinoma of the stomach in its early phase. The size, the location, the friability are all equivocal factors. Therefore, the only sure test is microscopic examination. It is our custom, therefore, in all gastric ulcers to have a microscopic examination made by frozen section at the time of surgery. The ulcer on the duodenal side is usually free from the threat of carcinoma; however, this also should be examined after resection, or if this is not possible, a small piece of the border of the ulcer should be removed for biopsy if at all possible. If carcinoma has been discovered, radical resection, including the lymph nodes, should be done.

Neoplasms of the Stomach

Neoplasms of the stomach may be benign or malignant. Benign tumors of the stomach include (1) polyps and papillomas, (2) myoma, (3) fibromyoma, (4) adenoma. The rare forms of benign tumors of the stomach include fibroma, adenomyoma, lymphangioma, hemangioma, dermoid cysts, cyst adenoma and simple cysts, lipoma, and myxoma. Benign tumors of the stomach and duodenum, in contrast to the malignant ones, are extremely rare. Added to the list mentioned may be included neurofibroma and the granulomas of tuberculosis and syphilis. The latter, of course, are not true neoplasms except in that they may resemble the benign growths.

The importance of benign tumors is not only that of their symptoms and signs and discomforts but also of their potentialities. Chief among the latter tendency is that of obstruction. However, in the case of papillomas or polypoid tumors, the danger of carcinoma is inherent. Furthermore, the relationship between benign tumors and pernicious anemia may be closer than seems apparent. As a matter of fact, pernicious anemia is not infrequently associated with benign growths, although it must be said that the malignant types are more often the associated factor. The actual proportion of benign tumors to malignant ones is about 1 to 200, and they constitute approximately 1.3 per cent of all

abdomen. This type of perforation will require surgery, but this is not an emergency. In this discussion we are concerned with perforation into the free abdominal cavity, the symptoms of which have already been described. The perforation of a small ulcer, the so-called slow leak or formes frustes type, may be treated by conservative measures: the introduction of a Levine tube with suction and large doses of morphine, with nothing by mouth. This conservative treatment has not been universally accepted although good results have been reported. Most surgeons prefer immediate surgery, and the earlier this is performed, the less the chance for bacterial peritonitis and complications such as pelvic abscess, subphrenic abscess, and adynamic ileus. The operation should be the simplest which is consistent with closing the leak. This usually consists of a folding over of the anterior wall of the stomach, thereby closing over the hole. Large perforations require much overlapping of stomach wall as in duodeno-gastric intussusception. Since this may result in a narrowing of the pylorus, a complementary posterior gastrojejunostomy may be necessary. If this is not feasible because of the size of the perforation or because of the friability of the stomach wall, a large omental graft may be used which will adequately seal the opening. We have not encountered a case where we could not fold over the anterior wall of the stomach. We have frequently used the omental graft as a reinforcement. There is, however, adequate clinical and experimental evidence to warrant the use of the living omental graft, and this may be used if desired, or if there is great edema of the stomach wall. All studies show that the bacterial infection in the peritoneal cavity and its results are the major cause of death in perforated peptic ulcers. Microorganisms are to be found in the peritoneal cavity soon after perforation because, as has been said before, the gastric acidity is low and bacteria are found in gastric contents. The peritoneal fluid obtained at operation has a hydrogen ion and a chlorine ion concentration approaching that of blood plasma and, therefore, would not be in itself conducive to severe chemical irritation.

Gastrectomy has been advised in the treatment of acute perforation. We have not found this necessary nor do we consider so extensive a procedure to be indicated. In those who have recurrent ulcer as determined by symptoms, signs, and fluoroscopic examination by barium meal, radical operation can be done at a second time or a second stage. The percentage of patients requiring secondary operation is between 10 to 15 per cent.

Obstruction.—Obstruction of the stomach requires surgery. However, this should not be attempted before emptying the stomach and keeping it empty for at least a week to ten days. It is a well-known fact that the dilated stomach wall has poor healing qualities. First, the blood supply is reduced to the stomach wall; second, the musculature and the mucosa and serosa have been stretched so that they are not in a normal state of tone. Therefore, the Levine tube is introduced and suction applied and the

more, it is important to know that the polypoid variety of gastric carcinoma portant in the treatment, for in the sessile variety it is perhaps wise to include a portion of the stomach wall, whereas in the polypoid variety the mucosa must be excised, but not necessarily the outer layers of the stomach wall.

Malignant Tumors of the Stomach

Malignant tumors of the stomach may be divided into epithelial and connective tissue types. The epithelial types are the carcinomas which are the same variety of carcinomas found elsewhere in the body. Chief among varieties of carcinoma are the adenocarcinoma, medullary, scirrhous, mucoid type, and the ulcerating type. The sarcomas include lymphosarcoma, fibrosarcoma, myosarcoma, angiosarcoma, and malignant endothelioma. By far the most common malignant lesion of the stomach is carcinoma.

Carcinoma of the Stomach

The stomach is probably the most frequent site for carcinoma, with the female genital tract and breast second. Carcinoma of the stomach is most common in men. It is said to cause more deaths than cancer of the lip, tongue, cheek, tonsil, pharynx, larynx, salivary glands, thyroid glands, male and female breast, ovary, uterine cervix, and corpus uteri combined, according to Livingston and Pack. According to Wangensteen, it ranked next to cardiac disease in this country, and of the 150.000 annual deaths from cancer in the United States, approximately 40,000 persons die of gastric cancer. The cause of the disease is unknown. Many theories exist as to the probable cause, and most of these concepts have been discussed in Chapter 15.

Clinically, there does seem to be a very close relationship between carcinoma of the stomach and pernicious anemia. One cannot say which is the cause and which is the effect, but this much is known: in a study of autopsies on individuals 45 years of age or over, 293 cases of pernicious anemia were found. Thirty-six of the latter also presented carcinoma of the stomach, an incidence of 12.3 per cent, which is more than three times as great as the incidence in the remaining autopsies of the individuals of the same age (Kaplan and Rigler). Other relationships which have been advanced to explain this disease are the transforming of a benign polyp or a gastric ulcer into a malignant growth and, last, the theory that atrophic gastritis plays a role. This idea, of course, gains its strong support from the work just cited, showing the frequency with which pernicious anemia is complicated by gastric cancer. Many other theories have been invoked such as the age incidence, which is usually said to be over 45. In our experience, this has not necessarily been true, because a fairly large group of patients under this age have been discovered with cancer of the stomach. The incidence in women is not as low as formerly thought. The hereditary nature or familial tendency toward cancer of the stomach is no greater than the tendency toward the disease in other

gastric growths. Depending upon the type, various possibilities as to their pathological trends are inherent. They may be complicated by bleeding or ulceration or, if they are extremely large, by obstruction. If small, they may find their way beyond the pylorus, acting as an intermittent obstructive lesion. This is particularly true of polyps. Another interesting complication of polyps is the high instance of achlorhydria. This makes the diagnosis of pernicious anemia, carcinoma, and benign growths a very difficult one to make. The symptoms and signs may vary from nothing except an occasional complaint of indigestion to those resembling advanced carcinoma or chronic peptic ulcer. Many individuals are diagnosed as having pernicious anemia and treated on that basis for periods of time until the true nature of the stomach lesion is discovered by x-ray examination.

The *diagnosis* is made by careful physical examination, gastroscopic examination, and fluoroscopic observation with the barium meal. If a polyp is discovered and the symptoms and signs of pernicious anemia are present, the possibility of malignancy degeneration must be borne in mind. The authenticity of the diagnosis of pernicious anemia has been established in these cases by blood smears, bone marrow studies, the presence of glossitis, the findings of subacute combined sclerosis, and achlorhydria after histamine, and the clinical and hematological response to liver therapy. The benign polyp may undergo a rapid change into malignancy, and to confuse the picture still more, very often benign and malignant tumors may exist side by side. Large benign tumors may give no symptoms at all until malignancy has been discovered. Metamorphosis from a small barely detectable lesion to a large inoperable carcinoma has occurred within a period of months in the experience of many observers. Patients with pernicious anemia should have a semiannual x-ray examination of the stomach. Although this will not discover all carcinomas or benign tumors of the stomach, yet in a large percentage these will be discovered at the earliest possible time. About 5 to 10 per cent of the patients who develop cancer of the stomach will have a pernicious anemia. *Treatment* of benign tumors is surgical removal. When discovered at operation or diagnosed preoperatively, these growths should be examined by opening the stomach. They should be removed, including the base, which may then be cauterized. Frozen sections should be made and then if there is any doubt, gastrectomy should be done. If none, and if the growth is benign, the local excision may be sufficient. In a large series of studies, as has been mentioned previously in this chapter, there are approximately 10 per cent of normal persons who have achlorhydria; about 5 per cent remain achlorhydric after two doses of histamine. It is significant that in this group may be found a fairly large percentage of patients with benign polyps. Furthermore, iti s important to know that the polypoid variety of gastric carcinoma is not very common, although this type is the most favorable for complete extirpation. Therefore, the sessile growth of epithelial variety is much

The Symptoms and Signs of Carcinoma.—Unfortunately the disease presents so many symptoms and signs and they are so variable that no group is pathognomonic. In fact, many patients have no symptoms at all, until the growth is beyond control. The older textbooks of surgery always included the presence of a mass. In our experience, when this is felt, surgery is palliative at best. The most consistent symptom is that which might be termed as persistent or recurrent indigestion. When this is found in a man past 40 years, x-ray examination with the fluoroscopic study of the barium meal should be done. If nothing is found and the symptoms persist, x-ray should be repeated at six-month intervals. Another important aid is the study of repeated blood counts, because this is a very important guide to possibilities of the growth. In addition to the fluoroscopic examination, the blood count, and careful study of symptoms and signs, the gastroscope may be of value. However, in many instances, in our experience, this too has failed, because often the lesion is difficult to find with the scope or is beyond the reach of the scope.

The problem of discovering the disease is intimately related to the rapidity with which it grows. If it is slow growing, no symptoms will be manifest, and if it is rapidly growing, symptoms will occur in direct

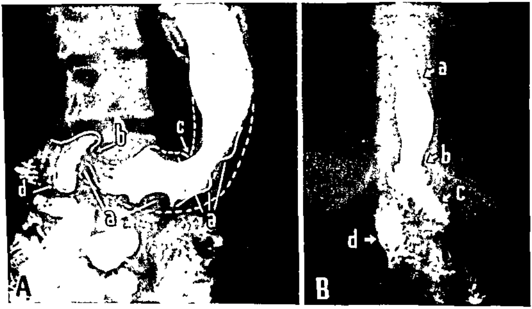

Fig. 286.—Linitis plastica or diffuse infiltrative colloid carcinoma accompanied by extensive fibrosis. *A*. Preoperative x-ray film. *a*, Filling defects; *b*, pylorus, *c*, incisura, *d*, duodenal bulb.

B. P., a woman 47 years of age, complained of loss of appetite, pain in the epigastrium while eating, and heaviness in the epigastrium. The patient had lost approximately twenty-five pounds in less than six months. X-ray examination of the gastrointestinal tract showed a "J" type stomach with defects in both the lesser and greater curvatures. At operation the entire stomach was involved by a diffuse carcinomatous process and accordingly a total gastrectomy was done. The jejunum was brought up to the esophagus as illustrated in Fig. 282. *B*. X-ray photograph showing the condition of the patient four weeks after surgery. *a*, Esophagus; *b*, site of anastomosis; *c*, proximal jejunal loop; *d*, distal jejunal loop. This patient recovered, lived for about two years, and then died of recurrence of the carcinoma. The type of operation performed is illustrated in Fig. 282. (Berman, J. K., and Fant, J. R.: Complete Resection of the Stomach; Quart. Bull. Indiana Univ. M. Center 3: 109, 1941).

parts of the body. Here, again, carcinoma behaves as an organ disease rather than a system disease, although exceptions to this statement are not too uncommon.

Pathological Studies.—Carcinoma of the stomach may take any of the different forms of carcinoma listed in Chapter 15. The more common varieties are the adenocarcinoma or the medullary type, which gives rise to a fairly large ulcerative growth, and the scirrhous carcinomas, formerly called "leather bottle" stomach. In between these groups are various subdivisions. Not infrequently the growth grows centrifugally, and in such cases negative x-ray findings are the rule. However, by the same token, since the growth grows externally, there is early metastases to regional nodes and adjacent organs. We have seen carcinoma of the

Fig. 285.—Adenocarcinoma of the stomach in a man aged 52 years. Arrow points to a probe which has been introduced in a perforation which caused the death of the patient.

greater curvature involve the greater omentum and transverse mesocolon as well as the transverse colon and still have a normal fluoroscopic examination with the barium meal. The scirrhous variety has also been called "linitis plastica" and was formerly thought to be due to syphilis. This has been disproved. Other varieties of carcinoma are carcinoma simplex and mucoid carcinoma.

Some times carcinoma of the stomach will grow very rapidly and cause symptoms of obstruction by its size. Sometimes it will perforate, although this is not common. Rarely multicentric carcinoma of the stomach may occur. In the upper portion of the stomach, extension of the growth may involve the esophagus. However, the phenomenal observation by all men who are familiar with the disease is that it rarely extends into the duodenum, although carcinoma of the duodenum does occur, both as a primary and secondary entity.

period without recurrence, the outlook for cure is extremely good. Another surprising observation made by many surgeons has been the fact that even in the presence of metastasis, palliative resection may prolong life so that the patient lives in comparative comfort for up to three years. This includes a small group in which resections were made in the presence of involvement of the liver, and the metastatic nodule has been removed from the liver. The best results are, of course, in those patients who have a small limited type of lesion. However, in the more extensive varieties radical surgery, including removal of all organs or tissues involved, may occasionally produce a cure and should be tried.

Treatment.—The treatment of carcinoma of the stomach is radical, complete surgical extirpation including the lymphatic extensions wherever

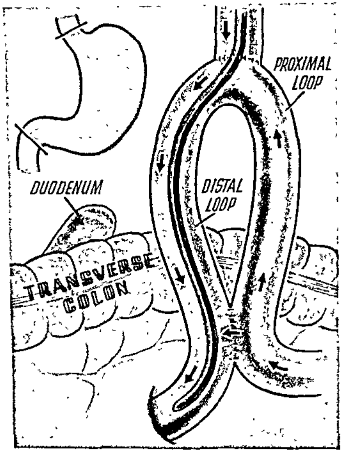

FIG. 287.—Diagram of operation done on patient reported in Fig. 286. Total gastrectomy with an anastomosis of the esophagus to the jejunum is done in cases of extensive carcinoma. The diagram illustrates the anterior method with jejunojejunostomy. This is done so that the pancreatic juice and bile may find its way across into the distal loop without having to go up into the esophagus and then down again. In producing the jejunojejunostomy, the anastomosis may be low down as illustrated in the diagram, or high, in which case if long enough it may simulate an artificial stomach. There have been various modifications of this procedure. For example, the jejunum may be brought up posterior to the transverse colon, or the duodenum may be brought up to the esophagus with an end-to-end anastomosis. Also, the jejunum may be divided, brought up to the esophagus and sutured as an end-to-end anastomosis and then its proximal end anchored to the side of the jejunum in the manner of a Roux Y anastomosis. The diagram gives the false impression that the distal loop penetrates the transverse mesocolon.

proportion to the rapidity with which it distends the organ. However, since the stomach has a large capacity, even this will be late. Blood in the stool may give a lead, but it takes over 7 c.c. of blood to be detected grossly, and the chemical test for blood must be carefully controlled since bleeding anywhere along the gastrointestinal tract will give a positive result. In an effort to discover the disease in an earlier state, mass fluoroscopy was done and, according to Harvey, after fluoroscopic examination of 2,413 men and women, only three cases of gastric carcinoma were found. Daily and Miller examined 500 apparently healthy men over 45 years of age, and no cases of proved gastric carcinoma were discovered. Since the discovery rate is so small, it is hardly worth while to use this as a method of attempting to find the disease in the early stages. Unquestionably in all of the studies, a large percentage of the patients examined will prove to have carcinoma later, but fluoroscopy is not the method by which the disease may be discovered in its early phases. Therefore, we may reiterate that a persistent or recurring indigestion of any sort in a man past 40 years should be carefully watched by repeated x-ray examination.

In the late stage a mass may be felt, and there is considerable amount of pain. Usually when this state is reached, nothing but a palliative operation can be done. Certainly a cure would be rare. In the late stages there is severe pain, but in the early stages the disease is notorious for its lack of pain.

The diagnosis is confirmed only by surgery. However, when the x-ray shows an organic lesion in the stomach, whether it be interpreted as a benign ulcer or other type of lesion, in our opinion, exploration is indicated. Even with the lesion in the surgeon's hands, diagnosis is often times impossible by gross examination and can only be made after microscopic study from the biopsy of the tissue.

The *prognosis* in carcinoma of the stomach is poor. Even with the most radical types of surgery, the percentage of five-year cures is extremely small. Various groups of statistics do not agree with the foregoing statements. One group of figures shows that the five-year survival rate of those who come through the operation is approximately 25 per cent; ten-year survival, 20 per cent; fifteen-year survival, 15 per cent. Of patients who did not have an extension or metastasis, 44.7 per cent are said to have lived five years after leaving the hospital. In contrast to these optimistic figures are those of another group of investigators who aver that five-year survival of unselected patients with gastric cancer is probably in the range of 2 per cent. In our experience the five-year survival rate is approximately 4 per cent. We use the term survival rate rather than cure because the percentage of those definitely cured is probably lower than this figure, but we may say that 5 per cent are alive and symptom free at the end of five years. If no operation is done, none are alive at the end of three years. For those who survive the five-year

a small group has shown that most of the patients live only from one and one-half to two years after total gastrectomy. The operation of partial gastrectomy has been described under the discussion of peptic ulcer. Total gastrectomy implies the removal of the entire stomach, including a cuff of duodenum as well as a cuff of esophagus. In this operation, done through a thoracoabdominal incision, if necessary the spleen, pancreas, and transverse colon also are removed, and any other organs which have been involved may be extirpated in part if necessary. Then the jejunum is anastomosed with the esophagus and an entero-enterostomy is made between the two loops of the jejunum. It has been our custom to make this anticolic. However, many prefer to bring the jejunum up through an aperture made through the transverse mesocolon.

Complications of *total gastrectomy* include diarrhea, dysphagia, and biliary regurgitation. The loss of the intrinsic factor of Castle should cause an anemia, but in our experience it does not do so. A mild secondary anemia is present as in any gastrectomy operation, but this may be easily controlled with liver and iron therapy. It has been our custom to take out the Levine tube after anastomosis has been done; also an enterostomy has been made for feeding in many instances, particularly in patients who are badly debilitated and in whom adequate preparation was not feasible prior to surgery. The tube is left in the stomach after vagotomy and after esophagectomy because the stomach becomes inactive. The presence of a foreign body after an anastomosis is certainly to be looked upon with a great deal of concern because it stimulates secretion and may increase the exudative phase and thereby prolong healing.

Carcinoma of the Duodenum

Primary carcinoma of the duodenum is a very rare condition; its incidence is reported as from .03 to 0.003 per cent of all autopsies. In other words, the percentage varies from 3 in 10,000 to 3 in 100,000 autopsies. Carcinoma of the ampulla of Vater is a more common lesion and is seen more frequently. This lesion is easier to diagnose because of the early obstruction to the common bile duct and, therefore, the possibility of the disease is entertained. However, in primary carcinoma of the duodenum, the lesion can be detected only by x-ray examination or the presence of obstruction due to its size. The treatment of carcinoma of the duodenum, exclusive of the ampulla of Vater, consists of resection of the duodenum or the portion of the bowel involved together with restoration of gastrointestinal anastomosis. In carcinoma of the ampulla of Vater, however, this may also demand resection of the duodenum which is so intimately related to the pancreas that pancreaticoduodenectomy may be necessary; in other words, the Whipple operation. At any rate, the growth should be excised in its entirety, and in carcinoma of the ampulla of Vater, the head of the pancreas may have to be removed in part, if not in its

they may occur. In several instances it has included resection of the transverse colon together with a radical resection of the stomach. Sometimes the head of the pancreas may be resected if it is involved. Again lymph nodes which are in juxtaposition to the common bile duct must be removed if the entire disease is to be eradicated. Total gastrectomy is sometimes necessary when the lesion involves so much of the stomach that leaving part of it would be hazardous. The mortality for total gastrectomy is about 15 to 20 per cent. However, some statistics quote a mortality rate of as low as 10 per cent. Obviously this will vary with the type of patient committed to surgery and the extensiveness of the disease. Certainly it is a justifiable procedure and should be done wherever the condition of the patient makes it at all feasible.

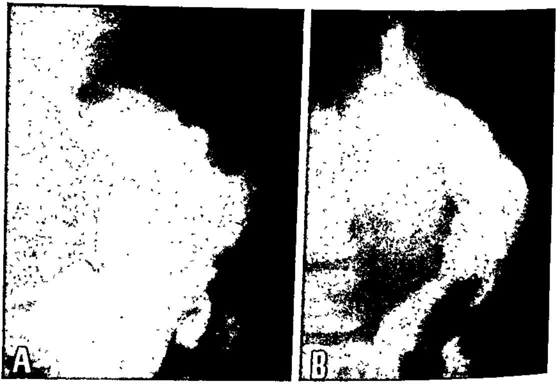

Fig 288.—Carcinoma of the upper third of the stomach in a man, 52 years of age, whose chief symptoms were those of pain, occasional vomiting, and loss of weight. *A*. X-ray photograph showing the preoperative condition. Note the irregularity of the upper third of the stomach and the lower end of the esophagus. At operation a very large adenocarcinoma was encountered involving the entire upper third of the stomach and the lower portion of the esophagus. It had invaded the gastrocolic omentum to a small degree and had spread to the pancreas and the gastrosplenic ligament. A total gastrectomy, splenectomy and resection of the tail of the pancreas was accomplished and then the jejunum was brought up to the lower third of the esophagus as shown in the postoperative x-ray photograph *B*. The surgical approach was a combined thoracoabdominal incision. The exposure by this incision was excellent, and the lower third of the esophagus could be easily resected along with the entire stomach, tail of the pancreas, spleen, and a portion of the gastrocolic ligament. The patient, at the end of one year, was without apparent recurrence.

The recurrence rate after a total gastrectomy is not so encouraging because it is very high. In our experience it is even higher than after partial gastrectomy. This is to be expected because the extent of the disease made the more extensive operation necessary. Our experience with

causes may be included such as prolapse of a benign tumor through the pylorus, transpyloric prolapse of the mucosa, intussusception, volvulus. Most of these conditions have been described previously in this chapter. However, we have not considered the effects of prolapse of the mucous membrane, intussusception, and volvulus.

Prolapse is a rare condition and is so intimately connected with the pedunculated adenoma or polyp that the two conditions are difficult to differentiate. Usually there is an associated pyloric stenosis. The diagnosis is made by the symptoms and signs of obstruction and careful fluoroscopic study with barium meal. The treatment for the condition is to remove the benign tumor, if this is the cause, together with its pedicle, as has been previously described. In cases in which there is a prolapse of the mucous membrane, the treatment of prolapse consists of making a longitudinal incision through the pylorus, excising the redundant mucous membrane and closing the pylorus in a transverse manner in accordance with the Heineke-Mikulicz pyloroplasty.

Intussusceptions occur all along the gastrointestinal tract. The most common site is the terminal ileum and consists of an ileocecal intussusception. This will be described later in the chapter. Rarely an intussusception of the stomach will occur along with a submucous fibroma of the stomach or other types of benign tumors, very much like an intussusception caused by a Meckel's diverticulum in the ileum. Here, again, the diagnosis is difficult to make except that the symptoms and signs lead to the supposition of a stenosis or an obstruction, and the diagnosis is confirmed more or less adequately by the barium meal and fluoroscopic examination. Treatment of the condition is surgical and includes the reduction of the intussusception in a retrograde manner. If this cannot be done with ease, a pyloroplasty may be necessary to accomplish it. In addition, the removal of the benign tumor, if this has been the cause, is indicated.

Gastric volvulus has been reported infrequently. It consists of a torsion from left to right or from right to left and rotation upward. The torsion must be a 180 degrees or more in order to produce an obstruction. The cause of the condition is usually a very redundant gastrohepatic ligament. It must be remembered that the stomach originally is a straight tube and that its lesser curvature faces anteriorly. Failure to rotate may produce partial torsion or volvulus, but these cases rarely produce symptoms However, they leave the patient with a long gastrohepatic ligament so that a torsion may occur. The diagnosis is made by symptoms and signs of obstruction which are usually extremely high and are thought to be in the cardiac orifice. X-ray is not of great value because the barium may not find its way into the stomach. Exploratory operation is usually done to determine the cause, and this is readily observed at the time of operation. Volvulus is reduced and several tucks are made in the gastrohepatic ligament to prevent the recurrence of the abnormality.

entirety, at the same time. The common bile duct is then transplanted into the jejunum, and the latter is anastomosed to the divided stomach as is done in a partial gastrectomy, as previously described. This operation, which has come to be known as the Whipple operation, will be described again under the discussion on carcinoma of the pancreas in Chapter 22.

Sarcoma of the Stomach

Sarcoma of the stomach occurs in the form of a leiomyosarcoma which is rare or a lymphosarcoma or any of the other combinations of tissues with which it may be involved. Leiomyosarcoma is interesting because it has been thought that this lesion may be the cause of the pernicious anemia rather than the reverse. (See discussion on Carcinoma of the Stomach.) In many cases of pernicious anemia there is a hypertrophy of the pyloric musculature, which, after all is what leiomyosarcoma consists of except that it has neoplastic components. Lymphosarcoma is a lesion of the stomach with very rapid potentialities and growth. Because of this rapidity of growth and because of the great variability in age with a tendency toward the more youthful patients, lymphosarcoma may be suspected preoperatively. If the x-ray shows a large organic lesion, probably carcinoma, the disease may be suspected. Roentgenologists sometimes are able to make the diagnosis because of the smooth margins of filling defect and the localized infiltration which it usually shows. This is not at all pathognomonic and, therefore, it is at best a guess. Sometimes the therapeutic tests by x-ray treatment will make the diagnosis, because reticulum-cell sarcoma and the small round-cell sarcoma are sensitive to x-ray, particularly the latter type. Usually the lesion will be diagnosed as a carcinoma, and gastric resection will be made before the diagnosis can be established.

Sarcoma of the Duodenum

Sarcoma of the duodenum is extremely rare, and only a few cases have been reported. Here, too, the diagnosis is usually that of carcinoma of the duodenum, if that diagnosis can be made, and the nature of the lesion is discovered when microscopic examination or biopsy is made.

The treatment for the lesion is the same as that for carcinoma, although the response to x-ray therapy is encouraging. Usually response is transient and the lesion will recur if x-ray alone is used. Occasional cures have been reported.

Obstruction of the Stomach and Duodenum

Obstruction may be caused by congenital anomalies such as atresia or stenosis, by congenital hypertrophic pyloric stenosis which occurs in the first six weeks of life, inflammations such as corrosive gastritis, peptic ulcer, new growths including benign and malignant tumors, and foreign bodies such as the bezoars. In addition, a miscellaneous group of

The prevalence of this congenital abnormality warrants inspection of the terminal ileum for possible Meckel's diverticulum in abdominal explorations.

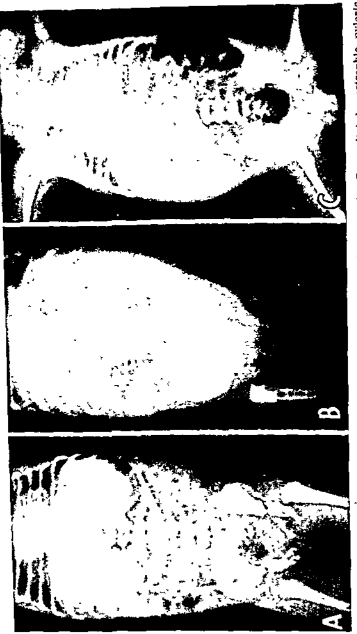

Fig. 289.—Types of congenital obstructions in the gastrointestinal tract. *A*. Congenital hypertrophic pyloric stenosis in an infant. A small amount of barium was given. Note the enormous dilatation of the stomach. Rammstedt pyloroplasty was successfully done. *B*. Congenital atresia of the ileum. Flat plate of the abdomen shows absence of gas in the colon and distention of small bowel and stomach above the obstruction. At operation a congenital atresia of the lower ileum was found. Double enterostomy was performed and then resection and lateral anastomosis done four days later. *C*. Imperforate anus in a newborn infant. X-ray made in the upside-down position, revealing the position of the blind hind-gut. Operation was done from below. The hindgut was brought down to the perineum, with good recovery.

The foregoing discussion shows that Meckel's diverticulum may have various pathological changes, the most common of which are inflammation leading to a diverticulutis, heterotopia of gastric mucous membrane, with peptic ulcer and hemorrhage, and intestinal obstruction with intussusception or volvulus. In the latter group it should be mentioned that we have recently seen an 18-month-old baby who had an acute Meckel's

THE MID-GUT

The mid-gut includes the small bowel from the duodenal papilla down to the middle of the transverse colon. It will be convenient to discuss the lesions of the small intestine as a group and then include the cecum with the rest of the colon in another group.

Congenital Anomalies

We have already discussed earlier in the chapter congenital anomalies of the small bowel. These include atresia, stenosis, malrotation, and duplication. We have also described enteric cysts which are probably another example of duplication. Duplications occur in the large intestine including the appendix. Indeed duplications of the entire large bowel have been reported and even a case of triplication of the large intestine is on record. The enterogenous cysts have been described under the term of enteric cysts, enterocystoma, ilium duplex, and unusually Meckel's diverticulum, giant diverticulum, etc. In our discussion of the peritoneum and mesentery we described congenital cysts, subdivided into lymphatic or lymphangiomatous cysts, urogenital cysts, dermoids or teratomas, developmental cysts, and inflammatory cysts due to intrauterine accident. In the latter group we also included a localized collection of pus which follows a perforated diverticulum or duplication which may be completely encapsulated and surrounded by connective tissue, producing an inflammatory cyst of nonspecific bacterial origin.

Meckel's Diverticulum.—It is generally believed that in 2 per cent of normal adults some remains of this diverticulum are present. The literature is full of various reports concerning changes which may occur in the diverticulum or as a result of its presence. Heterotopia of the mucous membrane and associated glands, superficial and deep, may occur and become implanted in various portions of the alimentary canal. The esophagus, stomach, pancreas, common bile duct, and lung all are part of the original endodermal canal and its derivatives in the 5 mm. embryo. This explains the possibility of heterotopia.

Greenblatt divides the various groups into the following divisions:

1. Peptic group in which gastric mucosa is present with ulcers, hemorrhage, or even perforation.
2. Obstructive group which may give rise to intussusception, volvulus, bands and adhesions, contents of inguinal or femoral hernia.
3. Diverticulitis group which may be simple acute, acute with perforations, and gangrenous or chronic.
4. Umbilical group which may give rise to fecal fistula, umbilical adenoma, or prolapse of intestine through umbilical fistula.
5. The tumor group which may be benign, malignant, or heterotopic tissue such as pancreatic tissue or embryonal rests.
6. Incidental group which contain normal intestinal structure.

Heterotopic gastric mucous membrane may produce a definite syndrome in adults. It probably represents an ulcerative condition in the diverticulum and the marginal portion of it. Rarely, Meckel's diverticulum may be the seat of carcinoma. Approximately nine cases have been reported which were adenocarcinomas of the intestinal mucosa. We have seen one case of adenocarcinoma of gastric mucosa in a child of 7 years.

The diagnosis of a Meckel's diverticulum which is not the seat of a pathological change is extremely hard and cannot be made even with the aid of x-ray, although occasionally the roentgenologist may be able to demonstrate it by giving a barium meal and following through with films every half hour. The inflammatory lesions are frequently mistaken for appendicitis, and it is our custom to examine the last two feet of ileum in all cases of diagnosed appendicitis in which the appendix is found to be normal. Not infrequently the surgeon is rewarded by finding an inflamed diverticulum. The heterotopic mucous membrane of gastric origin in the diverticulum leads to an ulcer which in turn may cause perforation or hemorrhage; usually the chief symptom is hemorrhage which, in a child, is bright red, and it may be profuse. It invariably leads to the suspicion of a Meckel's diverticulum.

Hemorrhage in the child requires careful consideration of the following possibilities: (1) Meckel's diverticulum with peptic ulcer. (2) Intussusception. The symptoms and signs will be discussed later. (3) Duplications of the terminal ileum in which there is a connection between the pouch of the ileum with the lumen of the normal bowel. Ulceration occurs and hemorrhage takes place. (4) A single polyp in the lower colon which may sometimes produce severe bleeding in the child. (5) Multiple polyposis which also occasionally produces bleeding. Although multiple polyposis produces bleeding invariably, hemorrhage is not as common as from a single large polyp. We have seen several cases in which the polyp is in the small intestine rather than in the large bowel. The diagnosis of polyposis is by x-ray or proctoscopic examination. Some of the rare causes for bleeding in the child are: (1) duodenal ulcer; (2) hemangioma of the intestine; (3) Banti's syndrome with portal hypertension; (4) a hypertrophy of the lymphoid tissue of the ileum which may occasionally be seen in the child with ulceration and bleeding; (5) very rarely, terminal or regional ileitis which has been reported in the child with bleeding; (6) extremely rarely a jejunal diverticulum with ulceration—occasionally there may be multiple diverticula of the small bowel. (7) Two cases of repeated massive hemorrhage and the passage of bright red blood by rectum have been reported due to neurofibroma of the ileum. This is extremely rare.

Intestinal Obstruction

Anything which interferes with the propulsion of the contents of the intestinal tract causes marked local symptoms throughout the entire

diverticulitis, and the child was admitted to our service at the Methodist Hospital. The diverticulum was attached to another loop of small bowel, and then the proximal portion of the ileum rotated itself around this newly created band, formed by the diverticulum and its adhesions, to an adjacent loop of small intestine, producing a volvulus with gangrene. Resection was necessary with lateral anastomosis. This was done in two stages, but the *second stage was done within eight days after the first stage.* The reason for this is that children of this age group withstand enterostomy poorly, and the mistake that has been made in the past has been

Fig. 290.—Meckel's diverticulum with intestinal obstruction. *X-ray photograph* of a scout film of the abdomen in a 2-year-old child who came to the hospital complaining of persistent vomiting, no bowel movement, enormous distention, fever of 106° F. and extreme abdominal tenderness. The diagnosis was that of obstruction in the lower ileum with perforation and peritonitis. The child's blood count was 23,000 leucocytes with 95 per cent polymorphonuclears. A Levin tube was anchored, suction applied, and water balance restored. At operation an intussusception was *encountered* due to a Meckel's diverticulum with gangrene of the intussusceptum. Due to the precarious condition of the child, the intussusception was resected and the two ends of the ileum brought out through the incision in the manner of a double-barrel enterostomy. Four days later the child was operated upon again and the enterostomy was taken down, both ends inverted, and a side-to-side anastomosis done. The child was last seen in April, 1949. At this time he was in perfect health. (Case *referred by Dr.* S. Kaufman.)

that the child was permitted to have the enterostomy as long as an adult, which is wrong because water balance cannot be maintained. By doing the second stage eight days after the first, the child's condition was improved sufficiently so that a successful anastomosis was established. The child made an uneventful recovery.

tinal obstruction these three factors must be considered. *Mechanical obstruction* is produced by some organic cause which occludes the bowel from within (obturation), or within the bowel wall itself, or from without (compression). *Obturation* is caused by congenital anomalies (atresia, stenosis), new growths such as carcinoma of the pylorus and carcinoma of the colon or rectum, large polyp, foreign bodies such as barium meal, fecal impaction, a large gallstone which has eroded through the gall bladder into the bowel, or the rare bezoars, balls of hair (trichobezoar) or plant fiber (phytobezoar). Within the bowel wall may be listed inflammation (regional enteritis), trauma, thrombosis, hemorrhage, embolism, and strictures from regional enteritis or colitis, lymphopathia venereum, syphilis, and tuberculosis, diverticulitis, intussusception. *Compression* is caused most commonly by postoperative dense adhesions or bands. A more transient variety occurs after perforative appendicitis, or diverticulitis, due to inflammatory swelling. Incarcerated, or strangulated, hernia is also a very common cause, and, in addition obstruction may be caused by internal hernia, due to congenital bands or defects in the mesentery, especially in the mid-gut and diaphragmatic hernia. External tumor masses, abscesses, or inflammatory masses may compress the bowel. In children, obstruction may be due to *intussusception* (or telescoping) of the bowel, caused by small tumors (polypi) in the lumen, or congenital defects in the wall or in its nervous innervation. It usually occurs at the ileocecal valve, and because it does not produce complete obstruction until late, it is apt to present difficulties in diagnosis. In infants, congenital anomalies such as Meckel's diverticulum (complicated), malrotations, and bands may cause obstruction. *Volvulus* is a twisting of the bowel on its long axis. It is more common in the aged, but may occur in the newborn. There is always a long mobile mesentery.

There is another cause of obstruction due to an imbalance of the autonomic nervous control of the bowel. *Overaction* of the sympathetic and parasympathetic nerves supplying the muscular coat causes intense and prolonged spasm known as *dynamic* or *spastic ileus.* Or there may be an impairment of motor function, leading to inhibition, *adynamic* or *paralytic ileus.* This is an improper term because the bowel is not completely paralyzed as evidenced by the passage of the Miller-Abbott tube. The former is seen in angioneurotic edema, lead colic, or toxic food poisonings. The latter is most commonly seen in inflammatory lesions of the peritoneal cavity with *peritonitis.* However, reflex causes, from disease or injury outside the bowel or even outside the peritoneal cavity, may cause a paralytic ileus. Some of the more commonly encountered causes are postoperative ileus (due to prolonged handling of the intestines), biliary and renal colic, twisted ovarian cyst, pneumonia, spinal or hip fractures, tabes dorsalis, and injuries to the spinal cord. Mesenteric thrombosis or embolism and pancreatitis may also cause a paralytic ileus. The former is distinguished from the latter by the presence of blood in

alimentary canal and also affects the patient as a whole, not infrequently causing death. This interference may be acute or sudden in its onset, though the actual cause may have been present for some time. It may be chronic, due to a stricture or band, and in this case it must necessarily be an incomplete obstruction. If the loop of bowel is occluded sufficiently to obstruct the fecal current without damaging the blood supply, it is known as *simple obstruction*, whereas if the blood supply is impaired, it is a *strangulated obstruction* and leads to gangrene of the bowel. Obstruction of the upper bowel, or *high* obstruction, occurs in the pylorus, duodenum, jejunum, and upper ileum, whereas the *low* variety occurs in the lower ileum or in the large bowel. The time element is important and physicians speak rather arbitrarily of *early* and *late* obstructions according to the severity of the symptoms as well as the duration of the obstruction.

Fig. 291.—Atresia of the ileum. Preoperative x-ray photograph of an infant, 24 hours old, who had vomited constantly since birth and whose abdomen was enormously distended. There had been no passage of flatus or meconium. The x-ray photograph reveals enormously distended loops of bowel which end in the right lower quadrant. At operation three distinct atresias were encountered. The first approximately 20 cm. from the ileocecal valve; the second, about 10 cm.; and the third at the ileocecal juncture. The entire lower ileum and cecum were resected and a side-to-side anastomosis was done. Between the areas of atresia the bowel was normal. The child had mild diarrhea for approximately six months following surgery. This probably occurred because of a *decrease in the absorption area of the large bowel.* However, when last seen in June, 1949, at 2 years of age, she was in excellent health. (Case referred by Dr. George L. Compton and Dr. H. Call.)

More important to the surgeon is the cause of obstruction. This occurs in one or more of three ways: (1) Occlusion of the intestinal lumen so that there is an actual barrier against the propulsion of enteric content; (2) lack of propulsive power due to decreased intestinal peristalsis; (3) embarrassment of the circulation which affects the movement of the bowel and decreases the size of the lumen by swelling. In every intes-

and coronary vasoconstriction which is produced not only by the vasovagal reflex but the anoxemia as well and results in more anoxemia due to cardiac inadequacy and stagnant anoxemia. Here oxygen, as well as atropine, in deeded.

The sludge in an obstructed loop is toxic. It is composed chiefly of dead bacteria. The supernatant fluid is nontoxic. Normal intestinal content is more toxic than the material from an obstructed loop when injected intravenously into experimental animals. There is experimental evidence to show that in an obstructed loop outside the abdomen, absorption will not take place unless the pressure in the loop is less than diastolic. In the abdomen there is absorption, even if the distended loop has a pressure above systolic, due to diffusion through the bowel wall. This absorption is limited by adhesions. The chief dangers are perforation and peritonitis. Strangulation usually occurs from *outside* interference with the blood supply. However, *inside* pressure may be so great as to cause gangrene. This occurs usually in the duodenum or ileum, rarely in the stomach or large bowel, due to the fact that the blood vessels enter the wall of the duodenum and ileum at the mesentery, whereas in the stomach and colon, they almost surround the wall before they enter it. In all types of obstruction, local thromboses ultimately occur. Some absorption occurs through marginal veins in loops that are greatly distended with gas. The intestine of the dog is very muscular and he vomits easily. The rabbit cannot vomit and therefore death occurs early from gangrene and perforation.

Symptoms, Prognosis, and Treatment of Intestinal Obstruction.—The cardinal *symptoms* and *signs* are persistent vomiting, which becomes steadily more stercoraceous, violent cramplike pain, absolute constipation, including an inability to expel flatus, distention, and absence of bowel sounds. *Early*, the vomiting is not fecal in character, cramps are slight, and sounds are present and strong, due to violent peristalsis, and there are slight distention, constipation, and few constitutional symptoms (simple obstruction). *Later*, the vomiting becomes dark and foul, bowel sounds are not heard, distention is great, and constitutional symptoms are prominent (obstruction with strangulation). The greatest help in diagnosis is derived from a scout x-ray plate of the abdomen. It will show the typical stepladder gas pattern and may indicate the site of the obstruction. Although the typical gas pattern may not be present, if there is gas in the small bowel of an adult, it means some type of obstruction. This is not true of children. Gas appears within a few hours after obstruction. Gas in the large bowel unless inordinate is normal. If in small and large bowel, an ileus is probably present. A barium enema is also helpful, but a barium meal should never be given. In addition, blood counts (showing hemoconcentration, high leucocytosis), blood chemistry (showing increases in nonprotein nitrogen and carbon dioxide combining power), and urinalysis (showing a high specific gravity and alkalinity) help to establish the degree of constitutional effects. There may be variations in these symptoms which are confusing to the novice

the stool. Also, in thrombosis, before complete occlusion of the vessel, there is pain following a meal. This is due to inadequate blood supply to the intestinal muscle—very much as in intermittent claudication in peripheral vascular disease.

Pathological Physiology of Intestinal Obstruction.—In simple obstruction the intestine attempts to force its content onward by strong and vigorous peristaltic waves. Since this is unsuccessful, the bowel *above* the site of obstruction is distended with gas and feces, and *below* the site of obstruction it is collapsed. Some reverse peristalsis occurs and vomiting is the result. This causes *dehydration* due to loss of fluid from the bowel (6 to 8 liters per day may be lost). Furthermore, loss of hydrochloric acid depletes the blood chlorides and causes a hypochloremia (except in pyloric obstruction due to carcinoma associated with anacidity). Since chloride exists principally as NaCl in the blood, sodium is retained, combining with plasma bicarbonate and causing an increase in sodium bicarbonate. *Alkalosis* results and the blood shows an increase in the carbon dioxide combining power. We have learned in Chapter 11 that the retention of body water is dependent upon electrolytes. In alkalosis there is a loss of base in the urine (chiefly sodium), which is accompanied by a loss of water, and there is a further loss of water into the obstructed loop, resulting in further dehydration. Absorption of food or water from the bowel does not occur due to disturbance in osmosis. In addition, there will be hemoconcentration and a rise in nonprotein nitrogen and urea (due to tissue destruction and renal impairment). If the bowel wall is damaged because of an impaired blood supply (strangulation), the selective absorptive power of the mucous membrane is lost. (Normally the mucous membrane selects for absorption substances useful to the organism.) When this occurs, there is *toxemia*, due to the absorption of toxins. Since the veins are occluded, the toxins are absorbed by being forced into the peritoneal cavity through the injured bowel wall by the intraluminal pressure. There will be a loss of plasma into the wall of the bowel and peritoneal cavity caused by anoxic anoxemia due to the great distention and stagnant anoxemia caused by venous stasis in the abdomen, which is also due to distention; last, the distention ultimately produces a local tissue anoxemia with leaky capillaries and edema of the bowel wall; thus there is loss of water and electrolytes, alkalosis, hypoproteinemia, and hemoconcentration. The latter increases the stagnant anoxemia, further deflecting plasma proteins; this, in turn, favors edema in the entire body, including the bowel wall, adding an adynamic ileus to all types of obstruction which persist. Contributing to the anoxemia as a result of an overdistended stomach is the coronary vasoconstriction which occurs in older individuals probably through a vasovagal reflex. In the experimental animal this reflex can be produced by overdistention of the stomach, and it can be abolished by sectioning the vagi or using large doses of atropine. Thus another vicious circle may occur in intestinal obstruction: anoxic anoxemia due to the great distention pushing upward on the diaphragm

The prognosis depends almost entirely on the time element. Most obstructions may be handled successfully if seen early, or if there is not too extensive involvement of the bowel.

The *treatment* will depend on the type of obstruction and the general condition of the patient. In general, there must be a correction of the local and systemic pathological disturbances as indicated and then a restoration of bowel function by surgical intervention. In all cases, lost fluid electrolytes and plasma must be replaced (see Chapters 11 and 14). Morphine is given to relieve pain and increase the tone of the intestinal wall. Decompression of the bowel with the Miller-Abbott or Levine or Harris mercury weighted tube and suction apparatus may sometimes cause an obstructed loop of bowel to be released without operative intervention. The Miller-Abbott tube is useful to deflate the bowel in mechanical as well as "adynamic" ileus. Deflation permits absorption of fluid and liquid food in the small intestine. After the tube has descended to the site of obstruction, a very small amount of barium may be introduced, outlining the obstruction and even revealing its cause in some cases. If left in place, the surgeon can immediately find the obstruction by finding the tip of the tube. It should not be left in too long because of injury to the larynx and ulceration of the aryepiglottic folds; also in devitalized bowel it may cause a perforation, and rarely esophageal varices are made to bleed by its use. We may conclude that the medical treatment of bowel obstruction is in every sense an emergency.

Surgical intervention is indicated for the release of the impinged or occluded intestine. Immediate operation should be done in all early cases or in those in which gangrene is suspected. The criteria for suspecting gangrene are (1) history of a sudden onset of crampy colicky pain coming in episodes with persistence of pain between the episodes, (2) palpable mass or localized tenderness, (3) fever, rapid pulse, and leucocytosis which persist in spite of treatment for dehydration. Sometimes it is difficult at operation to determine the viability of the bowel after it has been strangulated. Usually the application of warm moist packs will encourage the return of circulation if infarction with necrosis has not occurred. Other methods to determine viability include the fluorescein test. This consists of the intravenous injection of 5 c.c. of a 5 per cent solution of fluorescein, to which sodium bicarbonate has been added to make a 5 per cent solution. The rays of the ultraviolet bulb, which is covered with a purple glass filter, are directed on the questionable loop. Soon a golden-green color appears except in the areas devoid of blood supply. If, in addition, a 10 per cent solution of procaine is injected into the mesentery, the effects of vasoconstriction are diminished, permitting a more accurate evaluation of the blood supply. A quick and reliable test is the inhalation of 100 per cent oxygen which results in a prompt change in color in viable bowel. In late obstruction the operation may consist of enterostomy alone, or if gangrene is present, resection with enterostomy. Seldom will the

and mature alike. In *high obstruction* there are *early vomiting, no distention, early dehydration,* and *bowel movements* for some time, whereas in *low obstruction vomiting comes very late and distention is early* and there is no passage of flatus or stool. Paralytic ileus causes very little pain. In obstruction at the pylorus there is vomiting, but the vomitus contains no bile; in obstructions below the pylorus, the vomitus contains bile. In lower obstructions the vomitus is more stercoraceous than in those higher up in the intestinal canal. Obstructions of the small intestine and of the sigmoid are apt to be strangulated due to their long mesentery. In most obstructions of the large bowel (which *has no*

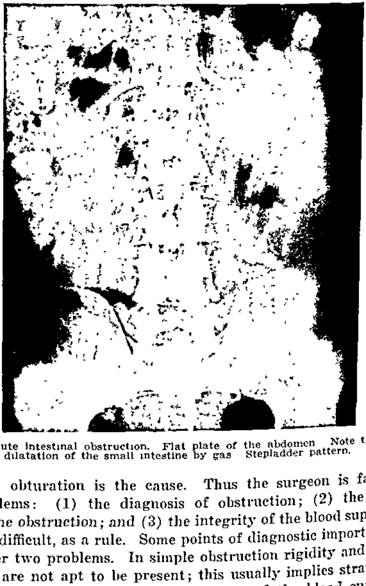

FIG. 292.—Acute intestinal obstruction. Flat plate of the abdomen. Note the enormous dilatation of the small intestine by gas. Stepladder pattern.

mesentery) obturation is the cause. Thus the surgeon is faced with three problems: (1) the diagnosis of obstruction; (2) the probable nature of the obstruction; and (3) the integrity of the blood supply. The first is not difficult, as a rule. Some points of diagnostic importance help in the latter two problems. In simple obstruction rigidity and localized tenderness are not apt to be present; this usually implies strangulation in small bowel obstruction with impairment of the blood supply. In simple obstruction gas may be centrally located with a transverse long axis, while in loop obstruction all sorts of bizarre patterns may be seen and proximal distention is slow.

two later. Early intestinal obstruction of any variety belongs in Group 1 and is probably best treated by surgery as soon as the patient can be properly prepared.

Group 2: An example of bowel obstruction which requires immediate operation, even though the patient's condition is unfavorable, is that of strangulation. The operation should be delayed only long enough to prepare the patient for surgical intervention. This is done by an attempt to replace the water-electrolyte loss and to replenish the loss of blood or plasma. The diagnosis of a strangulated loop is made when there is intestinal colic with vomiting, intestinal distention, and absolute constipation, combined with the signs of local inflammation and peritonitis. Usually the venous rather than the arterial circulation of the bowel is disturbed. Ultimately, however, the latter is also impaired when the pressure within the vein equals the arterial pressure. However, even before this stage, there is a tremendous passive congestion which soon gives way to hemorrhage in the tissues of the intestine, then into the lumen of the intestine, and finally into the free peritoneal cavity. This initiates the so-called "aseptic" peritonitis, although bacteria are probably present. The cardinal signs of peritonitis have already been described and include tenderness, distention, adynamic ileus, and a silent abdomen. Although there are local tenderness and rigidity over the area of strangulation, these may be absent when gangrene occurs. In addition, there are fever and leucocytosis, although these are found in all types of obstruction. If in doubt, the surgeon will prepare the patient and proceed with operation immediately in all cases of suspected strangulation. Here, again, the scout film of the abdomen will be of great help in distinguishing early strangulations from such conditions as perforated appendicitis or diverticulitis, because the film will show a distended loop of small bowel, whereas in diverticulitis or appendicitis there will be an ileus of the so-called paralytic type in which both large and small intestine may be distended. In volvulus, one large distended loop may be seen. Two conditions which may be indistinguishable by physical and roentgen signs from volvulus are mesenteric thrombosis and an internal strangulated hernia.

Another example of Group 2 obstruction is intussusception. This requires immediate operation in all instances to avoid gangrene. Reduction by barium enema is not advisable unless it should occur while the diagnosis is being made and even here it is not reliable.

Group 3: Examples of those conditions which are amenable to delayed operative intervention are the incomplete or intermittent obstruction. Careful studies should be made to reveal the site and nature of the obstruction so that a correct evaluation of the condition may be obtained. Such cases may be prepared by restoration of electrolytes, blood volume, and plasma, and the administration of penicillin and streptomycin; enemas may be tried to relieve discomfort. The causes responsible for this group of obstructions are gallstones or foreign bodies, internal hernia, loops of

surgeon elect to do a complete operation in late cases, because the patient's condition will *not* permit it. Later he may finish his work in a deliberate manner.

Some General Rules in the Treatment of Bowel Obstruction.—From the standpoint of treatment, intestinal obstruction may be divided into four groups based upon the pathology present and the condition of the patient: (1) Obstructions which require immediate operative intervention and in which surgery may be safely undertaken; (2) obstructions requiring immediate surgery in patients whose general condition may not tolerate it; (3) obstructions in which delayed operative intervention is feasible and desirable; and (4) those types of obstruction which may be amenable to nonsurgical treatment in patients not dangerously sick. Examples of the various groups may be cited.

Group 1: Complete obstruction of the transverse, descending, or sigmoid colon *must be considered as a closed loop obstruction* because of the competence of the ileocecal valve on the proximal side and the presence of the obstruction distally. Therefore, this type of obstruction when complete may cause tremendous distention and must be relieved by operative intervention. The Levin or the Miller-Abbott tube with suction will be useless because of the ileocecal valve. The diagnosis of this particular type of obstruction is *usually made by the history*. The patient will describe *successive attacks of cramping pains* with a change in the habit time of bowel action, finally resulting in more or less complete constipation. Also, he may tell of alternating diarrhea and constipation, nausea but rarely vomiting, and mucus and blood in the stool. The patient is usually 50 years old or over and he does not look ill. Physical examination shows early distention, however, bowel sounds may be *heard*. *Digital examination of the rectum will usually reveal the neoplasm.* If it is too high up for the finger to feel the mass, a proctoscopic examination may be done, and this will help make the diagnosis. If the physician depends upon the patient's history or statement that he can take a large enema and, therefore, cannot be completely obstructed, he will be misled. *It is true that the normal colon will accept a quart or more but usually not the obstructed one.* This is, however, a debatable type of criterion because many normal patients cannot accept much water by enema. Furthermore, it is not wise to introduce too much water for fear of perforation. X-ray studies *help* to confirm the diagnosis. A barium enema may be tried but *should not* be introduced under great pressure because *the barium will find its way above the obstruction where it becomes dehydrated and converts an incomplete obstruction into a complete one.* The barium finally becomes extremely hard and may be very difficult to remove before surgery. *A* scout film of the abdomen usually reveals the greatly distended *colon.* The type of operation in such cases will ordinarily be *palliative (that is, cecostomy or transverse colostomy)* and will be a preliminary measure to deflate and empty the colon so that this organ may be removed safely a week or

two later. Early intestinal obstruction of any variety belongs in Group 1 and is probably best treated by surgery as soon as the patient can be properly prepared.

Group 2: An example of bowel obstruction which requires immediate operation, even though the patient's condition is unfavorable, is that of strangulation. A barium enema may be tried but should not be introduced under great pressure because the barium will find its way above the obstruction where it becomes dehydrated and converts an incomplete obstruction into a complete one. The barium finally becomes extremely hard and may be very difficult to remove before surgery. A scout film of the abdomen usually reveals the greatly distended colon. The type of operation in such cases will ordinarily be palliative (that is, cecostomy or transverse colostomy) and will be a preliminary measure to deflate and empty the colon so that this organ may be removed safely a week or

already mentioned previously in this chapter the fact that bezoars may find their way through the stomach and cause an intestinal obstruction. One other type of foreign body obstruction should be mentioned which is rare, and this is an obstruction due to *gallstones*. Practically all gallstones which cause an obstruction are dislodged into the intestine through a cholecystenteric fistula. This in turn is due to a very large gallstone with cholecystitis, causing the gall bladder to adhere to the duodenum as a rule; then by pressure necrosis, the large stone is sloughed through into the small intestine. After the stone finds its way into the small bowel, it may be arrested anywhere along its course. Not uncommonly this will be near the ileocecal valve. The characteristic stages in gallstone obstruction are, first, an antecedent acute cholecystitis, chronic cholelithiasis, the passage of the gallstone through the fistula into the intestine, and then the recurrent bouts of intestinal colic and finally obstruction due to impaction of the stone. In addition, the stone, once it is lodged, begins to pick up foreign matter, causing it to increase in size, completing the obstruction. Then, of course, there is impaction behind this stone causing an obstruction. The final arrest of the stone may occur at any level of the intestinal canal, depending upon its size and the size of the bowel. Normally, however, since the lumen decreases as it reaches the ileocecal valve, the latter site will be more common. The symptoms and signs of obstruction due to gallstones are not characteristic. However, in most instances a careful history will give or reveal symptoms referable to disease of the gall bladder, usually of long duration, and the symptoms will be referable to the migration of the stone into the intestine from the gall bladder, and then there will be the symptoms and signs of recurrent obstruction. The diagnosis is rarely made prior to operation, although it may be suspected. X-ray examination reveals the site of the obstruction, the cause of which cannot be ascertained by the flat plate unless the stone is heavily infiltrated with calcium and forms a definite shadow; then it may be suspected. Rarely the x-ray film will show the air in the biliary tree, and this may help in making the diagnosis. Since barium given by mouth is contraindicated in all obstructions, the cholecystoduodenal fistula could not be visualized by this means. However, where this has been done, the fistula has been visualized.

The treatment of obstruction due to gallstone impaction is the same as that of any type of bowel obstruction; namely, a decompression with the Miller-Abbott tube. A very small amount of barium may be introduced through the tube which would lead to the site of the obstruction, should this be found necessary. As a rule, however, as soon as the distention has been removed and water and electrolytes have been replaced, operation is the treatment of choice. Enterotomy, removing the stones and suturing the bowel, gives good results. The longitudinal incision of the bowel should be adequate and be closed transversely so as not to produce a narrowing. The prognosis in the condition is usually good if the

intestine which have slipped under an adhesive band, forming a sort of pseudointernal hernia, external hernias which have been reduced enmasse, and large accumulations of pus such as in pelvic abscess and appendiceal abscess which partially occlude the bowel by extrinsic pressure.

Group 4: Obstructions which are amenable to conservative therapy are those which occur in patients who are in good general condition and who show a good response to conservative management in the first twenty-four to thirty-six hours. Such patients usually develop the obstruction in the early postoperative period. The cause is ordinarily an inflammatory edema.

The Treatment in Special Types of Intestinal Obstruction.—In addition to the rules which have been briefly reviewed, certain types of obstruction require special consideration. Atresias, stenoses, and duplications of the bowel have been considered in previous paragraphs.

Perhaps the most common type of obstruction by obturation is that of *fecal impaction.* This is seen only rarely in the normal individual, yet often enough to demand a rectal examination in every patient who has symptoms and signs of obstruction. The condition is seen not infrequently in the insane or in the aged due to the neglect of bowel function. Not too rarely, it is encountered following surgical procedures. Unless the charting is accurate, the attending surgeon may be misled into believing that the enema has been effectual when in fact it has not. The symptoms and signs are those of a low obstruction which is incomplete, and following surgery this is apt to be misleading. There is great distention and no vomiting or rarely so, and a "scout film" of the abdomen immediately shows the distended large bowel. Digital examination reveals the true condition. The treatment will require digital breaking up of the impaction and repeated use of enemas with glycerin. Very often the entire hard incretion must be removed manually, and this is particularly true in the insane. A more common type of impaction is that induced by the use of barium which has been injected beyond an incomplete obstruction due to stricture or new growth in the lower bowel. Here the barium is difficult to force through, but once it enters, it immediately or very shortly thereafter loses its fluid content and becomes hard, converting an incomplete obstruction into a complete one. It is very difficult to remove this barium. Usually a colostomy must be done to wash it out. This can be accomplished with large quantities of saline solution, and sometimes peroxide is used to break it up. Children with megacolon or Hirschsprung's disease very frequently have incomplete obstruction due to fecal impaction. This, too, must be manually extracted.

A rare form of obstruction may be due to *foreign bodies.* This is seen in the insane occasionally. It is also seen in children who have stenosis. On several occasions we have seen children with imperforate anus and rectoperineal fistula suffer complete bowel obstruction due to ingestion of a prune seed which completely occludes the small lumen to the outside. This also requires removal in order to relieve the obstruction. We have

already mentioned previously in this chapter the fact that bezoars may find their way through the stomach and cause an intestinal obstruction. One other type of foreign body obstruction should be mentioned which is rare, and this is an obstruction due to *gallstones*. Practically all gallstones which cause an obstruction are dislodged into the intestine through a cholecystenteric fistula. This in turn is due to a very large gallstone with cholecystitis, causing the gall bladder to adhere to the duodenum as a rule; then by pressure necrosis, the large stone is sloughed through into the small intestine. After the stone finds its way into the small bowel, it may be arrested anywhere along its course. Not uncommonly this will be near the ileocecal valve. The characteristic stages in gallstone obstruction are, first, an antecedent acute cholecystitis, chronic cholelithiasis, the passage of the gallstone through the fistula into the intestine, and then the recurrent bouts of intestinal colic and finally obstruction due to impaction of the stone. In addition, the stone, once it is lodged, begins to pick up foreign matter, causing it to increase in size, completing the obstruction. Then, of course, there is impaction behind this stone causing an obstruction. The final arrest of the stone may occur at any level of the intestinal canal, depending upon its size and the size of the bowel. Normally, however, since the lumen decreases as it reaches the ileocecal valve, the latter site will be more common. The symptoms and signs of obstruction due to gallstones are not characteristic. However, in most instances a careful history will give or reveal symptoms referable to disease of the gall bladder, usually of long duration, and the symptoms will be referable to the migration of the stone into the intestine from the gall bladder, and then there will be the symptoms and signs of recurrent obstruction. The diagnosis is rarely made prior to operation, although it may be suspected. X-ray examination reveals the site of the obstruction, the cause of which cannot be ascertained by the flat plate unless the stone is heavily infiltrated with calcium and forms a definite shadow; then it may be suspected. Rarely the x-ray film will show the air in the biliary tree, and this may help in making the diagnosis. Since barium given by mouth is contraindicated in all obstructions, the cholecystoduodenal fistula could not be visualized by this means. However, where this has been done, the fistula has been visualized.

The treatment of obstruction due to gallstone impaction is the same as that of any type of bowel obstruction; namely, a decompression with the Miller-Abbott tube. A very small amount of barium may be introduced through the tube which would lead to the site of the obstruction, should this be found necessary. As a rule, however, as soon as the distention has been removed and water and electrolytes have been replaced, operation is the treatment of choice. Enterotomy, removing the stones and suturing the bowel, gives good results. The longitudinal incision of the bowel should be adequate and be closed transversely so as not to produce a narrowing. The prognosis in the condition is usually good if the

condition is taken care of early. The cholecystoenteric fistula should not be attacked at this time. Later it should be treated by cholecystectomy and closure of the fistula.

Intestinal obstruction due to adhesions and bands will give rise to either the simple or strangulation type. Usually if it is occlusion or compression, it will be the simple type. *Volvulus* or *torsion* may occur as a result of the presence of abnormal bands in the peritoneal cavity. In a very large series the frequency of obstruction due to bands and adhesions will equal about 30 per cent. In fact, it is now more common to find an obstruction due to adhesions or bands than to hernia. The clinical features are not unusual. The history of previous operations makes the diagnosis even more likely. If the adhesive bands simply impede the fecal current, there is very little tenderness, but if there is strangulation, tenderness is present. Diagnosis is made by the history, physical examination, symptoms and signs, and x-ray studies. It is in the immediate postoperative period that this diagnosis is particularly difficult, because it must be distinguished from an inflammatory lesion and postoperative ileus and peritonitis. Here it may be wise to use a decompression tube of the Miller-Abbott type until a diagnosis can be established. The outlook is good, and in most instances when the surgery is judicious and properly timed, recovery will follow.

Intestinal obstruction due to hernia has been discussed under complicated types of hernia. However, it should be mentioned that internal types of hernia may cause obstruction. This is particularly true of diaphragmatic hernia, hernia into the foramen of Winslow, periduodenal fossae, persistent hole in the mesentery, and other areas of internal hernia.

A volvulus or torsion of the bowel usually occurs in the sigmoid. A long flexure in which the ends of loop are closely approximated predisposes to its occurrence. It has also been reported in the ileocecal region, and in congenital types it is not uncommon. The latter have been previously discussed and will not be reviewed here. It has been our observation that any bowel that is completely obstructed and has a long mesentery may undergo volvulus due to the distention of the proximal loop which may fall in a clockwise or counterclockwise direction. We have seen this in bands around Meckel's diverticulum or in long bands due to postoperative adhesions and also in congenital types of obstruction. The clinical features are those of extreme distention. Very frequently the distended loop of cecum or sigmoid may be seen as well as percussed. Sometimes visible peristalsis is observed. The x-ray will show a large loop of distended bowel which is clearly defined and then distention proximal to this very large blind loop. In the differential diagnosis, mesenteric thrombosis, acute pancreatitis, peritonitis, and strangulation of an internal hernia may mimic the condition so closely that frequently the diagnosis is not made until operation is done. However, the local tenderness and the mass may suggest volvulus as soon as deflation has been effected by the Miller-Abbott

tube and electrolytes restored; operation should be done immediately. The mortality in intestinal torsion is about 50 per cent, and in cases requiring excision, it rises to 75 per cent. One of the reasons for this is the delay in operation. If the condition is diagnosed early and surgery instituted, the mortality is lowered. In several cases we have been able to unwind the torsion and the bowel has regained its color and did not require resection. In most instances, however, the bowel is devitalized and resection is necessary. Primary anastomosis at the time of resection may be done if the general condition of the patient permits. However, not infrequently a double barrel enterostomy will be necessary.

There are apparently two types of volvulus of the large bowel: (1) The acute type which is very fulminating and occurs in young people. It causes severe generalized cramping pain, only transient vomiting, acute distention which is great, prostration, and tenderness of the entire abdomen, particularly the twisted loop. The process is very acute and the bowel becomes gangrenous very early. (2) The subacute type which occurs in older groups of patients. The same course is present as in the acute type only it is much slower in developing. The x-ray is perhaps the best aid to the diagnosis because it shows the tremendously dilated sigmoid which, by the way, is situated on the right side of the abdomen when it twists, moderate distention of the colon above the volvulus, and the absence of collection of fluid within the twisted loop. A barium enema may be given, and this may lead to further information, although the appearance may not be entirely unequivocal. The steeple or "spire" appearance of the barium is almost characteristic. The normal appearance of the mucosa of the sigmoid and rectum distal to the volvulus is to be expected. Most patients cannot hold a large barium enema, and this in itself leads one to think of low obstruction.

Volvulus of the cecum and ascending colon is not as common in our experience. However, it does occur for the same reasons as on the left side; namely, an unusually long mesocolon. The causes of volvulus on the right side are strong peristalsis following heavy purgation or overeating, abdominal tumors, mesenteric cysts, fecaliths, foreign bodies, direct violence, habitual constipation, and, rarely, acute appendicitis. Perhaps pregnancy may be added to this list because of the position in which it places the cecum.

The diagnosis is usually not made with accuracy. However, the symptoms and signs are those of intestinal obstruction, and the roentgenological study may make the diagnosis. The cardinal points are demonstration of the dilated cecum which is enormous and variable lengths of dilated ascending colon and terminal ileum. The cecum is in an abnormal position and is found in the left upper quadrant in 90 per cent of the cases. Cecal outline is abnormal. A barium enema will enter the bowel much more readily than when the volvulus is on the left side. However, it will be found by this method of examination that the dilated portion of the large bowel is proximal to the point of obstruction and that there is no outline

of the cecum. In the differential diagnosis, the presence of obstructing tumors within the bowel, obstructing adhesions, dilated obstructed stomach, and redundancy of the colon must be considered. However, with the symptoms and signs of intestinal obstruction and the picture outlined, one suspects the presence of a volvulus which is sufficient to indicate surgery. On the left side, surgery consists of removal with primary anastomosis, if the bowel is devitalized, and if the patient can stand it; if not, exteriorization. Since volvulus tends to recur after detorsion, some method of fixation of the cecum will be sufficient to prevent recurrence. Resection is indicated where the blood supply is compromised. A simple untwisting of the volvulus on either side is perhaps unwise because of the danger of recurrence. Some method of fixation or plication is indicated. A word

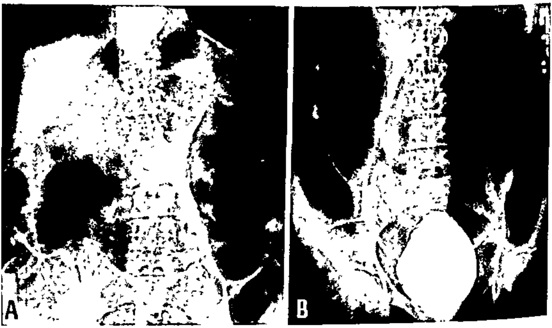

Fig 293.—Volvulus of the large intestine. *A*. The x-ray photograph is a scout film of the abdomen of a woman, 71 years of age, who came to the hospital complaining of enormous distention and constipation with some vomiting. Note the great dilation of the large bowel. *B*. X-ray photograph of a barium enema. The findings are characteristic. There is a steeple, or rather a cone outline of the superior margin of the barium. Immediately above this is the enormously dilated sigmoid. At operation the bowel was so large that a purse-string suture was placed in the serosa and a No. 18 hollow needle introduced to deflate the large intestine. After this manuever the bowel resembled a deflated innertube of a tire The purse-string suture was tied after the needle had been removed. The sigmoid had become rotated 360 degrees in a clockwise manner. Shortly after the colon had been untwisted, its color returned to normal. The patient was last seen one month after surgery and was without symptoms.

should be said about primary anastomosis. In dealing with greatly distended bowel, particularly large bowel, the danger of leak in primary anastomosis, whether it be *ileotransverscostomy or a colocolostomy*, is great, and therefore many observers have stressed the point that primary anastomosis should not be done and that exteriorization is the treatment of choice. While in principle this is true, if some form of drainage is instituted proximal to the anastomosis, we have found that this will save a second operation and will be successful in a large number of cases. In other words, it is

our practice in volvulus on the left side to do a cecostomy with a large tube to protect our suture line. On the right side the suture line is protected by temporary ileostomy made by introducing a large catheter into the ileum in the manner of a Witzel procedure. In all doubtful cases or in patients who cannot stand a primary anastomosis, a Mikulicz type of resection is the operation of choice.

Intussusception means a telescoping of one portion of the intestine or colon into a more distal segment of the enteric tube. The entering wedge is the intussusceptum and the receiving portion is the intussuscipiens. An extremely rare condition is one in which the proximal portion is the intussuscipiens. This is extremely rare. The cause of intussusception in the adult is usually brought about by some mechanical abnormality, whereas in childhood and infancy this is not true. In a large series of cases, Meckel's diverticulum, intestinal polyp, duplications, and lymphoma are found to be predisposing factors.

The types of intussusception, depending upon the anatomical position, are as follows; ileocecal, which means that the ileum is forced into the cecum (most common type), ileoileal, ileoileocecal, ileoileocolic, colocolic, and other multiple types. In other words, the intussusception may be single, double, or triple. We have had one case of triple intussusception which was ileoilealcecalcolic. The condition usually occurs in fat and healthy-appearing babies between the ages of 5 and 10 months, although it may occur in childhood or adult life. In the child the clinical manifestations are fairly pathognomonic. There will be recurrent colicky abdominal pain. This can be detected in the infant by the fact that the baby becomes intermittently pale and doubles up, drawing his legs up to his abdomen. This will last for ten to fifteen seconds, sometimes a minute. The child will burst out crying and may vomit. Indeed, vomiting is an early symptom. This recurrent pain, together with pallor, sweating, dehydration, and shock, accompanied with the passage of bloody mucus from the stool, is sufficient to make the diagnosis. Light red or dark brown mucoid material is a pathognomonic sign. If the condition is seen early, the child may appear well in between attacks of colic. However, by careful examination the mass may be felt within the abdomen or by rectal examination. Late, the child shows all the symptoms and signs of dehydration and late intestinal obstruction as previously described. Barium enema may be given and not infrequently shows the intussusception clearly. Indeed, it may partially or totally reduce it. Some have advocated this as a method of treatment. The rectal examination is important because usually bloody mucus appears on the finger and the mass may be palpated. We have had several cases in which the intussusception has proceeded so far that it could be easily felt within the rectum. This leads sometimes to the diagnosis of a prolapsed rectum. However, by passing the finger into the rectum between the intussusceptum and the surrounding anal sphincter, the diagnosis may be established. In a prolapsed rectum there is no such space to admit a finger, whereas in an intussusception this may be

of the cecum. In the differential diagnosis, the presence of obstructing tumors within the bowel, obstructing adhesions, dilated obstructed stomach, and redundancy of the colon must be considered. However, with the symptoms and signs of intestinal obstruction and the picture outlined, one suspects the presence of a volvulus which is sufficient to indicate surgery. On the left side, surgery consists of removal with primary anastomosis, if the bowel is devitalized, and if the patient can stand it; if not, exteriorization. Since volvulus tends to recur after detorsion, some method of fixation of the cecum will be sufficient to prevent recurrence. Resection is indicated where the blood supply is compromised. A simple untwisting of the volvulus on either side is perhaps unwise because of the danger of recurrence. Some method of fixation or plication is indicated. A word

should be said about primary anastomosis. In dealing with greatly distended bowel, particularly large bowel, the danger of leak in primary anastomosis, whether it be ileotransverseostomy or a colocolostomy, is great, and therefore many observers have stressed the point that primary anastomosis should not be done and that exteriorization is the treatment of choice. While in principle this is true, if some form of drainage is instituted proximal to the anastomosis, we have found that this will save a second operation and will be successful in a large number of cases. In other words, it is

palpated again, where diagnosis can usually be established by feeling the mass. A longitudinal incision is made and the intussusception is reduced by the process of milking, or taxis of the proximal segment. Extreme gentleness is used so that the bowel will not be torn and so that the toxic substances are not milked out through the devitalized bowel. If it is found that the reduction cannot be effected, or if the bowel is gangrenous, resection should be done with a minimum of handling. A word of caution is necessary. After the intussusception has been reduced, the bowel wall will be edematous, and sometimes the surgeon will be misled into believing that he has effected complete reduction when another loop may be telescoped in the one already reduced. Should gangrene be present, resection is necessary and this should be done speedily and without much handling. Since the adoption of this policy, we have been successful in resecting large lengths of bowel even in very young infants where previously the mortality was extremely high, up to 50 per cent.

Intussusception in adults is known to occur through pathological influences as a rule. These may be listed as follows: typhoid ulcer, tuberculous ulcer, dysentery, acute appendicitis, Meckel's diverticulum, congenital polyp or band, submucous lipoma, foreign body, sudden dietary change, and neoplasms. Three forms are usually encountered: (1) Enteric, in which the small intestine invaginates; it occurs in older children and in adults and is usually of organic causation. (2) Colocolic, which occurs in elderly persons and not infrequently is caused by a polypoid carcinoma or benign polypoid growth. (3) Enterocolic (which accounts for 75 to 85 per cent), in which the ileum invaginates into the colon; this is not so commonly seen in adults. Following gastroenterostomy the afferent loop may telescope into the stomach or the afferent loop may find its way into the stomach by retrograde pulling up or by the stomach falling down over it. Thus, either of the loops may intussuscept into the stomach.

The symptoms and signs in adults are very vague since the obstruction is not complete. There are colicky pains in the abdomen, some nausea and vomiting, constipation, and blood stools. A mass may be felt, but only in very thin individuals. The diagnosis is made mainly by barium enema, and not infrequently barium is given by mouth with the supposition that the obstruction is partial. The differential diagnosis in children lies between acute appendicitis, acute enterocolitis, simple colic, mesenteric lymphadenitis, and tuberculous mesenteric lymphadenitis. In the adult, as in the child, operation is indicated. If reduction is easily accomplished, this may be all that is necessary. However, should the blood supply of the bowel be impaired, resection must be done. It does not carry the high mortality that the same operation carries in children, provided that the operation is done early and that the patient is properly prepared for surgery.

Obstruction Due to Vascular Lesions.—This type of obstruction may be due to mesenteric thrombosis or embolism. The arterial occlusion is

traced as high up as the finger can reach. Usually there is no fever in either case. The barium enema shows an obstruction with a cupola effect; a thin cylindrical shell of barium surrounds the intussusception which remains after evacuation of the enema; and there is a partial or complete regression of the intussusceptum if the barium is injected with sufficient pressure.

The *treatment* of the condition is immediate operation. Although some observers still believe that the barium enema is useful in reducing the obstruction, we have considerable doubt about this method because one cannot be sure that the entire intussusception has been released. It is therefore proper to conclude that barium enema should be used for diagnosis rather than for treatment. The patient should be prepared the same as in other type of intestinal obstruction, and under ether anesthesia the abdomen

Fig. 294.—Triple intussusception. J. D. was a boy 7 months old, who came to the hospital with a history of cramping pains in the lower abdomen accompanied by the passage of a small amount of bloody mucus. The mother stated that the child had vomited at frequent intervals and that he was quiet for periods varying from ten to thirty minutes, then he would suddenly cry out and draw up his legs as though he were in violent pain and pass a little bloody mucus. The x-ray photograph shows the preoperative condition. At operation a triple intussusception was encountered. The first occurred about 12 cm. from the ileocecal valve. This was an ileo-ileal intussusception. This, then, pushed its way into the cecum, forming an ileo-ileocecal intussusception (white arrow). In turn, the cecum invaginated into the ascending colon, converting the intussusception into an ileo-ileocecal-colic intussusception (black arrow). At operation the three intussusceptions were reduced by the retrograde "milking" technique. Fortunately, no gangrene was present and the child made an uneventful recovery. (Case referred by Doctor H. Call.)

thought to be the cause of 60 per cent and thrombosis of a vein in 40 per cent. However, regardless of the type, after the obstruction is established, both components become occluded. The superior mesenteric artery is more frequently concerned in embolism than the inferior, partially because of its earlier exit from the aorta, but mostly because it is of more direct continuation. Furthermore, it is important that in inferior mesenteric thrombosis due to a better and freer anastomosis which occurs between the end vessels, occlusion of the vessel may fail to produce gangrene. Last, thrombosis of the portal vein may cause a type of infarction of the upper bowel, including the stomach. We have recently encountered two cases with thrombosis of the celiac axis in which the hepatic artery was involved. Vegetations on the valves of the left side of the heart are usually the etiological factor. However, this is not uniformly true. The causes of embolism as previously described may predispose to mesenteric thrombosis. In addition, such conditions as arteriosclerosis and thromboangiitis obliterans have been reported. We have had one case of the latter. This was present in a patient who did not have peripheral Berger's disease. The aching, gnawing periumbilical pain was always exaggerated after a meal when it became so severe that we termed it "intermittent intestinal claudication." Last, we have recently reported a case in which we think

---

and was dismissed from several hospitals because there could be found no actual cause for his excruciating pain. Finally, he was thought to be a morphine addict.

On admission to the hospital he had a temperature of 101.4° F. with a pulse of 100 and respirations of 25. The systolic blood pressure was 130 and the diastolic was 70. The entire abdomen was soft, but the patient complained of severe pain. The lower abdomen seemed to be more full than the upper, and there was some tenderness in the region of the left costovertebral angle. Physical examination disclosed no gross abnormalities. Some significant laboratory tests should be mentioned. The white blood count was 40,100. The urine had a specific gravity of 1.033 and had albumen and ten to fifteen pus cells per high-power field. The P.S.P. kidney function test of two hours was 55 per cent. The spinal fluid examination was normal. This patient became steadily worse and the generalized abdominal pain finally was so excruciating that a grain of morphine failed to relieve it. The patient was vomiting. At this time surgical consultation was requested and a diagnosis of mesenteric thrombosis was made. However, before surgery could be instituted the patient expired.

Post-mortem examination showed the peritoneal cavity to contain a small amount of brownish fluid. The small intestines were distended with gas and were necrotic. There was a small amount of fibrinous exudate on the peritoneal surfaces. The necrosis extended from the duodenal jejunal flexure to within 20 cm. of the ileocecal juncture. The cause of this thrombosis is extremely interesting. *A.* Proximal portion of the superior mesenteric artery hematoxylin-eosin stain. The dark area in the center is a fresh thrombus. *B.* Proximal portion of the superior mesenteric artery elastic tissue stain. Dark area in center is fresh thrombus around which is a pale vascular fibrous tissue (old organized and canalized thrombus or possibly thickened intima.) At the upper right inside the internal elastic lamella is a crescent-shaped dark area composed of fibrous tissue containing many elastic fibers (which stain black). The crescent-shaped area may be a thickened intima or an older organized thrombus. *C.* Cross section of the aorta showing a plaque in the intima. Note the pale lipoid areas in the depths of the plaque and the dark-staining, fresh, organized thrombus on the surface. *D.* Aorta with many plaques. Note the large pale lipoid area in the plaque on the right and thrombus on the surface of plaque on the left.

This illustrates a case of internal thromboangiitis obliterans. There was no evidence of the disease in the extremities either clinically or at post-mortem examination. This case exemplifies many well-known clinical features of mesenteric thrombosis, but by far the most important feature is pain out of all proportion to the physical findings. The radiation and location of the pain did not fit any other clinical picture and as in thrombosis anywhere in the body, the pain is severe but particularly so when the mesenteric vessels, either arterial or venous, are occluded. The pain may be compared to that of an acute hemorrhagic pancreatitis and, indeed, can only be distinguished clinically from this by the presence of bloody stools in mesenteric thrombosis. Another feature of this pain is the fact that it occurs in characteristic episodes before it finally becomes continuous. Undoubtedly, the episodes of pain are due to vasospasm before the occlusion is complete. This is aggravated by increased peristalsis after eating very much, as *intermittent claudication* is brought on by muscular activity in peripheral vascular disease. Obviously, when the blood supply is completely shut off, the pain is continuous and excruciating. (Berman, J. K., and Thornton, J. C.: J. Indiana M. A. 33: 138, 1940.)

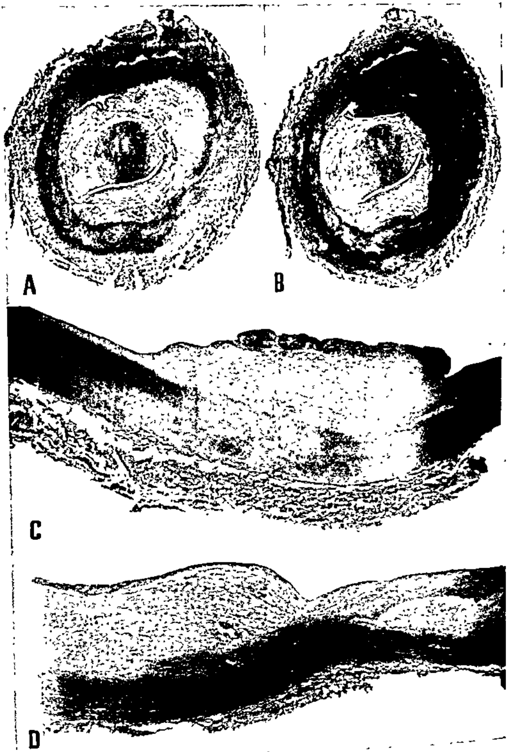

Fig. 295.—Occlusive vascular *disease of the abdomen.* The cause of mesenteric thrombosis is discussed in the text. However, a rare cause is that of occlusive vascular disease similar to some of the varieties which are found in peripheral vascular disease discussed in Chapter 6. The patient whose vessels are shown in the photomicrographs was a white man, 38 years of age, who came to the hospital complaining of a severe generalized, constant abdominal pain, made worse by the ingestion of food or water. He had attacks of vomiting, pain in the scrotum, burning on urination, and constipation. He had been sick for about seven months; however, x-ray examinations and careful studies failed to reveal the cause of the severe pain. He was diagnosed as a psychoneurotic

(Continued on opposite page)

that large doses of ergot predisposed to an endarteritis affecting the mesenteric vessels. In this patient, a thrombosis of the superior mesenteric artery occurred following the ingestion of large quantities of ergot. Embolism is more frequent than thrombosis of the artery. Venous thrombosis is usually associated with an infection within the abdominal cavity, such as appendicitis, strangulated hernia, septic pylephlebitis. Should obliteration of the mesenteric artery occur slowly, it is conceivable that a collateral circulation could be formed and that gangrene would not occur. The condition may be diagnosed by the symptoms and signs. Usually the patient complains of severe abdominal pain which comes on suddenly. There is vomiting in large copious amounts of dark, bloody fluid. If the inferior mesenteric artery is involved, a diarrhea may occur with large amounts of blood. This will not be true until late if the superior mesenteric artery is involved. Shock is usually present, and distention of the abdomen is progressive and the bowel sounds are absent. The pain is extreme. In no condition is pain more severe than in that of mesenteric thrombosis, not even the pain of acute hemorrhagic pancreatitis. There is a high leucocytosis. The flat plate of the abdomen shows the distended loops of bowel which are widespread and which give the idea of a paralytic ileus rather than a mechanical obstruction. Therefore, in patients with predisposing causes, such an endocarditis or inflammatory lesions within the bowel, the sudden onset of pain with distention and vomiting of blood-stained fluid in large quantities, silent abdomen, bloody diarrhea if the inferior mesenteric artery was involved, together with no fever, shock, the distended bowel as seen by x-ray all point to the diagnosis of mesenteric thrombosis. The *treatment* is *immediate surgery*. Large amounts of intestine may be *successfully resected with primary anastomosis. There should be careful* attention to water balance and blood volume balance, and it is our opinion that chemotherapy aids in the protection of the patient against peritonitis. Therefore, large doses of penicillin and streptomycin are used. We have recently reported a case in which we resected 216 inches (549 cm.)—539 cm. of small intestine and 10 cm. of large intestine.

Neoplasms of the small bowel rarely cause an obstruction. The neoplasms may be benign or malignant. The benign types include lipoma, myoma, adenomyoma, fibroma, adenoma, angioma, various types of cysts and polypi, and heterotopia of gastric, pancreatic, and other types of tissue. The importance of these benign tumors is that they very often start an intussusception. Sometimes they cause bleeding, particularly the angiomas. There may be colicky types of pain, and the diagnosis may be made by a careful examination by barium meal. However, usually the diagnosis is established at operation. Of the malignant types of growths in the small bowel, multiple carcinomas have been reported; also polypoid carcinomas, exclusive of the ampulla of Vater. Adenocarcinomas are sometimes found in the duodenum, the jejunum, or ileum. In addition, sarcomas, carcinoids, primary Hodgkin's disease, atypical reticuloendotheliomas, lymphosarcomas, and neurogenic sarcomas have been reported in the

Fig. 296.—Mesenteric artery thrombosis. Photograph of gross specimen of resected intestine which included the entire small bowel except for about eighteen inches (45.7 cm. of jejunum). The rest of the bowel, including the remainder of the jejunum, that is, all except eighteen inches, all of the ileum, the cecum, and ascending colon, were removed up to the hepatic flexure, and then the jejunum and transverse colon were anastomosed by a side-to-end anastomosis. Arrow points to thrombus in the superior mesenteric artery. L. B. was a woman, 51 years of age, who came to the hospital complaining of severe abdominal pain with continual epigastric cramping pain which radiated to the lumbar area, vomiting of copious amounts of thin, dark, foul-smelling grumous fluid. The abdomen was distended and a few tinkling sounds were heard on auscultation. Rectal examination did not show any abnormalities, and blood was not seen on the examining finger. The leucocyte count was 16,400. A roentgenogram of the abdomen revealed great distention of the stomach and multiple distended loops of small bowel with some distention of the colon. The excruciating pain, the high leucocyte count without fever, the suddenness of onset, lack of previous surgery, the type vomitus, the shock all pointed to a mesenteric thrombosis, and since there had been no passage of bloody material from the rectum, it was probably in the superior mesenteric rather than in the inferior mesenteric distribution. This was found at operation. The patient made an excellent recovery and was last seen in July, 1949. At this time she was still having approximately six to eight pasty stools per day. However, they had decreased in amount and the consistency was becoming more firm.

Recently the patient returned to the Indianapolis General Hospital for study. The following significant findings were present. (1) Although the patient was hypertensive before surgery, her blood pressure is now normal. (2) There is no free Hcl in the stomach. (3) There is a severe hypochromic microcytic anemia (4) There has been complete amelioration of symptoms with the use of B_{12}. (From Berman, Brown, Foster, and Grisell: J. A. M. A. 135: 918, 1947.)

that large doses of ergot predisposed to an endarteritis affecting the mesenteric vessels. In this patient, a thrombosis of the superior mesenteric artery occurred following the ingestion of large quantities of ergot. Embolism is more frequent than thrombosis of the artery. Venous thrombosis is usually associated with an infection within the abdominal cavity, such as appendicitis, strangulated hernia, septic pylephlebitis. Should obliteration of the mesenteric artery occur slowly, it is conceivable that a collateral circulation could be formed and that gangrene would not occur. The condition may be diagnosed by the symptoms and signs. Usually the patient complains of severe abdominal pain which comes on suddenly. There is vomiting in large copious amounts of dark, bloody fluid. If the inferior mesenteric artery is involved, a diarrhea may occur with large amounts of blood. This will not be true until late if the superior mesenteric artery is involved. Shock is usually present, and distention of the abdomen is progressive and the bowel sounds are absent. The pain is extreme. In no condition is pain more severe than in that of mesenteric thrombosis, not even the pain of acute hemorrhagic pancreatitis. There is a high leucocytosis. The flat plate of the abdomen shows the distended loops of bowel which are widespread and which give the idea of a paralytic ileus rather than a mechanical obstruction. Therefore, in patients with predisposing causes, such an endocarditis or inflammatory lesions within the bowel, the sudden onset of pain with distention and vomiting of blood-stained fluid in large quantities, silent abdomen, bloody diarrhea if the inferior mesenteric artery was involved, together with no fever, shock, the distended bowel as seen by x-ray all point to the diagnosis of mesenteric thrombosis. The *treatment* is *immediate surgery*. Large amounts of intestine may be successfully resected with primary anastomosis. There should be careful attention to water balance and blood volume balance, and it is our opinion that chemotherapy aids in the protection of the patient against peritonitis. Therefore, large doses of penicillin and streptomycin are used. We have recently reported a case in which we resected 216 inches (549 cm.)—539 cm. of small intestine and 10 cm. of large intestine.

Neoplasms of the small bowel rarely cause an obstruction. The neoplasms *may be benign* or *malignant*. The benign types include lipoma, myoma, adenomyoma, fibroma, adenoma, angioma, various types of cysts and polypi, and heterotopia of gastric, pancreatic, and other types of tissue. The importance of these benign tumors is that they very often start an intussusception. Sometimes they cause bleeding, particularly the angiomas. There may be colicky types of pain, and the diagnosis may be made by a careful examination by barium meal. However, usually the diagnosis is established at operation. Of the malignant types of growths in the small bowel, multiple carcinomas have been reported; also polypoid carcinomas, exclusive of the ampulla of Vater. Adenocarcinomas are sometimes found in the duodenum, the jejunum, or ileum. In addition, sarcomas, carcinoids, primary Hodgkin's disease, atypical reticuloendotheliomas, lymphosarcomas, and neurogenic sarcomas have been reported in the

small intestine. Diagnosis is usually established at the time of operation, although in cases which have a long history of colicky pain and in which no definite diagnosis can be made, a careful examination with the x-ray should be done. If this does not reveal the site of obstruction or the cause for the colicky pain, it may be necessary to do an exploratory operation with stripping of the bowel in an effort to locate the site of the growth. In benign or malignant neoplasms the growths should be removed, the former by enterotomy or resection, depending on whether the neoplasm is on a pedicle or is sessile, and, of course, in malignant types, resection with an adequate margin of normal tissue and with associated lymph nodes should be done. Sarcoidosis of the small intestines may simulate nonspecific types of enteritis or benign growths or malignant growths. *This is known as Besnier-Boeck-Schaumann disease.*

Jehgers and co-workers have recently reported a new syndrome which is recognized by two features: (1) melanin spots of the buccal mucosa and lips (sometimes also the face and digits), (2) polyposis (adenomatosis and papillomatosis) of the small intestine (rarely the stomach, colon, and rectum). The disease seems to be hereditary.

Other causes for obstruction may be due to *inflammations*. Of these the more common are tuberculosis and regional enteritis.

Adynamic Ileus.—True or idiopathic postoperative paralytic ileus is rare and is probably a misnomer because (1) it is not a true paralysis since the Miller-Abbott tube will go down, and (2) it is rarely, if ever, idiopathic. It may be associated with any type of obstruction and is usually the end stage in all obstruction. The causes of adynamic ileus are as follows:

I. Intra-abdominal
- A. Peritoneal irritation
  - 1. Traumatic
    - a. Postoperative
    - b. Penetrating wounds
  - 2. Bacterial: peritonitis
  - 3. Chemical
    - a. Extravasation of blood
    - b. Perforated peptic ulcer } Early
    - c. Bile peritonitis } Early
    - d. Acute pancreatitis } Early
- B. Vascular changes
  - 1. Strangulation
    - a. Intramural: distention following mechanical ileus
    - b. Extramural: compression of the mesenteric vessels
  - 2. Mesenteric thrombosis
  - 3. Abnormal permeability of capillaries—angioneurotic edema
- C. Extraperitoneal irritation
  - 1. Hemorrhage, especially retroperitoneal
  - 2. Infection
  - 3. Renal

II. Extra-abdominal
  A. Toxic
    1. Pneumonia
    2. Uremia
    3. Empyema
    4. Systemic infection
  B. Neurogenic
    1. Injuries and diseases of the spinal cord
    2. Lead poisoning
    3. Fracture of the lower ribs

The symptoms and signs include vomiting, constipation, great distention, "silent" abdomen, with or without tenderness, depending upon the cause, but with little pain. X-ray examination shows all of the bowel to be distended. Although the picture resembles peritonitis as previously described, there are differences in the so-called "idiopathic" type. There is absence of fever and leucocytosis; vomiting occurs in large quantities, yet there is expulsion of gas and even a mild diarrhea. Mental symptoms are common. There is severe dehydration and hypoproteinemia.

The treatment includes prevention—no strong cathartics preoperatively and during operation gentle handling of tissues, careful hemostasis, peritonealization; postoperatively, liquids only for forty-eight hours, minimal use of narcotics, early mobilization (which implies early and adequate urination without use of the catheter), no cathartics and no enemas until bowel action has become coordinated (about fourth day). The treatment consists of passage of the Miller-Abbott (and not the Levin) tube with suction, attention to electrolytes, water, protein, and blood volumes, and oxygen inhalation. In addition, careful examination to determine the probable cause of the ileus must be done. We have found that as long as the bowel remains distended, it will be difficult to restore water and electrolyte balance. Therefore, the Miller-Abbott tube must be used early. Enterostomy is not as effective but may be employed if the Miller-Abbott tube cannot be introduced. The tube should remain down until there are good strong bowel sounds, complete deflation, and normal passage of gas. Then the tube should be removed slowly over a period of at least forty-eight hours; x-ray studies with the tube in place may disclose the site of obstruction.

Multiple Causes of Obstruction.—In any bowel obstruction there may be many causes rather than one single factor. Although a list of causes are given, it is common experience to find more than one lesion or even more than one lesion of the same kind; for example, bands with volvulus, multiple tumors, appendicitis with pelvic abscess, strangulated hernia (postoperative) with bands inside the abdomen also obstructing, etc.

Rupture of the intestine may occur without external wound, simply from blunt force. Punctured wounds, made by bullets or sharp instruments, may cause a perforation. Perforative peptic ulcer may cause a leak in the stomach or duodenum. In any of these the primary peritoneal

insult may cause shock. This is followed by *violent pain, with boardlike rigidity of the abdominal muscles.* The x-ray may reveal free air between the liver and diaphragm. Unless immediate operation with closure of the perforation is done, peritonitis will result. Multiple perforations due to gunshot are better treated conservatively. Closure of all is almost impossible without endangering life. Nature effectively seals these small holes in most cases. If hemorrhage is a complication, the outlook is not as favorable.

Tuberculosis occurs usually in the lower ileum, attacking Peyer's patches of lymphoid tissue. Although a mass of tissue may be felt, usually the symptoms are those of tuberculosis plus intestinal obstruction (Chapter 8.) The treatment is surgical and consists of resection of the diseased bowel and ileocolic anastomosis. Typhoid fever also attacks Peyer's nodules. Sometimes severe hemorrhage or perforation occurs in typhoid, demanding surgical intervention.

Terminal ileitis (regional enteritis, nonspecific granuloma) occurs in the small intestine (lower ileum), although a similar lesion may occur in the colon (regional colitis). Rarely more than one side is affected at the same time. The lesion is inflammatory, begins and ends abruptly in the bowel, and may give rise to localized abscesses, due to penetration of the bowel wall. Fistulae may result. In the early stage there are swelling and edema, with regional lymphadenitis. Later, fibrosis occurs, with obstruction. The cause is not known. The disease may be related to lymphogranuloma inguinale, although there is no proof of this, which produces strictures in the rectum, or, like cardiospasm, it may be due to overactive sympathetics, with local spasm and ultimate fibrosis. There is evidence along this line because of the type person who usually contracts the disease. The so-called linear type is defined in Chapter 10 in which peptic ulcer or chronic ulcerative colitis as well as regional enteritis may be present. Symptoms are variable. They may resemble acute appendicitis or may be vague abdominal pain with alternating attacks of diarrhea and constipation. Diagnosis is made by fluoroscopic examination with barium enema. This shows a characteristic narrowing of the ileum (string sign). Other parts of the small or large bowel show deformities which involve fairly long segments. Treatment in the early stages may be palliative and includes the use of penicillin and streptomycin with succinylsulfathiazole or Sulfathalidine. Psychotherapy helps. The lesion may be discovered first when the surgeon removes a supposedly diseased appendix. Sometimes resolution occurs following this procedure; more frequently, resection is necessary, but is not always curative. Indeed short-circuiting operations may give the same results as resection, although the latter is preferable.

Appendicitis

The most common surgical condition encountered in the hospital is *appendicitis.* This is an inflammation of the vermiform appendix caused

by infection, obstruction of its lumen, or obstruction with infection. Obstruction is probably the deciding factor in every case. This may be edema, mucous fecalith or lymphoid hyperplasia, scarring or mechanical twist. In any event, there is created a blind loop obstruction which interferes with venous return, causing more obstruction. Soon the venous pressure *equals arterial pressure, and gangrene with perforation may result and* may be followed by peritonitis or abscess (local pelvic, subphrenic pericolic, or horseshoe which extends across the pelvis and up the right and left colic gutters). Seepage of contaminated fluid may occur through the appendix wall due to great intraluminal tension in addition to the devitalization without actual perforation, thereby accounting for abscess and peritonitis without perforation; if the obstruction is evolved slowly or if the secretory power of the appendiceal mucous membrane is impaired, atrophy takes place.

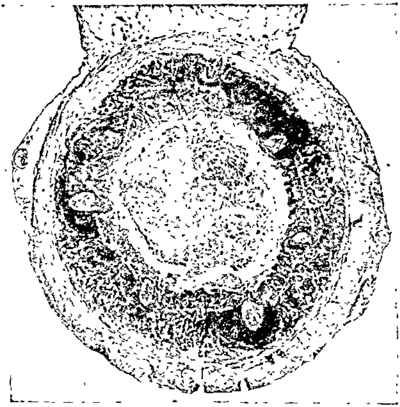

Fig. 297.—Acute appendicitis. The mucus membrane is swollen and filled with leucocytes and dilated capillaries. All coats are edematous. Early stage.

Abscesses may occur in the following positions: ileocolic, retrocecal, pericecal, pelvic, subhepatic, subphrenic, left colic, horseshoe abscess. This is especially true if a strong purge has been given, increasing peristalsis and intraluminal pressure. The appendiceal vein is thrombosed early and a septic pyelophlebitis with multiple liver abscess may ensue. The *cause*

is unknown. However, various factors play a role; namely, the seasons fall and spring with upper respiratory infections and lymphoid hyperplasia, position (retrocecal) with mechanical obstruction, familial tendency.

Symptoms and Signs.—Since the appendix in children has a large amount of lymphoid tissue, this becomes swollen when there is a cold or sore throat through the action of the same virus that invites inflammation in the lymphoid tissue of the pharynx, tonsils, and cervical lymph glands. Hence, a cold with pain in the abdomen may be misleading. Appendicitis begins with pain in the upper abdomen or around the umbilicus; then, as it develops, the pain localizes at the site of the inflamed appendix, which is usually, but not always, at McBurney's point. The difference in symptoms in appendicitis is due, in a great measure, to variations in the position

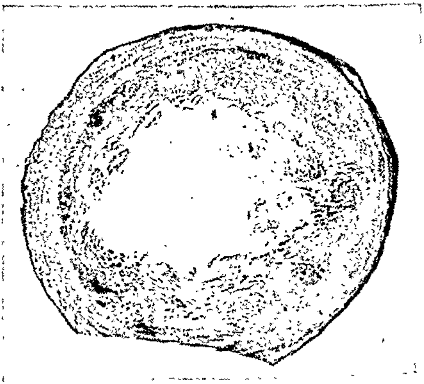

Fig. 298.—Gangrenous appendicitis. The mucosa has been destroyed. The site of perforation would probably have been at the lower portion, for here all layers are necrotic.

of the appendix. It will be low in the pelvis in the individual of the linear type with visceroptosis and high in the lateral type. Sometimes it lies under the liver when the cecum remains in the fetal position. Since the disease is rapid in its progress, it either subsides (resolution or release of obstruction), or goes on to suppuration, or even to perforation, within twenty-four to forty-eight hours. Therefore, *any abdominal pain, with or without vomiting, must be considered appendicitis until proved otherwise.* The diagnosis is made from a history of pain and constipation (if no cathartic has been taken). Cathartics should never be used in children with abdominal pain. There are tenderness and rigidity over the appendix.

The pain may be increased if the appendix is retrocecal by elevating the leg and keeping pressure over it, causing contraction of the iliacus muscle, or by turning the patient partially on the left side and making lateral pressure. Rectal examination is done especially in children, for the entire pelvis can often be felt, including the inflamed appendix, if it is in the normal position. Vomiting is almost universal in appendicitis in children. Bowel sounds are diminished in appendicitis, increased in early peritonitis, absent in late peritonitis. In women, vaginal examination is made to rule out adnexal or pelvic disease. There is very little fever at first. Should suppuration or perforation or pylephlebitis occur, a septic temperature may appear. The leucocyte count is usually elevated. However, it may be normal even in perforated appendicitis and is therefore interpreted as one of the symptoms. The urine must be examined to rule out pyelitis or diabetes, either of which may cause comparable symptoms. X-ray examination is not done routinely, but in doubtful cases it may show a basal pneumonia or free air in the peritoneal cavity. More important is the fact that gas is usually present in the cecum and practically always present in the cecum in appendicitis. A flat x-ray plate of the abdomen will, as a rule, reveal the position of the cecum and show the surgeon where to make the incision, whether high (in the fetal position), low in the pelvis, or over McBurney's point. The x-ray is not useful in diagnosing appendicitis per se, but it does help to rule out other conditions (such as kidney stone and perforative ulcer) and demonstrates the *location of the cecum*, to which the appendix is always attached. Differential diagnosis includes the following conditions: (1) In children, mesenteric lymphadenitis (often in upper respiratory infections mesenteric lymph glands will be involved, giving rise to symptoms that resemble appendicitis; microscopic study of such glands shows them to be the site of a nonspecific inflammation; for unknown reasons, appendectomy frequently relieves the symptoms); pyelitis and "idiopathic" peritonitis (usually in girls); bronchopneumonia; acute enteritis; rarely, anomalies of the right ureter, regional enteritis, and Meckel's diverticulitis. In adults the above conditions plus pelvic disease in the female, ureteral stone, gall bladder disease, and perforated peptic ulcer. *Operation is indicated as soon as the diagnosis is made.* There is no other treatment. The revered ice bag simply masks symptoms by its analgesic action and invites gangrene by vasoconstriction. Heat is preferable because it hastens localization while the diagnosis is unestablished, but heat does not cure appendicitis. The appendix should be removed through a McBurney (muscle splitting) incision. (See discussion under peritonitis.) The stump of the appendix is inverted by purse string after location and cauterization of the stump or by inversion as in any bowel suture. Peritonealization is very important and should be done unless the cecum is acutely inflamed. Here the appendix is ligated and soft drains are inserted down to it so that if a fistula results external drainage will follow. If the cecum is edematous, appendectomy is useful, provided too much manipulation is not done to accomplish it. Appendiceal abscess

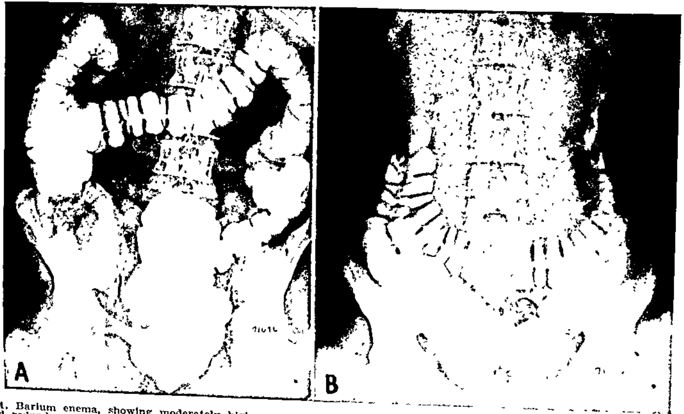

Fig. 299.—*A*. Barium enema, showing moderately high cecum at about the level of the crest of the ilium. *B*. Barium enema, showing very low cecum and redundancy of transverse colon. The position of the cecum is important in the diagnosis of appendicitis. It is not good practice to introduce a barium enema in suspected appendicitis. However, a scout film may be made which will show the distended cecum and show its position; then if the clinical symptoms and signs correspond to the position of the cecum, the diagnosis is more certainly established and, what is more important, the proper position for the incision is easily determined. The cecum is distended with gas in the presence of an inflammatory lesion because it loses its propulsive power. The barium enema shown in *A* reveals a cecum which is slightly higher than normal and has not descended to its normal position. *B* shows a cecum which is low, but the transverse colon is also low. This position is apt to give rise to symptoms which are those of an incomplete obstruction. Very often after pelvic operations the surgeon will place the greater omentum down in the pelvis and drag the transverse colon with it. This practice sometimes leads to a low position of the transverse colon with partial obstructive symptoms.

requires drainage, and in most cases appendectomy can be done but not if the appendix is part of the abscess wall. Simple drainage is safe, and later the appendix can be removed and with surprisingly little difficulty. The question of drainage in general peritonitis is a moot one because drains do not evacuate the entire peritoneal cavity and are soon isolated; in addition, there are foreign bodies. However, if placed where pools of exudate collect (pelvis, right colic gutter, and right shoe fossa), they will at least empty these pockets temporarily of material that would otherwise have to be absorbed. The drains are soft Penrose drains and are never placed among coils of intestine. If the exudate is clear and a good inversion of the cecum is possible, drains are not used (See discussion on Peritonitis.)

Recurrent Appendicitis

Recurrent appendicitis is due simply to repeated temporary obstruction to the lumen of the appendix by edema, hyperplasia of appendiceal lymphoid tissue, or fecalith, resulting in thickening and fibrosis. The appendix does not act as a focus of infection but may interfere with the mechanical movements of the gastrointestinal tract, causing "indigestion" and even vomiting, and for this reason it should be removed.

Nonspecific Types of Appendicitis

The appendix is sometimes inflamed by parasites such as the *pinworm* or the *Oxyuris vermicularis*. This may have its effect by causing an obstruction or by producing an irritation within the appendix. It cannot be diagnosed preoperatively. However, a high eosinophil count, together with the symptoms and signs of appendicitis, may give a clue. In addition to parasitic infestations, fungus infection such as *actinomycosis* may cause appendicitis. Indeed, a diseased appendix is the site of the primary focus in most cases of abdominal actinomycosis. This has been discussed in Chapter 7. The diagnosis again is made at the time of the operation. This is one of the reasons that all appendices removed should be carefully examined by the pathologist. The treatment of actinomycosis, once the appendix has been removed, consists of potassium iodide and thymol and the use of sulfadiazine as well as penicillin.

Neoplasms in the appendix include the myxomas which may give rise to a pseudomyxoma peritonei. In addition and perhaps the most important of the tumors found in the appendix is a group known as paraganglioma or carcinoid tumors or argentaffine tumors. These growths get the name carcinoid because they resemble carcinoma. The mass of paraganglioma cells invades the submucosa. The cells come from the chromaffin system and therefore belong to the paraganglioma groups. They occur twice as frequently in the appendix as in the small bowel, although they are seen uncommonly in all of these locations, including the large bowel. There have been cases reported in the stomach and even in the rectum. The diagnosis is never made preoperatively because the symptoms and

signs are those of appendicitis. When the appendix is removed, the carcinoid tumor is found. In the small intestine the tumor may produce diarrhea with or without bleeding. The appendicitis which accompanies the tumor is probably due to obstruction. Usually the growths are benign; however, we have seen several cases with metastases to the regional lymph nodes and even to the liver. The treatment is complete removal, and if it is suspected at the time of operation, a more radical resection of the mesoappendix and adjacent structures, including the lymph nodes, is practiced.

Lastly, adenocarcinoma of the appendix has been reported. This is a rare condition and again cannot be diagnosed preoperatively. A more common condition which is very important and which we have observed on several occasions is acute appendicitis associated or rather as a complication of carcinoma of the cecum. It is therefore proper to make a careful examination of the cecum at the time of appendectomy. The diagnosis having been made by surprise, the operation would be of the Mickulicz type of resection. Although this discussion would lead the reader to believe that it would be sheer carelessness if carcinoma of the cecum were overlooked, yet occasionally there is an acute suppurative appendicitis even with abscess superimposed upon a carcinoma of the cecum. This makes diagnosis very difficult. Every bit of tissue should be sent to the laboratory, and this is another reason for insisting on routine laboratory examination and microscopic study of every bit of tissue removed at the time of operation.

THE COLON

There is no digestion in the large bowel. The fecal current is liquid at the cecum and solid in the sigmoid.

Many toxic substances are formed in the large bowel as a result of the decomposition of protein by the normal bacterial flora. However, absorption of such products does not occur if the mucous membrane remains intact. The so-called "toxic" symptoms resulting from constipation have been produced by mechanical distention of the large bowel with balloons. Three types of motion are seen in the large bowel: (1) retrograde waves (most common in the ascending colon) which favor absorption; (2) coordinated waves in which haustrations disappear; (3) powerful waves of the left colon of which the individual is aware and which help in defecation. Since the patient is unaware of (1) and (2), a disease such as carcinoma gives few symptoms when it occurs on the right side, more when it is on the left side.

Continual spasm may occur at various sites in the alimentary canal, the cricopharyngeus muscle, the cardia and pylorus of the stomach, the ileocecal valve, the iliac and pelvic colon, and the anal sphincters, the large bowel, and the rectum.

Congenital Anomalies

Anomalies of the large bowel roughly mimic those that occur in the small intestine. The malrotations have been discussed in previous para-

graphs. There remains a group of congenital anomalies or anomalies which may be related to congenital defects that may be discussed here:

Atresias and Stenoses.—Most atresias and stenoses of the large bowel occur at the distal end; namely, in the hind-gut, where it joins the proctodeum. These will be discussed in subsequent paragraphs. There are other sites, however, in which atresias and stenoses may occur. The most common of these is in the middle of the transverse colon. This is due to the fact that the mid-gut in its earliest development is a convex loop with its end attached to the duodenocolic isthmus and is supported

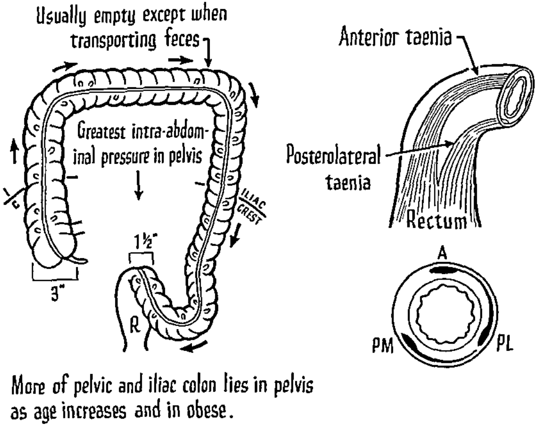

Fig. 300.—Anatomical peculiarities of the large bowel are illustrated in this figure. On the left the large bowel is shown to be roughly a cone with its wide part at the cecum and its narrow part at the rectosigmoid junction. Upper right, the taeniae are shown to expand as they approach the rectum, completely encircling the bowel at this point. Lower right, the lower portion of the pelvic colon is devoid of longitudinal muscle over a small area on either side. *A*, anterior taeniae; *PM*, posteromedial taeniae; *PL*, posterolateral taenia.

through its length by common dorsal mesenteries. At this site, which approximately corresponds with the left half of the transverse colon, atresias and stenoses may occur. Far more common, however, are the atresias and stenoses of the hind-gut close to the point of fusion with the proctodeum. The hind-gut at its distal end may remain blind or may be stenotic for a distance of 5 or 6 cm. The symptoms and signs of atresias of the large bowel are very much like those of imperforate anus and will be discussed later. In general, however, vomiting is late, distention is early, and the

x-ray film reveals not only small but large bowel dilation. At operation a thorough search should be made for the point of obstruction, and then the surgeon must satisfy himself that there is only one stenosis or one site of atresia. Primary anastomosis can be done if sufficient bowel remains below the site of obstruction. In the extremely low cases, such as occur in the pelvic colon or the iliac colon, a colostomy must be done with the thought in mind that at a later date the large bowel may be brought down to the patent rectum and anastomosed. Although babies stand enterostomy poorly, they do stand colostomy well if attention is given to water balance and blood volume replacement.[7]

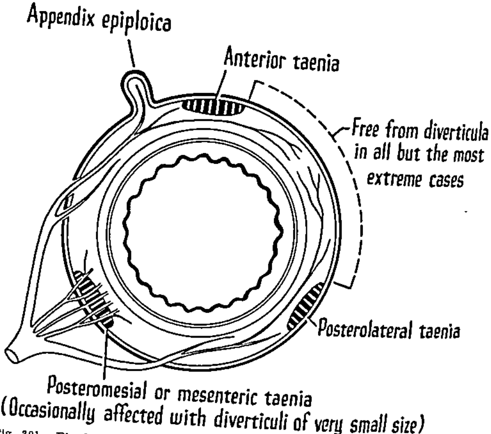

Fig. 301.—Blood supply of large intestine. Diagram illustrating the blood supply of the large intestine and the areas which are predisposed to the formation of diverticula. The blood vessels of the large bowel enter from the mesentery along with mesenteric side of the lateral and medial posterior taeniae and also with some small vessels between them. Since the longitudinal muscle is incomplete, the vessels lie rather superficially between the posterior and anterior longitudinal bands beneath the serosa. This accounts for the enormous distention which is possible in the large intestine without complete interference of the blood supply as compared with the relatively small amount of distention tolerated in the small bowel where the vessels are covered by both circular and longitudinal muscles. (From Berman, J. K., and Bower, T. B.: J. Indiana M. A. 35: 197, 1942.)

Duplications of the Large Bowel.—Duplications, as we have seen, may occur anywhere along the gastrointestinal tract. We have encountered two cases of duplications of the pelvic colon. Cases are on record of duplication of the entire large bowel, including the appendix. Even triplications are on record. Our diagnosis at first was that of a mesenteric cyst. Careful examination, however, revealed this to be a duplication. In

neither instance was it necessary to resect the colon. If the blood supply to the duplication and the bowel are one and the same, it may be necessary to do a resection. We have also encountered a duplication of the rectum. This presented itself as a pararectal cyst. Upon microscopic examination it was lined with a mucous membrane, characteristic of the large bowel. This was removed and was entirely separate from the rectum. In all duplications the diagnosis is greatly facilitated by the use of barium enema, and in duplications of the pelvic colon and rectum an anterior meningocele or a sacrococcygeal tumor presenting anteriorly must be borne in mind. A barium enema will outline this, at least giving the surgeon a clue as to the nature of this pathological entity. Two facts must be borne in mind in all duplications; (1) The intimate relationship of the duplication and the parent bowel. If it is small, it does not present much of a problem to remove the duplication, the point of contact being resected and turned in. If the relationship is extensive, resection of the duplication as well as the parent structure will be necessary. (2) The blood supply. Many times the vessels are contiguous, coursing over the duplication in such a manner that removal of the duplication cannot be accomplished without interfering with the blood supply of the parent structure. This, too, will demand resection.

Malrotation.—Malrotation of the large bowel has been considered in connection with a discussion on malrotation of the small intestine. It remains for us briefly to outline the more common abnormalities which may be encountered.

The position of the large bowel may be abnormal. The cecum, for example, may be found in the left upper quadrant with the ileum entering from right to left. The cecum with its attached appendix may also be found in the right upper quadrant, having remained in a fetal position. From here it may be found in any position, including the pelvis. Also it is common in the newborn to find the sigmoid in the right side, entering the pelvis from right to left. Later the sigmoid rotates over to the left side and here comes to lie in its normal position as the iliac and pelvic colon. In addition to the anomalies of rotation already described, we should mention the attachment of the cecum high up on the right, producing obstruction to the duodenum. This condition is handled by dividing the adhesions and permitting the cecum to assume a left-sided position. We have also seen that in volvulus in the small bowel, after the volvulus is untwisted there still remains a broad band or sheath from the cecum to the right wall of the abdomen, obstructing the duodenum. This is treated in a similar manner.

Last, a condition known as mobile cecum occurs in which there is not a normal posterior attachment. Such individuals not infrequently have a mesentery which is common to both small and large intestines. The cecum may be attached high on the right end of the liver or it may be unattached or the mesentery may be short and drawn over to the left side

with adhesions on the right. The diagnosis of a mobile cecum may be difficult. Patients complain of vague abdominal symptoms with intermittent bouts of obstruction. On exploration, mobile cecum with a normal oblique attachment of the mesentery can be tacked down posteriorly with suitably placed sutures. If, in addition, the mesentery does not have a normal posterior attachment, then it is probably better to slit the peritoneum at the right of the hepatic flexure so that the entire right half of the colon shifts over into the left side of the abdomen. This principle of mobilizing the colon so that it comes to lie on the left side, its primitive embryological position after re-entering the coelomic cavity, is one which is frequently utilized in colonic abnormalities with abnormal attachments. Volvulus of the ileocecal region and of the sigmoid have been discussed under the heading of intestinal obstruction. These are made possible by the unduly long mesocolon or mesocecum.

Congenital Megacolon or Hirschsprung's Disease or Idiopathic Dilatation of the Colon

The condition known as *megacolon* was described by Hirschsprung in 1886. It is generally believed that the cause of the greatly enlarged colon is due to a nervous imbalance. This is difficult to prove, and at times seems to be reputed by the various types of megacolon which may be limited to certain sections of the bowel. The parasympathetic nerves stimulate, whereas the sympathetics inhibit peristalsis of the colon. Also, the parasympathetics are said to relax the internal anal sphincter, whereas the sympathetics cause its contraction. To state this more simply, the stimulation of the parasympathetics increases bowel tone and causes relaxation of the sphincters, whereas stimulation of the sympathetics inhibits intestinal activity and causes a contraction of the sphincter. This is known as reciprocal or contrary innervation, and the external sphincter is under voluntary control. Thus an overactive sympathetic innervation or underactive parasympathetic may contribute to the development of megacolon. This undoubtedly is a factor in the causation of congenital megacolon. However, it cannot be the only factor because very often only small segments of the intestine are involved. There are probably various causes for megacolon. Reduced sensitivity of the bowel has been given as a cause; that is, in addition to the alterations of peristalsis of the colon and the tone of the sphincter muscle, there is a reduced sensitivity of the bowel so that the patient apparently does not know or does not receive the stimulus to empty the bowel, and because of this he will go for many days without defecating. There is, in addition, a great diminution of peristaltic movements and this, combined with the fact that there is no desire to defecate, accounts for the enormous dilation of the large intestine. The types of megacolon which are accompanied by some forms of obstruction due to congenital anomalies have been called *pseudomegacolon*. We have encountered these types more commonly than the usually described

general enlargement or uniform involvement of the large bowel which extends from the ileocecal valve down to the rectum. It has been our experience that the majority of these cases have an involvement down to the iliac colon or even lower, perhaps down to the superior valve of Houston. From here the enlargement is greatest immediately above this area and is diminished as the cecum is reached. This is exactly the reverse of the normal colon. There is a definite obstruction which can be demonstrated in such cases which accounts for this dilatation. There is a third group in which the dilatation is limited to one segment of the bowel. In such cases some type of obstruction can usually, although not invariably, be demonstrated. One last point which is important in the discussion of the etiology is the effect of drugs upon the megacolon. The response to atropine has been excellent in some cases. This is undoubtedly the type of case in which the function of the bowel is deranged due to nervous imbalance.

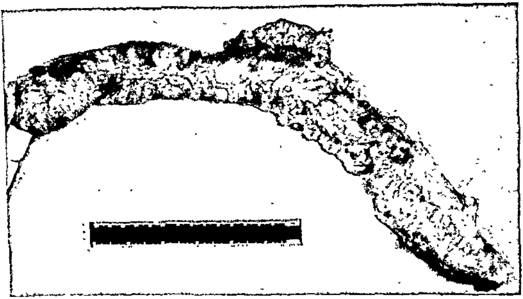

Fig. 302.—Hirschsprung's disease or megacolon. Photograph of gross specimen removed from R. B., a boy, 5 years of age, with Hirschsprung's disease. The operation consisted of a total colectomy with an anastomosis between the ileum and the pelvic colon at its lowest point. The boy had been in and out of hospitals since he was 2 years of age, with attacks of what was diagnosed as intestinal obstruction. When he entered the hospital there were five intestinal fistulae on the abdomen. These resulted from five different attempts at colostomy and enterostomy to relieve obstruction. Although the obstruction was finally relieved by the fifth operation, it was made in the small intestine so high that extreme emaciation resulted and excoriation of the abdomen took place.

The operation was planned in stages. At the first stage the ileum was divided near the ileocecal valve and the distal end brought out through a stab wound in the right abdominal wall. At the same time the sigmoid at its lowest point was divided and the proximal end of this was brought out through a stab wound on the left side of the abdomen. The distal end of the sigmoid at its junction with the rectum was left open, the proximal portion of the divided ileum was closed and anastomosed to the rectum in the manner of a side-to-end anastomosis and the abdominal incision was closed. The result of this first stage operation was an ileoproctostomy; the entire colon was left in situ with both ends protruding through stab wounds in the manner of a horseshoe.

At the second operation, which was done approximately four weeks after the first, the entire colon was removed through an upper transverse incision. This child has been followed in the outpatient clinic for the past four years. There was diarrhea for approximately eight months. When last seen in February, 1949, the child was in excellent health and attending school regularly. This illustrates the more complicated types of megacolon. The simpler varieties are those which have not had previous surgery. We have performed total colectomy in several of these with excellent results.

However, it is difficult to explain why diminishing the function of the parasympathetics which tend to stimulate contraction should produce improvement, and yet this is the case. It is easier to understand why such drugs as physostigmine, Prostigmine, and Mecholyl bromide, which are parasympathetic stimulants, would produce good results. In the same group of drugs is Syntropan, an atropine-like drug which paralyzes the parasympathetics.

Recently Swenson and co-workers have demonstrated that the primary lesion is in the distal portion of the colon at the rectosigmoid juncture and also in the rectum. This portion of the large bowel appears to be normal grossly. It is nondilated, and its wall appears to be of normal thickness. However, it has been shown that there is an absence of normal propulsive waves in the rectum and rectosigmoid by studies with a balloon in the rectum attached to a long catheter. This portion of the colon also shows an absence of ganglion cells which may account for the lack of peristaltic waves. Based upon this concept, Swenson and co-workers have designed an operation for the removal of the rectosigmoid and the rectum preserving the sphincter, and they have reported good results.

Pathological Changes.—The colon becomes enormously enlarged, sometimes being six or seven inches in diameter. The wall of such a colon becomes thick and the haustrations completely lost. There is a hypertrophy of the muscular coat, whereas the mucosa shows ulceration. Sometimes there is sloughing, and we have encountered two cases in which the bowel perforated spontaneously, producing peritonitis. Rarely the terminal ileum may be involved as well as the colon, and sometimes a megaloureter accompanies the condition.

The symptoms and signs of the condition are, (1) the greatly enlarged abdomen and (2) obstinate constipation. Children are known to go for days and even weeks without a bowel movement. In adults the same condition prevails, although the symptoms are not as marked. Diarrhea occasionally occurs due to the fact that there is a central fecal mass which permits only the liquid portion of the fecal current to go through. Late in the disease all the symptoms and signs of a chronic intestinal obstruction are present. There is great loss of weight, the abdomen is greatly distended, the diaphragm is elevated, there is atelectasis in the base of the lungs, the patient will not eat, and occasionally will begin to vomit, particularly those who have an incompetent ileocecal valve. Rectal examination shows, as a rule, the sphincter to be relaxed and the entire colon to be filled with fecal matter. In fact, the impaction is so great that the fecal matter must be removed manually. Barium enema with x-ray examination will show the enormously dilated colon. Postevacuation film shows an inability of the colon to empty itself. As a rule, the flat plate of the abdomen by the x-ray will give sufficient information to make the diag-

nosis. The reason for barium is that at times it may reveal the site of the obstruction in the particular type of megacolon.

Treatment.—Treatment of megacolon depends upon the stage that it is in. In all cases the treatment should be begun early in life. As soon as the diagnosis is made, the mother is instructed in the care of the bowel function of the child. A careful regimen of bowel habit, including a low residue diet together with a suitable cleansing agent such as physiological saline by enema, is useful. Occasionally when an impaction occurs the bowel must be cleansed by manual extraction. Drug therapy is helpful. The first group of drugs include parasympathetic stimulants such as Prostigmine, acetyl beta methylcholine (Mecholyl chloride), acetyl beta methylcholine bromide (Mecholyl bromide), tetra ethyl ammonium bromide, and Priscoline. These drugs have been used with a varying degree of success. In our experience, however, they have not been very beneficial over a long period of time. Prostigmine is useful and occasionally helps. However, here again, after the drug has been used for a while, the bowel ceases to respond as it does when it is first employed. The second group of drugs are the atropine group, of which atropine itself is perhaps as good as any, although we have had fairly good success with Syntropan. Most of these cases of the particularly obstinate type ultimately demand some type of surgical intervention, although patients with minor degrees of this condition go through life without help but with a good deal of bowel difficulty. This is proved by the fact that so many times we are astounded to find in older individuals who have had x-ray examinations with the barium enema enormous dilations of the large intestine and yet they live in comparative comfort.

Among the surgical procedures which have been recommended are (1) cecostomy to relieve the distress and to serve as a life-saving procedure in cases of obstruction; (2) resection of the dilated loop or complete colectomy; (3) removal of a portion of the sympathetic nervous system. Of the three, the removal of a portion of the sympathetic has been favored by many observers. Before this is attempted, it is well to perform a therapeutic test by inducing a spinal anesthesia. With anesthesia as high as the nipple, flatus and feces are passed per rectum if the overactive sympathetic is at fault. Sometimes after the use of spinal anesthesia there will be several large bowel evacuations during the following twenty-four hour period. A barium enema may be given, after which a spinal anesthetic or acetylcholine bromide should be injected. Twenty-five minutes later a film is taken and the effectiveness of these drugs may be determined. It has been generally believed that if the bowel does not empty after the injection of spinal anesthesia the tone is gone and the changes are irreversible and lumbar sympathectomy will not help, whereas if it is successful in emptying the bowel, sympathectomy will be useful. The abdominal sympathetic chain has an outlet through the first, second, third, fourth, and fifth lumbar ganglia which lie on either side of the great abdominal vessels.

Fibers pass medially from each ganglion to form a plexus over the aorta. This is continued down over the promontory of the sacrum and is known in this region as the hypogastric or presacral plexus which gives off fibers to supply the rectum, pelvic viscera, and genitals. The lumbar chain may be removed or the presacral plexus and its branches may be excised. This is an easier operation than lumbar sympathectomy perhaps, but it may interfere with the ejaculatory apparatus and produce sterility, while in the female it may interfere with sexual orgasm. The lumbar sympathectomy does not permanently alter the function of the bladder or the reproductive system provided the first ganglion is not disturbed. It does, however, produce vasodilation in the leg on the operated side. Most surgeons recommend the transperitoneal approach. This, of course, is safe and gives the surgeon the opportunity of studying the condition of the bowel. The mesosigmoid is incised, and the colon is rotated medially until the sympathetic plexus is encountered, and here the second, third, fourth, and possibly the fifth ganglia can be excised. The operation may be done on the right side in a similar manner to that on the left if the entire bowel is involved. It is perhaps well to do this in one stage. We have performed lumbar sympathectomy extraperitoneally through a transverse incision just above the umbilicus. The first lumbar usually lies under the renal and the fourth under the common iliac vessels. This is described in Chapter 6 in connection with the treatment of Berger's disease. This extraperitoneal operation is much simpler and in most instances can be accomplished with little difficulty, particularly in the adult. In the child it is perhaps better to explore and carry out the operation transperitoneally. Our experience with the operation has not been as good as has been reported by some observers. Several of our patients have returned after ganglionectomy with recurrence of the condition, although it must be admitted that they did receive temporary relief. Some have advised that in addition to excision of the ganglia that there should be carried out at the same time an excision of the hypogastric plexus and its branches. The operation of sympathectomy should not be done in children under 3 years of age, because a more conservative management should be tried until the child is at least 3 or 4 years old. The operation of cecostomy or appendicocecostomy is usually done because of an acute intestinal obstruction. It is a temporary procedure and is of very little value because the cecostomy, as a rule, does not function. It should be remembered also in the performance of a cecostomy that the sigmoid, being large and tending to be on the right side in the young child anyhow, is apt to be mistaken for the cecum in doing a cecostomy. We have seen two patients who have been referred to the Riley Hospital in which the treatment was recorded as cecostomy but at operation it was found that in reality there had been a sigmoidostomy. Any type of drainage is to be regarded as a temporary measure and not in any way curative. The treatment of megacolon before irreversible changes have occurred in the wall of the large bowel may be that recommended by Swenson and co-workers; namely, the re-

section of the rectosigmoid with preservation of the sphincters. In this type case, however, we have felt that perhaps a simple procedure may be used; namely, the division of the normal-appearing bowel by a longitudinal incision and then suturing it transversely very much like a Heineke-Mikulicz pyloroplasty. Although this does not remove the nonpropulsive segment, it does provide ample space for drainage and at least in one portion of the circumference enables the peristaltic waves to follow through. In particularly obstinate types of megacolon which fail to respond to the ordinary medical regimen or to sympathectomy, colectomy is indicated. In fact, we have come to employ this method more frequently now than formerly after making sure of the type of megacolon that is present. This attitude has come about due to the effectiveness of the sulfonamides, such as Sulfasuxidine and Sulfathalidine, which are useful in reducing the flora of coliform organisms in the large intestine. Resection may be done in one stage which is not so difficult in the young child, or if the case is complicated and has had previous surgery, it may be done in two stages. The first may be an anastomosis between the ileum and the lower sigmoid, bringing out the distal end of the ileum as a marker and also to prevent any inside leakage from the inverted distal end; then at a second stage the bowel may be removed. We have one child in whom we performed the first stage and brought out the distal end of the ileum as well as the proximal end of the sigmoid, after performing an anastomosis between the proximal ileum and the lower sigmoid. This horseshoe of small and large bowel which remained was later successfully removed (see Fig. 301). It has been interesting to note that the child has improved greatly, has grown normally, and has absolutely no symptoms. Further observations concerning medical management of megacolon has led us to favor radical surgery because mortality rates varying from 19 to 79 per cent and averaging 58 per cent appear in the literature when medical management is the treatment that is persisted in. The results from sympathectomy are much better. The mortality for this operation is low, and great improvement ensues in a large number of patients. Although the mortality of colectomy was formerly forbidding, under present treatment, preoperative preparations, and postoperative care, the mortality has been reduced to a degree which has brought about its use more frequently.

Last, the treatment of associated conditions must be considered. Since the condition may result from organic obstruction of congenital origin, it is, of course, obvious that if there is a congenital stenosis of the rectum or anus, this must be corrected. Also in the cases of redundancy of the colon or the so-called dolichocolon, which are notoriously apt not to be benefited by sympathectomy, colectomy is probably the treatment of choice. Other factors such as hyperthyroidism, avitaminosis, and malnutrition should be corrected whether the surgery is performed or not. Acetyl beta methylcholine bromide is given in doses of 1/10 Gm., increased if necessary to 2/10 Gm. within two to three days. Then after several more days

with this daily dose, 1/10 to 2/10 Gm. in mid-afternoon may be prescribed in addition to the morning dose; later, 2/10 Gm. given each morning and in mid-afternoon. The abdominal sympathectomy is perhaps best done transperitoneally because it gives the surgeon an opportunity to examine the entire colon. Both sides may be done at the same time. However, it should be stated that sympathectomy does not always immediately restore the involved bowel to normal functional activities. In one last point, in colectomy, due to the poor healing quality of the distended bowel, every effort should be made to keep the bowel clean for a period of two weeks before surgery and sulfasuxidine is administered. The anastomosis should be low and into as healthy bowel as possible and should be of the lateral type rather than the end-to-side or the end-to-end variety. However, in the last patient that we operated upon, this was not feasible and a side-to-end anastomosis between the terminal ileum and the lower sigmoid was successful.

Congenital or Familial Polyposis of the Colon

Although many types of polypi may occur within the alimentary tract, we are especially interested here in multiple polyps which occur chiefly in the large bowel in children. This has been called congenital polyposis of the colon rather than hereditary polyposis because babies are not born with the disease (see Chapter 10). Later in the chapter we shall consider other types of polypi; however, this discussion is limited to the congenital types. The etiology is obscure. However, it is thought that it is a congenital error of the development of the epithelium itself. Since the disease does not occur at birth but develops later in life, it is perhaps better to use the term congenital rather than hereditary polyposis. Perhaps the forerunner or the soil in which the polypi develop is hereditary. The hereditary aspect of the disease has been studied by many observers, most of whom believe that it occurs in mutations of the genes of the individual who has not exhibited the disease and he passes the mutated genes on to his children. These may be passed on as a dominant or recessive. If dominant, the disease occurs in every generation; if recessive, both parents must carry the mutated genes before the condition may be seen. Many observers believe that in multiple polyposis the gene is a mendelian dominant. It is certain that whenever the disease is found in any individual all members of the family should be examined and should be subjected to repeated examinations at least at six-month intervals because the disease does not necessarily appear before puberty. Multiple polyposis may occur as a result of chronic irritation or infection, and in chronic ulcerative colitis there is a tendency toward polyposis due to the fact that there is a destruction of areas of mucous membrane interspersed with areas which are not completely destroyed, giving a polypoid appearance. The polypi in this disease vary in size from 1 mm. to 2 or 3 cm., and they may be pedunculated or sessile. We have seen patients in whom the polypi were so numerous that there was hardly an area of normal mucous mem-

brane between them. A further interesting observation concerning the pathology relates to the tendency toward malignancy. The tendency is so great that some observers believe that all patients who have congenital polyposis ultimately will develop malignancy in some of the polypi if they live long enough. Perhaps nowhere else can change from normal mucosa to inflammation, gland cell hypertrophy, adenoma, and adenocarcinoma be so clearly demonstrated as in multiple polyposis of the colon.

The *symptoms* and *signs* of this disease vary, but chiefly there is bleeding. When the polyp is high up, the blood may be darker in color and when low down it may be bright. If there is a very small amount of bleeding, the occult blood in the stool would be demonstrable only by chemical tests. By far the more frequent cause of bleeding comes from

Fig. 303.—Congenital polyposis of the colon. This patient was a young woman, 29 years of age, who came to the hospital because of bleeding from the rectum. The onset of the symptoms occurred two years prior to her admission. However, there had been times, even in childhood, when the patient's family reported that she had had bloody stools. Her family history is interesting because her father and a sister died of cancer of the rectum at the respective ages of 41 and 26 years. Both paternal grandparents died of cancer of the rectum. The sigmoidoscope showed multiple polypi, some of which were ulcerating and bleeding. The barium enema demonstrated numerous polypi in the entire ascending colon and left half of the transverse colon. The photograph is a close-up of the gross specimen removed by radical resection of the entire colon. No areas of carcinoma were found in the polypi. Because of the patient's history and the family history and extensiveness of the polypi, radical resection was indicated and was carried out The incidence of carcinoma in congenital polyposis of the colon is so great that even though there is no proved carcinomatous degeneration, total colectomy should be done.

polyposis of the lower colon. Sometimes there is abdominal pain, or there may be a prolapse of the anus. If the polyps are low enough, they may be felt by digital examination. The abdominal discomfort and pain may resemble that of an intussusception, and indeed sometimes the diagnosis between the two is difficult. Rarely there may be symptoms of nausea, indigestion, fatigue, loss of weight, and loss of appetite. The diagnosis is made by the proctoscope and by a barium enema examination by the x-ray. Fortunately those polyps which cannot be demonstrated by barium enema

are usually present in the lower portion of the sigmoid and in the rectum. These, however, can be demonstrated by proctoscopic and sigmoidoscopic examination. Since congenital polyposis may be accompanied by polypi in the small intestine as well as in the stomach, it is also our custom to do a complete gastrointestinal examination with the barium meal in the hope that by repeated x-ray examinations, as the meal courses through the bowel, polypi will not be overlooked high in the alimentary canal. The differential diagnosis is as follows: Bleeding from the rectum in a child is usually not serious and implies a gastroenteritis. Sometimes there is constipation, and rectal bleeding will occur from that. There may be an anal fissure which will break open and cause some bleeding. Other conditions which cause bleeding are Meckel's diverticulum, intussusception, scurvy, and blood dyscrasias. These have been discussed previously in this chapter, however, routine hemoglobin red blood and platelet count, clotting and bleeding time, together with red blood cell fragility tests, may be necessary to rule out systemic causes for the bleeding.

The *treatment* of multiple polyposis of the colon depends upon the extent of the disease and the portion of the bowel involved. With a limited number of polypi, abdominal exploration may be done with ileotomy or colotomy and the polyps excised with a cautery. With modern methods of preparation with Sulfasuxidine or Sulfathalidine, the large bowel may be opened at various sites, the polypi removed, and then the colon may be closed safely without fear of peritonitis provided that a careful technique is followed. The treatment of choice, however, is colectomy followed by an ileosigmoidostomy. This is true because one cannot be sure even using the utmost of care that all polyps have been removed, and, furthermore, since the colon has a fertile soil for future development of polypi, we have found that in those patients in whom we thought we had removed all visible and palpable polypi new polypi occurred at the sites which had not been previously involved. Since the lower six or eight inches of the bowel also contain polyps, these are removed through the proctoscope; then an ileosigmoidostomy and a colectomy are performed. We have recently done this as a two-stage operation. The first stage consisted of destroying the polyps with the sigmoidoscope and the second stage consisted of a colectomy with an ileosigmoidostomy. Ladd has recently reversed this procedure, using the following technique in a child who was bleeding profusely from many polypi in the colon. The first stage consisted of transection of the lower ileum, establishment of an ileostomy, resection of the terminal ileum, cecum, and entire colon down to the lower sigmoid, and turning in of the lower sigmoid to make a blind rectal pouch about six inches long. In the second stage the polyps were removed through the proctoscope. In the third stage the ileostomy was taken down and an ileosigmoidostomy was performed. The number of stages required would obviously depend on the condition of the patient. If the patient is in a desperate condition, it is always better to perform the operation in stages;

however, if the patient can be properly prepared, colectomy and anastomosis between the ileum and the lower sigmoid may be safely performed in one stage.

Hereditary Hemorrhagic Telangiectasia

One last congenital defect which produces bleeding from the gastrointestinal tract must be mentioned for completeness. It is extremely rare and is known as *hereditary hemorrhagic telangiectasia.* It is an inherited dominant characteristic. The sexes are equally affected and either sex may transmit it. Sometimes epistaxis beginning in childhood is the first manifestation. Hemorrhages are not limited to the large bowel and may occur anywhere, including the mucous membranes and skin. The diagnosis rests upon the visible demonstration of telangiectases which is often difficult without exploratory operation. The basic pathology is a thinning of the vessels, particularly of the muscular coat. This results in a bulging of the wall and a defect which may be extensive. The lesions are noted most commonly in the stomach and the sigmoid colon. The treatment of the lesion has been unsatisfactory, although remedies for the anemia, such as iron and repeated transfusions, are indicated; also vitamins C and P have been used with equivocal results.

Hemangioma

Another condition which appears extremely rarely and which may be classed as a congenital anomaly is the presence of a tremendous type of hemangioma. We have encountered one case in which the lowest sigmoidal artery spread out and formed a tremendous hemangioma. This bulged into the sigmoid and produced bleeding. The vessels were tied off and resection with anastomosis was done. The patient recovered and has had no recurrence of bleeding.

Spastic Colon

The *colon*, like the stomach, is subject to nervous disorders, which may cause *spasm* (spastic or irritable colon), or great *dilatation* (because of spasm at the sphincter), or *atonicity*. In fact, *megacolon* of minor degree is said to be due to overaction of the sympathetic nerves (which constrict the sphincters and decrease peristalsis). The x-ray reveals the spastic colon as a contracted tube and the colon of megacolon as a widely dilated one. The treatment of spastic colon consists of dietary management and sedation and the use of atropine or atropine-like drugs. Megacolon is treated by dilation of the rectal sphincter, repeated colonic irrigations, and a low residue diet. Sometimes sympathetic ganglionectomy is done. If all other methods fail, *colectomy* is indicated.

Diverticulitis of the Colon

The word diverticulum means, literally, a by-path. It is a blind tube, or sac, branching off from a principal channel. We may look upon four

classes of diverticula: (1) a normal functioning pouch for storage and absorptive purposes, such as the gall bladder, or (2) those natural pouches whose function is unknown, such as the appendix; (3) a congenital defect, or so-called "true diverticulum," containing all the layers of the wall of the organ involved, such as Meckel's diverticulum, or other congenital diverticula of the small or large bowel; (4) acquired, or so-called "false diverticula," such as esophageal, urinary bladder, and colonic diverticula.

Sometimes diverticula occur as a compensatory mechanism, not only to relieve pressure but to increase retention space or provide more area for absorption of fluid. An example of this is the dilatation of the bile ducts, with the formation of parietal sacculi after extirpation of the gall bladder.

Incidence.—A study of diverticulosis of the large bowel and its complications is timely because of its commonness. An accurate survey of world statistics, including the twenty-three cases we are reporting, has led to the following conclusions: (1) the disease is practically always acquired; (2) it is rarely encountered in persons under 30 years of age, where the incidence is about 0.5 per cent; (3) over 40 years the incidence in the general population is variously estimated at 5 to 10 per cent and is more common in males, 1¼ to 1; (4) complications develop in about 15 to 25

TABLE XVII

CLINICAL TYPES OF DIVERTICULOSIS

TYPE		NUMBER OF CASES
I	Diverticulosis without symptoms	2
II	Diverticulitis with vague abdominal pain and bowel dysfunction (constipation and diarrhea or both)	6
III	Diverticulitis with symptoms and signs of appendicitis	2
IV	Diverticulitis with symptoms and signs of large bowel obstruction and the presence of an abdominal tumor	5
V	Diverticulitis resembling left-sided appendicitis, with perforation and general peritonitis	1
VI	Diverticulitis with urinary bladder symptoms	2
VII	Diverticulitis with external fistulae	1
VIII	Diverticulitis with colonic bleeding	3
IX	Diverticulitis associated with ulcerative colitis	1

TABLE XVIII

COMPLICATIONS OF DIVERTICULOSIS

I. Acute diverticulitis
  A. Gangrene with perforation
    1. Spreading peritonitis
    2. Localized abscess
      a. Secondary abscess by continuity
      b. Pylephlebitis with multiple liver abscess
      c. Subphrenic or perinephric abscess
      d. Empyema
    3. Rupture into bladder, bowel, or other viscera, or to exterior
II. Chronic diverticulitis
  A. Colitis
    1. Hemorrhage and ulceration
  B. Pericolitis
    1. Obstruction
    2. Adhesions to other viscera

per cent of this group; and (5) from 25 per cent to 50 per cent of these complications demand surgical intervention for relief. In other words, 3 to 5 per cent of all cases of diverticulosis demand surgery, and these complications are more common in females, 2¾ to 1. Thirteen cases in our group, or 56.5 per cent, were treated medically; surgery was necessary in seven, or 30.4 per cent, whereas three were not treated. (Tables XVII, XVIII, XIX, XX.)

Table XIX

Age Distribution in Diverticulosis

20 to 30	3
30 to 40	2
40 to 50	2
50 to 60	6
60 to 70	5
Over 70	4

Table XX

Location of Diverticula in Twenty-Three Cases of Diverticulosis of the Colon

LOCATION	NUMBER	%
Sigmoid (sigmoid includes iliac and pelvic colon) colon	8	34.7
Descending and sigmoid colon	6	26.0
Transverse and descending colon	3	13.0
Transverse, descending, and sigmoid colon	3	13.0
Transverse colon	1	4.3
Ascending colon	2	8.6

Etiological Factors.—Although the exact etiology of diverticulosis is unknown, *many factors are known to contribute to its occurrence.* These may be grouped as follows: (1) embryological, (2) anatomical, (3) physiological, (4) pathological, (5) physical (Table XXI).

A careful review of the evidence concerning the cause of this disease reveals the following facts:

1. Diverticula are usually acquired, and are seen frequently in people past 40 who are more often of the lateral than the linear types, although they must be thought of in all ages and types.

2. They are usually found in the pelvic and iliac colons but may occur throughout the large bowel.

3. They may be present anywhere on the circumference of the bowel, but are usually found (a) along the anterior taenia and (b) on the mesenteric side of the anterior and posterolateral taenia, where vessels penetrate the wall of the colon.

4. The cause of diverticulosis is probably a combination of factors due principally to an increase of intraluminal pressure and a decrease in the resistance of the intestine's wall to this pressure. The former may be influenced by (a) the smallness of the bowel lumen at the junction of the rectum and sigmoid, (b) constipation (although *this is doubtful*), (c) spasm of circular muscle, and (d) obesity, causing increased intra-abdominal pressure (although diverticula also are found in thin persons).

The latter, that is, the decreased resistance of the bowel wall, may be influenced by (a) large canals for the entrance and exit of vessels, (b) congenital defects, and (c) wear and tear of muscle as age is increased.

5. The foregoing factors are all present in the pelvic colon, where there is a small space in a transverse position which bears the brunt of

TABLE XXI

ETIOLOGICAL FACTORS IN DIVERTICULOSIS

I. *Embryological Factors*

1. Congenital anomalies are rarely found in hind-gut except at its terminal portion, which may be blind, or in rectum. The anus is a common site.

2. Many congenital (true diverticula) may occur as determined by the presence of all layers of the colon; however, these layers may become thinned or separated later in life, leaving only the mucosa and submucous coat.

3. Congenital anomalies usually are not so multiple in an organ, although they may be in various organs coincidentally.

4. The incidence increases with age.

5. At birth, only the terminal part of the pelvic colon lies in the pelvis.

6. The bowel in its development grows away from the vessels, tending to produce traction upon its walls.

II. *Anatomical Factors*

1. The colon is wider at the cecum (3 inches) and narrower at the sigmoid (1½ inches or less).

2. The pelvic colon lies in a horizontal plane, giving rise to stasis.

3. The longitudinal muscles only partially cover the large bowel by three longitudinal bands known as "taeniae." Even in its lowermost portion these muscles do not completely encircle the bowel.

4. The taeniae are one-sixth shorter than the bowel, giving rise to sacculations These form three rows and are definitely divided by the well-developed circular muscle. The sacculations, when distended, resemble large diverticula.

5. The appendices epiploicae along the anterior longitudinal band offer a site of least resistance.

6. The blood vessels create a real defect in the circular muscle layer and according to Edwards, are the points of least resistance.

7. Passive congestion in the veins, which are normally larger than the arteries, or lymph vessels seem to play an important role.

III. *Physiological Factors*

1. There is little peristalsis in the colon except for the powerful rush waves which fill the pelvic colon from below upward.

2. The Sigmoid is the most sensitive portion of the large bowel, giving rise to spasm here. When fully distended, the sacculi bulge outward, providing more space for storage.

IV. *Pathological Factors*

1. Spasm of circular muscles.

2. Adhesions cause traction diverticula.

3. Muscle deficiency on either side of the anterior taeniae which leads to herniations into the appendices epiploicae. This deficiency is due to:

   a. Wear and tear of age.

   b. Muscle degeneration

   c. Increased pressure within, due to constipation or other causes.

4. Muscle atrophy sometimes occurs.

V. *Physical Factors*

1. Diverticula can only occur as a result of two forces:

   a. Increased pressure from within; that is, pulsion.

   b. Pulling from without, that is, traction.

   These factors are effective when there are local points of lowered resistance.

2. Experiments in cadavers, in which an increase in intraluminal pressure was produced, caused a rupture of the bowel at the mesenteric border. In living persons, air injected under high pressure into the rectum may cause a perforation in the antimesenteric border. In living dogs, such pressures also cause a break in the antimesenteric border.

3. Sudden increase in intraluminal pressure following obstruction resections or the injection of large amounts of water for enema may cause perforation at various points on the circumference of the bowel.

high intraluminal pressure because of the weight of the fecal content; the rush peristaltic wave with filling from below upward and the squeezing action on the outside tend to force pouch formation if any weakness exists in this area. This probably accounts for the fact that about 86 per cent of all diverticula of the large bowel are found here. (Tables XX and XXI.)

Pathology.—Diverticula may be covered with mucosa and submucosa only, or with fibrous tissue and a few longitudinal muscle fibers, subserous fat and serosa, or variations of these layers, but hardly ever by circular muscle. Diverticula may be microscopic in size and thereby evade detection by x-ray or gross inspection, yet give rise to symptoms and signs.

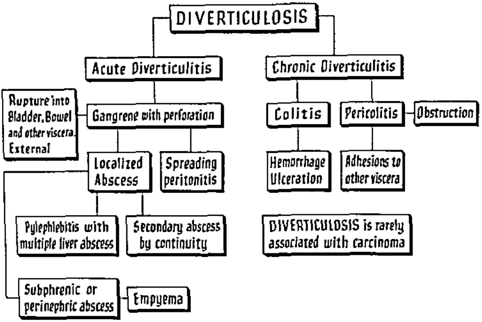

Fig. 304.—Chart indicating complications which may ensue from diverticulosis of the colon.

We are here more interested in complications of the diverticula. These may be simple inflammation, which may be severe enough to interfere with the blood supply, causing gangrene with perforation. This complication may in turn give rise to (1) local abscess formation, (b) general peritonitis, and (3) fistula. In addition, the diverticula may become chronically inflamed, causing a thickening of the entire bowel wall or sigmoiditis with or without pericolitis with fibrosis (gas pipe colon). Last, as a result of either the acute or chronic processes, obstruction of the lumen of the bowel may occur with all of the pathological changes and effects of intestinal obstruction. (Table XVIII.)

We must also mention the complications of acute inflammations in the abdomen, such as pylephlebitis with liver abscess, subphrenic abscess, and empyema, or even septicemia, and in all instances the enormous area

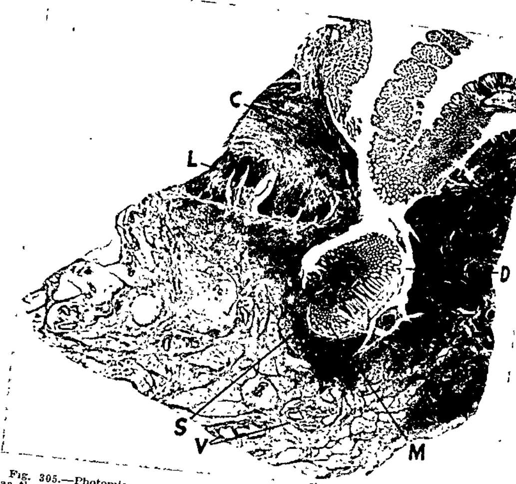

Fig. 305.—Photomicrograph of a small diverticulum from a resected sigmoid which was the seat of a chronic diverticulitis with obstruction. *C*, Circular muscle; *L*, longitudinal muscle; *D*, diverticulum; *M*, mucous membrane; *S*, submucous coat; *V*, blood vessel. (From Berman and Bauer: J. Indiana M. A. 35: 197, 1942.)

involved in widespread inflammation gives rise to hemoconcentration and stagnant anoxia, which may be more important in the causation of severe systemic effects than the infection.

Symptoms and Signs.—Uncomplicated diverticulosis causes few, if any, symptoms or signs, and its diagnosis depends entirely upon the barium or double contrast enema. The complications present signs readily interpreted in most cases; however, almost any lesion of the large bowel may be mimicked. There may be sudden pain which begins and remains *in the left lower quadrant, together with* little nausea or vomiting, but with great tenderness and rigidity, with or without demonstrable air beneath the diaphragm on x-ray, indicating a perforation. This must be

Fig. 307.—*A*. Diverticulosis of the descending colon. Arrows point to the diverticula. *B*. Polyposis of the colon. Arrows point to some of the polypi. The patient was a young woman aged 28 years whose mother also had malignant degeneration from polypi of the colon. At operation the entire colon was found to be filled with polypi. Radical resection was done.

contrasted with the chronic case which presents symptoms of bowel dysfunction not unlike carcinoma, with alternating constipation and diarrhea. Last, the classical finding of gas and foul urine through the urethra is diagnostic of vesicocolic fistula. The relatively low temperatures (that is, without pylephlebitis or liver abscess) and low counts are interpreted as being due to the diffusion of the inflammation, which does not accumulate under pressure. This is not true when abscess or spreading peritonitis is present.

A word of caution is necessary concerning the presence of a mass, blood in the stools, and x-ray interpretations. All may point to a car-

cinoma, but all may, and often do, occur in diverticulitis. The pouches fill with granulation tissue which bleeds easily, and because of this, or swelling, or foreign bodies, they will not fill with barium, giving only the long ragged outline which, except for the length of the bowel involved, resembles carcinoma. One must always consider malignancy in these cases, because they occur in the proper age group, yet the incidence of this disease in diverticulitis is very low. One of our patients had a carcinoma of the prostate, another carcinoma of the colon, arising in polypi.

Prognosis.—The prognosis in diverticulitis, regardless of the mode of treatment, is not good. Hayden reports forty-four unoperated cases, of which three died in the hospital, fourteen died later, and twenty-seven are alive, with eight having recurrent attacks. Of forty-nine operated cases, twenty-eight died and twenty-one are living, five having recurrences. Of this latter group, thirty-one had only one operation, whereas eighteen had two or more operations. Arnheim reports an operative mortality of 62 per cent. Lockhardt-Mummery is less lugubrious in his outlook. Of one hundred and thirty-six cases, ninety-one were treated by operation and forty-five were not. The mortality was just over 10 per cent.

In the twenty cases treated in our series, seven were operated upon, with one death, the mortality rate being 14.2 per cent. In thirteen cases, no surgery was used and the mortality rate was 7.6 per cent (one death). The total mortality for the twenty cases was two deaths, or 10 per cent (Tables XXII and XXIII).

TABLE XXII

TREATMENT

Nonsurgical	13
Surgical	7
No treatment	3
Types of surgical treatment	
Resection of sigmoid	1
Inversion of diverticulum	3
Drainage of abscess	2
Cecostomy	1
Cecostomy—exteriorization of loop of sigmoid and later replacement	1
Closure of fistulae	1

Mr. O. K. had two operations—cecostomy and later drainage of abscess.
Mr. H. Y. had two operations—inversion of diverticulum and drainage of abscess.

TABLE XXIII

MORTALITY RATES

Nonsurgical	1 death in 13 cases
Surgical	1 death in 7 cases
Death from other causes	3
Diverticula an incidental finding	2 deaths in 20 cases
Total mortality rate	(10%)

Treatment.—Uncomplicated diverticulosis requires no treatment. Diurnal evacuations are desirable, and large enemas or cathartics may

be harmful. It is best to use agar or other bulk laxatives to keep the stool in one mass.

1. Acute diverticulitis should be treated with low residue diet, bed rest, sulfonamides, attention to water balance, and blood transfusions when anemia or hemoconcentration occurs. Unnecessary exploration should not be done because it is not innocuous.

2. Sudden perforation requires surgical intervention with turning in of the perforated diverticulum, if feasible, and then wrapping with omentum. If not feasible, the loop should be mobilized and placed outside the abdomen, and a tube anchored.

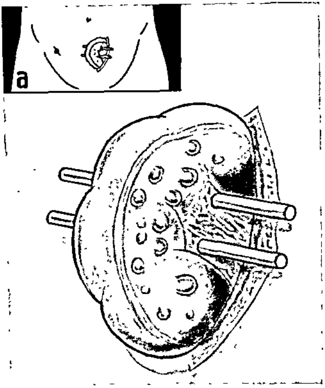

Fig. 308.—Loop colostomy.—Diagram illustrating a method of performing colostomy where a large loop of sigmoid is brought to the outside so that a complete exclusion may follow or in cases where the diseased loop is so large that a single bar will not permit the extrusion of the entire involved segment. The insert *a* shows the position of the colostomy. The same operation may be done by sewing skin beneath the colon as first described by Mixter. However, this necessitates dividing the mesocolon or mesosigmoid, interfering with blood supply and requiring a later open anastomosis. For a temporary colostomy, particularly in patients who are in poor condition and who will not stand much manipulation, it is, perhaps, best to bring a loop of sigmoid out and hold it out with a glass bar or a rigid rubber tube and loosely suture the bowel to the peritoneum. The bowel may be opened within twenty-four to forty-eight hours. If immediate decompression is required, a vent may be made by inserting a small catheter into the extruded loop and holding the catheter in position with a purse-string suture of silk.

3. Local abscess should be adequately drained through a muscle-splitting incision.

4. Spreading peritonitis is treated in the classical manner, with nothing by mouth, tube suction together with ample drainage, sulfonamides, blood and plasma transfusion, and intravenous medication.

5. Fistulae are treated by dividing the fistulous tract and turning in both sides, then interposing *omentum*. *In addition, some form of diversion* of fecal current may be temporarily necessary.

6. Chronic diverticulitis without obstruction is best treated by resection. *However, when we remember the forces active in the causation of* diverticula, we can readily see that in many instances there may be recurrence near the site of anastomosis. Mikulicz's operation is difficult because of the short, thick mesentery. End-to-size anastomosis is better.

7. Chronic diverticulitis with any degree of obstruction demands first a diversion of the fecal current. This is necessary to deflate the obstructed bowel. It also enables the surgeon to make further studies, so that carcinoma may not be overlooked. *The following* procedures may be used: (a) appendicocecostomy, (b) cecostomy, (c) ileostomy, (d) transversostomy, (e) colostomy.

Of these, "spur" transversostomy is the best except in acute obstruction. Here appendicocecostomy is the most feasible and is easily done.

8. If obstruction is present and the diverticula extend very low, *resection with anastomosis is done. It is best to drain after* this procedure through the cul-de-sac in the female, and posterior to the rectum beside the coccyx in the male.

9. Chronic complicated diverticulitis with "*gas pipe*" colon defies extirpation because of dense adhesions, and diversion of the fecal current is the only feasible procedure. For this reason recurrent diverticulitis should be looked upon as a serious progressive *disease* which should be treated by resection, especially in the segmental types.

Inflammations of the Colon

Inflammations of the colon are known as colitis. They are classified according to their position and extent as cecitis, sigmoiditis, or general colitis or according to their presumable cause. It is *the latter* classification which lends itself to clinical use. For practical purposes colitis may be divided into three big groups:

1. Nonspecific: (a) acute transient, (b) simple ulcer *of the* cecum or sigmoid, (c) chronic ulcerative colitis, (d) colitis of unknown origin, (e) regional colitis or segmental colitis.

2. Specific: (a) tuberculous, (b) lymphopathia *venereum*, (c) actinomycosis.

3. Allergic and psychosomatic.

From this classification it may be readily seen *that colitis* may have many and various causes. In this group we have not included bacillary dysentery which is caused by bacilli of Shiga and which is an acute, definite infection of the bowel. This belongs *in the* classification of specific types. Also, amebic dysentery belongs in the specific types. However, this is described in the chapter on Miscellaneous Infections, Chapter 7.

Fig. 309.—Chronic ulcerative colitis. *A*. Photograph of the abdominal incision on the twelfth postoperative day. The wound has healed by first intention. *B*. Portion of the excised descending colon. The entire bowel is involved. *C*. Ascending colon. Note the polypoid appearance of islands of mucosa which remain. N. F. was a woman, 36 years of age, who came to the hospital complaining of diarrhea with twenty-five to thirty stools a day consisting mostly of blood and mucus, loss of eighteen pounds in weight in six weeks, nervousness and vomiting, and a continual fever.

Operations were done in three stages. In the first stage an ileostomy was performed. This relieved the patient greatly but she continued to have fifteen to twenty stools a day which were mostly blood. The septic type of fever continued. The second stage consisted of resection of the cecum, and ascending, transverse, and a portion of the descending colon. At the third stage the descending colon, sigmoid, and rectum were removed. The operation was done in February, 1941. This patient has remained well. She is the mother of five children and is working in a department store as a clerk. The ileostomy functions well, and the stools are well formed. (Case referred by Dr. R. D. Rosenack.)

Acute transient colitis is caused by the paratyphoid bacilli or other forms of infection such as staphylococcus which produce a transient irritation of the bowel with all the symptoms and signs of colitis; namely, diarrhea, large watery stools, and perhaps a small amount of bleeding. In this group also belong amebic dysentery and bacillary dysentery which are more or less acute and are specific in origin. The disease is recognized by repeated cultures and smears from the stools, proctoscopic examination, and a barium enema. The latter is important because of the frequent association of the symptoms and signs enumerated under carcinoma of the bowel with superimposed infection.

The type in which the surgeon has a great interest is the so-called *nonspecific idiopathic ulcerative colitis*, also known as chronic ulcerative colitis.

In all types of *chronic ulcerative colitis* the soil may be made fertile by the psychosomatic background or may be made fertile experimentally by obstructing the lymphatic drainage of the bowel. It has been shown experimentally that the mucosa of the colon has a special tendency to ulcerate, after all lymphatic drainage has been blocked. By using sclerosing solutions, this method of producing a chronic type of ulcerative colitis may be utilized in studying the disease in the human being. It has been shown that organisms may be injected into the lymphatics without producing ulcerative colitis. Simple obstruction, however, of the lymphatics will set the stage for a colitis which in many ways resembles that of the chronic ulcerative form. When the lymphatics of the small bowel are blocked, a more generalized enteritis is produced rather than one of ulceration. These experiments are important only in that they emphasize the fact that local factors, no matter what they may be, which lower the resistance of the mucous membrane of the large bowel may be the start of a chronic ulcerative colitis.

This *group* of chronic ulcerative colitis includes many different varieties and causes of colitis. However, a common error is to group them all together and call them all chronic ulcerative colitis. In this group may be included *streptococcic ulcerative colitis* which is said to be a distinct entity. The disease is said to have more or less typical pathological manifestations. Principally the differentiation of this particular entity is in the fact that its lesions begin in the most distal segment of the rectum, just above the anal canal, and then there is a diffuse involvement of the bowel. Such patients frequently present themselves with a history of frequent rectal abscesses with fissures and fistulae and state that they have had many operations upon the rectum only to have recurrences. The disease spreads upward until the entire colon and even the lower part of the ileum become involved. The bowel becomes diffusely narrowed and haustral markings are erased; the barium enema with x-ray gives a more or less typical picture.

The clinical symptoms and signs of the disease may manifest themselves in one of two different ways. First, the onset may be sudden and

abrupt with diarrhea which is persistent; there may be many bloody stools during the day and excessive amounts of purulent rectal discharge; the patient complains of pain, has fever and leucocytosis and is profoundly ill. The second type is the one which has been referred to previously and the symptoms of which are chiefly those of the rectum. In this type the patient will complain of repeated rectal inflammation and infections with a diarrhea and purulent discharge. The diagnosis is made by careful proctoscopic examination and x-ray examination, and this particular type is usually grouped as one of the chronic ulcerative varieties. A second type

FIG. 310.—Ulcerative colitis. Barium-enema x-ray, showing the ragged filling of the mucosal outline in the transverse and descending colon due to ulceration.

of nonspecific chronic ulcerative colitis which belongs in this group is the so-called *ulcerative colitis of unknown origin*. This is the one which still retains the name nonspecific or idiopathic, and here the disease resembles that of streptococcic ulcerative colitis so closely that it is difficult to distinguish the two so that many observers do not believe that the streptococcic variety so-called is a definite clinical entity. A third form is the *regional ulcerative colitis*. This may appear anywhere in the bowel but seems to involve only a small segment. It has many of the characteristics of a

regional enteritis. The diagnosis of this condition is by the history, symptoms and signs, and proctoscopic examination. However, if the lesion is high in the colon, even the sigmoidoscope will not reach the site of the pathology; therefore, the barium enema provides the most reliable information. The remarkable pathological change in regional ulcerative or segmental ulcerative colitis is the fact that a segment of six to twelve inches is all that is found to be involved with an abrupt change to perfectly normal bowel distal and proximal to the lesion. The rectum is not involved in this condition.

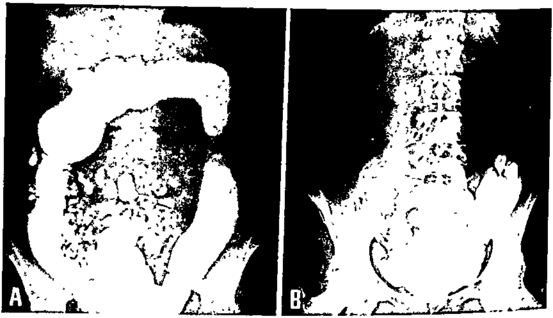

Fig. 311.—Regional colitis. A very unusual type of segmental nonspecific inflammation of the large bowel is regional colitis. *A.* Barium enema in a patient, Mrs. A. S., 42 years of age, who came to the hospital complaining of diarrhea, some blood in the stool, tenesmus, and cramping abdominal pain, with loss of weight of about twenty pounds within eight months. The x-ray photograph depicts the bizarre pattern of the large intestine. It will be noted that the cecum lies extremely high on the right side, and the appendix is visualized. Distal to the cecum are three knoblike projections from the smooth outline of the large intestine. Proctoscopic examination was normal.

At operation the entire ascending and transverse colon had shrunken and become fibrosed. What seemed to be a high cecum in the x-ray studies proved to be a contracted cecum and ascending colon. The cecum, ascending colon, splenic flexure, and descending colon down to the iliac colon was removed and the ileum was anastomosed to the iliac colon by side-to-side anastomosis. *B.* Postoperative barium meal study of the intestinal tract. The patient was last seen in February, 1949, three years after operation. She complained of occasional periods of loose stools, soon after operation. There was no loss of blood and no purulent discharge. Stools remained rather liquid. However, at the present time the stools have regained their normal consistency and the patient is now without symptoms. She has still failed to gain weight.

Lastly, another type of chronic ulcerative colitis which we placed in group three is the so-called *allergic* or *psychosomatic type*. There is evidence that ulcerative colitis may rest on a psychosomatic basis. The reason for this statement is that it seems to occur in a certain type person—the linear type, the introvert. Such individuals have frequently had bouts of regional enteritis and duodenal ulcer and then chronic ulcerative colitis. However, from a pathological and a roentgenological point of view the types which have been mentioned give pictures which are so similar that it

is difficult to state that they are each of them clinical entities. The different types of chronic ulcerative colitis have a fertile ground in certain type individuals, and whether or not the streptococcus or many bacilli and cocci are at fault depends entirely upon the flora which happens to be present in the greatest numbers. It is the "soil" rather than the "seed" which is the cause of the ulcerative colitis. Even in the regional types the entire bowel may ultimately be involved and frequently becomes diseased after resections and after anastomoses around the obstructed and inflamed areas.

In this chronic group belongs one other entity, *simple ulcer* of the *cecum* or the *sigmoid*. A single ulcer may appear either in the cecum or on the left side which spreads and ultimately may perforate. The entity has been seen more commonly on the right than on the left side, and moreover *an ulcer on the left side is usually a part or phase of chronic ulcerative* colitis. It cannot be denied, however, that simple ulcer of the cecum beginning on the mesial side near the ileocecal valve is a definite clinical entity. Its complications may include perforation or obstruction. Sometimes the entire cecum becomes involved and a resection may be required. chronic ulcerative colitis untreated is usually a progressive disease. However, it may undergo resolution and in the early types with proper management patients have been known to remain in a status quo or even to improve sufficiently to return to normal existence. We have seen women patients who have borne children without recurrence of the disease. However, the usual tendency is for the disease to involve all coats of the bowel. The mucosal surface is denuded to a greater or lesser extent, and although healing may occur here and there, there may be a heaping up of mucosal islands producing a pseudopolyposis, ultimately a stricture. The muscularis becomes thickened and the serosa is edematous, and although the bowel appears to be thicker, in reality it is extremely thin and friable. Healing of the muscular coat results in fibrosis and narrowing of the lumen, and frequently strictures occur.

Complications of the disease include perforation with general peritonitis or localized abscess, fistula formation, hemorrhage, stricture or narrowing of the lumen, pseudopolyposis, and malignant degeneration. The treatment of chronic ulcerative colitis includes medical management and surgery. There is a difference of opinion concerning the value of *ileostomy* in early cases of the disease. All are agreed that it should be done alone or as a complementary procedure in any of the above complications. Usually in the early phases of the disease, if there are remissions and exacerbations, in the periods of remission the patient believes that the condition has been arrested. The use of penicillin in large doses given in aluminum hydroxide gel and the use of Sulfasuxidine and Sulfathalidine may produce temporary remissions. Such patients are also given high vitamin, high protein diets with low residue, and on this regimen they may improve greatly. In addition, these patients frequently are

given neuropsychiatric care and this too seems to help. However, soon an emotional upset with acute infection occurs, and the process recurs with all its virulence. If the disease is allowed to progress and if the diarrhea is bloody, patients will develop severe anemia. Earlier, before the stools become bloody, there will be hemoconcentration due to loss of plasma in large amounts. This, in turn, is caused by frequent stools without blood. In either event, the blood volume is greatly reduced. Patients become extremely toxic. The formation of vitamin K_2 cannot take place because proper absorption does not occur, and very frequently there is a decided

Fig. 312.—Chronic ulcerative colitis in a child. Ileostomy performed in a case of chronic ulcerative colitis in a boy aged 14 years. There followed a great improvement of all symptoms and a gain in weight. The subsequent history of this child was as follows: Ileostomy was closed on two occasions but each time symptoms recurred. In addition, the lesion progressed until there was a constant bloody diarrhea so that the child deteriorated very rapidly. Because of this, a total colectomy was done in stages, with good results.

reduction in the prothrombin time. For this reason we have advocated the earlier use of an ileostomy if the patient fails to respond on a trial of medical management. The ileostomy can be disconnected and the continuity of the bowel may be restored if the patient becomes well. However, in most cases where ileostomy is employed the disease is in an irreversible form, and the ileostomy must remain. Therefore, when patients are getting

the benefit of an early ileostomy, there is a remote possibility that the bowel may be restored to normalcy. Our experience, however, has not borne out this fact. Perhaps it is due to the fact that we have not employed ileostomy early enough. However, even in a 16-year-old lad on whom ileostomy was done three times, the continuity of the bowel was restored, and each time the chronic ulcerative process recurred. The medical regimen included diet, psychogenic control, typhoid vaccine which has been advised by some, high vitamin intake, and the use of penicillin, streptomycin, aureomycin, Chloromycetin, and Sulfasuxidine. If the enterostomy proves effective in controlling symptoms, further surgery is not necessary. Vagotomy and lumbar sympathectomy may be used with ileostomy or as definitive measures. Their effectiveness remains to be proved in our hands. Ileostomy is done under local anesthesia through a McBurney incision. The ileum is divided and the proximal end is brought out through the incision in different planes of muscle so that sphincter action, which is primitive of course, may be attained. The distal end is brought out through a stab wound high up on the right side with a clamp on this end until the bowel wall has healed to the skin and to the peritoneum. The reason for this sort of procedure is that many of our cases have strictures in the lower rectum, and also many times the terminal ileum is not entirely free from the disease. Therefore, to turn in the distal end would be risky because of a chance for leakage. Furthermore, should colectomy be necessary, it will be unnecessary to dig up, so to speak, the turned-in distal end. Use of the transverse incision makes it possible to include the transplanted distal end in the incision, and in this way the ileum, cecum, ascending colon, and transverse colon may be removed at the second stage of the operation. In all cases in which ileostomy is unsuccessful in that the person still has chills and fever and still loses large quantities of blood as a result of diarrhea, it will be necessary to do a colectomy. This is done in two stages. The first includes removal of the terminal ileum and ascending colon, transverse colon, and the descending down to the upper sigmoid. The next stage includes the descending and the sigmoid and the rectum if necessary. In a few cases we have found that it is not necessary to do an abdominoperineal operation and that the distal end may be turned in. This is particularly true of the type which does not begin in the anus and the rectum. We have recently tried colectomy with preservation of the rectal sphincter and implantation of the ileum in the sphincter. The results were not as good as in abdominal ileostomy.

Of the *specific types of colitis,* tuberculous ulcerative colitis has been discussed in Chapter 8. It was shown in Chapter 8 that the tuberculous type of ulcerative colitis is primarily in the small intestine, although it sometimes may involve both small and large bowel. In the average case, tubuculous colitis is secondary to tuberculosis of the lungs or elsewhere in the body. Sometimes it is associated with tuberculous peritonitis with miliary tubercles on the serous surface of the bowel. Usually tuberculosis involves the ileocecal area, although the colon may be involved. Surgery

is indicated to relieve obstruction, and resection of the ileum and the cecum or the colon may be necessary.

Ulcerative colitis due to the virus of venereal lymphogranuloma has been described in Chapter 7. This usually results in a stricture, and the surgeon is frequently called upon to relieve the obstruction. There is no drug that has been successful in combating the disease, although emetine, streptomycin, the sulfonamides, penicillin, Frei antigen, estrogenic hormone, and other drugs have been used. Irradiation, diathermy, and solid carbon dioxide snow have also been employed with equivocal success.

Surgical methods include dilation with finger or bougies, internal proctotomy (division of the stricture within the rectum by means of an incision much like the operation of internal urethrotomy), complete or external proctotomy (incision through the stricture in the posterior midline through external posterior incision). Proctotomy gives only temporary relief and has not justified its use, although an occasional arrestment of the disease and alleviation of symptoms result. Permanent colostomy is the operative procedure of choice, although there are some objections to it. The disadvantages are: (1) the artificial anus, (2) stricture of the colostomy opening, (3) anterior herniation of the bowel, and (4) retrograde herniation. However, if the colostomy is properly performed, most of these objections are not valid. In addition to the permanent colostomy, an abdominal perineal resection may be indicated. Many other types of procedures have been advocated and all are variations of colostomy with or without excision. A word should be said concerning some of these. The two chief types are the so-called Pauchet's intrasphincteric excision operation and the large abdominal perineal resection. The Pauchet operation includes a preliminary colostomy and then a resection of the offending rectum, together with its stricture, from below and then suture of the proximal end of the upper sigmoid into the sphincter muscles. Later, at a third stage, the colostomy is closed. This operation can be used only in selected cases. It has in its favor the preservation of the sphincter and the closure of the colostomy. The operation can be used if the stricture does not extend too far upward; that is, if the stricture extends for more than six inches or about 15 cm. above the anus, the procedure cannot be used. It also cannot be used if the sigmoid is plastered down with adhesions within the abdominal cavity. However, there is much to be said for this procedure. Since the lesion is not a malignancy, if the sphincter can be preserved this is to be desired. If there is a failure, the patient is forewarned that colostomy may be necessary and the trial has been worth while. In extensive cases extending up into the peritoneal cavity with great and widespread adhesions or in those involving the entire rectum, the operation of abdominoperineal excision is best. Such cases defy the bringing down of the proximal loop, and to leave the disease in situ would mean to re-establish fistulae and sinuses.

Chronic bacillary dysentery follows the acute form and is due to one or several strains of *Shigella paradysenteriae.* The diagnosis depends upon

the presence in the blood of agglutinins in significant titer (at least 1 to 320 or higher) of one of the several strains of *Shigella paradysenteriae.* The treatment is based upon the use of the sulfonamides particularly succinylsulfathiazole and Sulfathalidine. In the more severe cases, and particularly those caused by the Flexner and Shiga strains of these organisms, specific serums and bacteriophages may be used, although these have not been of particular help.

Regional ulcerative colitis is difficult to diagnose even with the barium enema. This is due to the fact that there is extreme shortening and thickening of the bowel so that it resembles carcinoma, and differential diagnosis cannot be made without biopsy. In a recent case the entire ascending colon and cecum were pulled up, so to speak, into the transverse colon although not intussuscepted within the colon. The shortening of the ascending colon was so great that it appeared that the ileum entered a bulbous enlarged end of the transverse colon at the hepatic flexure. Resection and ileosigmoidostomy were done. It should be also stated that the disease tends to progress even after resection, which is the treatment of choice, and may recur very much as it does in regional enteritis.

Actinomycosis of the large intestine is found more commonly on the right than on the left side. It is said to originate in the appendix not infrequently. Diagnosis is rarely possible prior to operation. Even here the disease frequently is called a tuberculosis or malignancy. The biopsy proves the diagnosis. If the disease is localized to any segment of the bowel, resection should be done.

Sprue and *pellagra* may resemble ulcerative colitis of the idiopathic type. However, in most instances the appearance of the bowel through the sigmoidoscope will not show ulceration but rather a hyperemia. The x-ray examination shows dilatation of the large intestine with a minimal amount of change in the mucosal pattern. Also, these same changes are sometimes seen not only in avitaminosis but in certain *allergic types* of colitis. It has even been said that allergy may cause polyposis; that is, a piling up of the mucous membrane. Mucosal abrasions are seen through the proctoscope. However, there is no evidence that allergy causes a real severe form of ulcerative colitis. These conditions, as has been said previously, are amenable to dietary management, vitamins, iron, liver, calcium, and psychotherapy. Their importance lies in the fact that they provide the soil for virulent strains of bacteria to enter, causing the chronic ulcerative type of the disease.

One last entity which has been discussed in the literature at times has been the condition known as a *granuloma, nonspecific in type.* This is probably another form of so-called segmental or regional colitis and differs in no way that is apparent from the chronic ulcerative colitis previously described. In summary it may be stated that there are many diseases which are grouped under the heading of chronic ulcerative colitis. The

morbid process may vary in each of the different types, but in general there are gradual hyperemia and swelling and edema of the mucosa with or without small ulcers. The mucous membrane is covered with a mucopurulent exudate, and there are small petechial hemorrhages scattered about the tiny ulcerations. In any patient who has diarrhea with blood and mucus in the stool, careful examination should be made by the barium enema and by proctoscopy and sigmoidoscopy together with cultures and smears to determine the cause of the colitis. Late in the disease there is great dehydration because of the loss of fluid and acidosis because of the loss of the alkaline juices. Treatment should be directed against correcting the secondary effects of the disease. Since at times it is impossible to make an accurate diagnosis of the particular variety at fault, it is customary to put these patients on a medical regimen first. This will include dietary management, local antiseptic irrigations, succynilsulfathiazole, Sulfathalidine, penicillin in aluminum hydroxide gel, specific immunizing serums, for dysentery caused by the Shiga bacillus, and emetine because of the possibility of amebic dysentery. Last, in every instance a careful general physical examination should be made to rule out the possibility of tuberculosis or syphilis. In the presence of a stricture this is particularly important, and also the Frei antigen test should be done as well as biopsy to determine whether or not lymphopathia venereum is at fault.

Tumors of the Colon

New growths are common in the colon. They may be benign, such as lipoma, adenoma, and, more rarely, hemangioma and lymphangioma. By far the more important group of benign tumors of the large bowel produce a polypoid growth. Polypi may be due to fibroma, which are particularly common in the rectum, myoma, fibromyoma, and adenomyoma. Neurofibroma may be single or, in case of neurofibromatosis, they may be multiple. Other types of polypoid tumors are the adenomas, papillomas, or villous tumors, multiple polyposis, which has been described previously, and the inflammatory polyp. Also, more rarely, is the polyp which is said to be related to an allergic state and which is said to contain a great many eosinophils. Perhaps the most common benign neoplasm in the colon and rectum is the adenoma. This tumor usually begins as a sessile growth and the pedunculation comes as a result of the growth of the adenoma and a constant pull from the fecal current. The pedicle consists of normal mucosa and may become several inches in length, thus allowing the tumor considerable range of movement in the bowel. Histologically the adenoma may range from a tumor composed of almost normal mucosa to one of hyperplasia of the glandular elements as evidenced by branching tubules, multiple cell layers, and deep-staining nuclei. Sometimes the adenoma can be seen to contain cells which vary slightly in their staining reaction. The great danger of this growth is its liability to carcinoma. The virus tumor is much less common than the

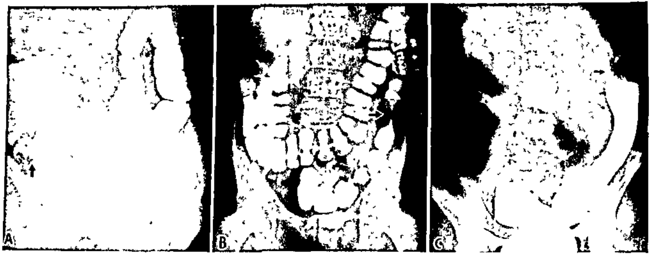

Fig. 313.—*A*. Carcinoma of the cecum (barium enema). Note the irregular filling defect in the cecal region. *B*. Carcinoma of the sigmoid (barium meal). Note the irregularity and narrowing in the upper sigmoid region, revealing the site of the carcinoma. *C*. Carcinoma of the descending colon just distal to the splenic flexure. Almost a complete obstruction is visualized by the barium enema.

adenoma. The papillomas attain great size and sometimes may be felt through the abdominal wall. They differ from carcinoma in that they are not indurated or ulcerated, and they do not invade the basement membrane. The liability of this type of papilloma to undergo malignant degeneration is so great that it is very often difficult to state even by microscopic examination whether or not the particular growth is or is not malignant.

The symptoms and signs of adenomatous polyp and a papilloma may be so similar that differentiation is impossible. Papilloma is almost never seen in children, whereas adenomatous ones are not uncommon. The symptoms and signs which are of greatest importance are: (1) bleeding which may be intermittent and which may be severe at times. The papilloma causes more bleeding than does the adenoma, although this is by no means always true. The blood may be bright red and free if it is low in the colon, or it may be mixed with the hard fecal mass if it is in the transverse colon, or it may be partially digested. Obviously the lower in the bowel the tumor and the more copious the bleeding the more bright red and the less mixed will be the blood in the stool. (2) Change in bowel habit. (3) Palpation of a tumor is sometimes possible.

The diagnosis is made by a careful digital examination in which the polypi in the lower bowel may be felt, proctoscopic and sigmoidoscopic examination for those in the upper rectum and lower sigmoid, and a barium enema or a contrast medium enema to demonstrate the polyps in the transverse colon, descending colon, and the cecum. The treatment is complete extirpation of the tumor together with a small portion of the mucous membrane. If there is any doubt concerning the malignancy, resection should be done. If the patient is properly prepared with sulfasuxidine and carefully cleansed with cleansing enemas the operation may be safely done. The large villous tumors in the rectum may require incision posteriorly in order to remove the growth. Frequently a large portion of the bowel must be removed with the growth because it is so large that it may completely encircle it. Multiple polyposis of the colon has already been described and its treatment discussed. In the adult multiple polyps may be removed if they are isolated and few in number. If they fill the bowel, of course colectomy is indicated.

Inflammatory polyps of the colon are due to prolonged ulceration from amebic dysentery or ulcerative colitis. Small islands of mucosa between the ulcers hypertrophy and become fibrotic, and they give the appearance of polypi. Some of them may be large, and they bleed profusely. Sometimes the polyp will develop a long pedicle, in which case it should be removed. Usually the disease has so destroyed the bowel that nothing short of colectomy will produce a cure.

The other types of benign growths in the bowel, as in the case of the polypi, are discovered either because of bleeding or because of intermittent obstruction. The polyp is notorious for this, since it may induce an intussusception or may occasionally become lodged in a narrow portion of

the colon. Also, this may be true of the large lipomas. In hemangioma, bleeding is a frequent complication. The diagnosis in each case is that of a solitary growth, and its nature cannot be determined preoperatively. The treatment in most cases is removal of the growth, and this is submitted to the pathologist for microscopic study. If benign, it is sufficient to excise the base and close the bowel in a transverse manner so as not to narrow its lumen. Hemangiomas, however, may require resection of the involved portion of the intestine.

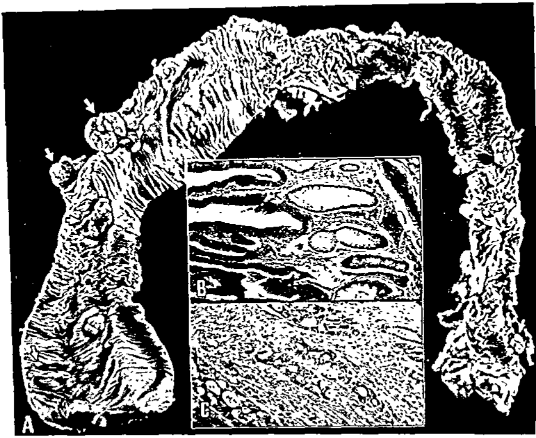

Fig. 314.—Acquired polyposis of the colon and carcinoma. *A*. Photograph of colon after total colectomy in a patient with acquired polyposis of the colon. Inset *C* is a photomicrograph of a resected carcinoma of the colon two and one-half years previously, and inset *B* is a photomicrograph of the present polypi within the colon which are benign. The arrows point to polypi throughout the entire colon. The healed scar of the previous resection may be seen in the extreme lower left. M. S. is a man 52 years of age who came to the hospital originally because of increasing constipation and an occasional streak of blood in the stool. Barium enema x-ray examination showed an obstructive lesion in the descending colon. At operation the descending colon was resected and an end-to-end anastomosis done. The neoplasm was an adenocarcinoma without involvement of the lymph nodes. The patient remained well for two and one-half years, after which he noticed occasional blood in the stools again. At this time a barium enema with air contrast technique revealed multiple polypi of the large bowel. Since these polypi were distributed from the cecum to the lowermost edge of the pelvic colon, a total colectomy was performed with the side-to-side anastomosis between the ileum and rectum. The lowermost portion on the left-hand side of the resected specimen was the site of the previous resection. There was no recurrence of the original carcinoma.

This illustrates the acquired type of multiple polyposis of the colon. The polyps were not present at the first operation and occurred within the two and one-half year period following the first procedure. It is easy to understand that, in this way, there may be carcinoma of the colon and then carcinoma at a later date or there may be multicentric carcinoma of the colon arising in the various polypi as shown in the gross specimen. (Case referred by Dr. H. Cahn.)

If a polyp is within the lower sigmoid or upper rectum so that it may be easily visualized with the proctoscope or the sigmoidoscope, it may be desiccated or removed with the snare. This should not be done where there is a broad base, because there is the danger of protracted bleeding. Desiccation is a very satisfactory method of destroying polyps that are within reach of the proctoscope or the sigmoidoscope. The danger of the benign polyp is that of carcinoma. It may begin as a patch of epithelial hyperplasia which occurs as a result of an inflammatory change or due to adenoma. Since the hyperplasia may become asessile and then pedunculated adenoma, there is a great chance of carcinoma being in one of these adenomas or the surrounding tissue. It is highly probable that a potentially malignant state which may or may not cause carcinoma may be present around an adenoma. It has been stated that a polyp may give rise to the "pile carpet" appearance and then traction due to the passage of fecal matter may cause a pedunculation to occur. The stem is filled with lymphoid tissue which is replaced by connective tissue, forming the stalk of the polyp. However, its transition into a malignant state can hardly be denied. Local excision of a solitary polyp which is malignant and which is not invading the rectal wall is sufficient provided that careful observation of the patient follows. However, radical operation should be performed if and when invasion of the rectal wall is discovered. For this reason it is perhaps judicious to remove the polyp with the knife rather than the cautery wherever possible.

Malignant Tumors of the Colon

Carcinoma of the colon is one of the most common types of cancer. About 50 per cent of all patients who die of cancer have the disease in the gastrointestinal tract and of these, five-eighths die of cancer of the stomach and approximately three-eighths die of malignant disease involving the colon or rectum. In other words, about 10 per cent of all deaths caused by cancer are traceable to malignant disease of the colon and rectum. Carcinoma of the stomach is the most frequent site of the disease and is followed in frequency by carcinoma of the colon and rectum. Cancer of the uterus and breast are third and fourth, respectively. Carcinoma of the colon and rectum is more common in males than in females. The incidence is highest in the sixth decade but a little earlier for women than men. The site of the growth in a combined survey of statistics from large clinics throughout the United States is as follows: the cecum, 6 to 8 per cent; the ascending colon, 4 per cent; the hepatic flexure, 2 to 3 per cent; the transverse colon, 4 to 5 per cent; the splenic flexure, 2 to 3 per cent; the descending colon, 3 to 4 per cent; the sigmoid, 13 to 14 per cent; the rectal sigmoid and rectum, 62 to 64 per cent. It would perhaps be better to speak in terms of the iliac and pelvic colon and pelvirectal juncture rather than the rectosigmoid. However, this is a rough estimate of the frequency of the site of the growth.

The cause of carcinoma is unknown. Much work has been done in an effort to evaluate a possible etiological factor. Some observers believe that a potentially malignant region exists in the colon prior to or coincidently with the development of cancer and that this region is larger than the growth itself. The region is the site of an inflammatory reaction, and the cells concerned are primarily mesoblastic, which are the natural defensive cells of the body, rather than epithelial. The effect on the epithelial cells is said to be secondary and represents a stage of destruction or impairment of nutrition followed by a stage of attempt at repair. If this repair becomes disordered and if the epithelium is isolated from the rest of the mucous membrane by a ring of lymphoid tissue as occurs

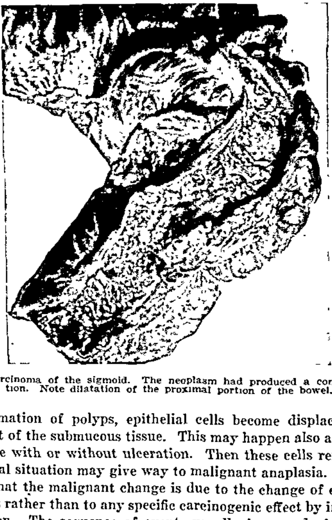

Fig. 315.—Carcinoma of the sigmoid. The neoplasm had produced a complete obstruction. Note dilatation of the proximal portion of the bowel.

in the formation of polyps, epithelial cells become displaced into the deeper part of the submucous tissue. This may happen also after rupture of a follicle with or without ulceration. Then these cells removed from their normal situation may give way to malignant anaplasia. One theory supposes that the malignant change is due to the change of environment of the cells rather than to any specific carcinogenic effect by inflammation or irritation. The sequence of events usually is a gradual histological transition from hyperplasia to adenoma or papilloma to carcinoma. Whether the inherent tendency to carcinoma is present in the cell is not known. Carcinomatous changes in papillomas can be diagnosed only by histological examination, and this must be based upon the observation of

If a polyp is within the lower sigmoid or upper rectum so that it may be easily visualized with the proctoscope or the sigmoidoscope, it may be desiccated or removed with the snare. This should not be done where there is a broad base, because there is the danger of protracted bleeding. Desiccation is a very satisfactory method of destroying polyps that are within reach of the proctoscope or the sigmoidoscope. The danger of the benign polyp is that of carcinoma. It may begin as a patch of epithelial hyperplasia which occurs as a result of an inflammatory change or due to adenoma. However, radical operation should be performed if and when invasion of the rectal wall is discovered. For this reason it is perhaps judicious to remove the polyp with the knife rather than the cautery wherever possible.

Malignant Tumors of the Colon

Carcinoma of the colon is one of the most common types of cancer. About 50 per cent of all patients who die of cancer have the disease in the gastrointestinal tract and of these, five-eighths die of cancer of the stomach and approximately three-eighths die of malignant disease involving the colon or rectum. In other words, about 10 per cent of all deaths caused by cancer are traceable to malignant disease of the colon and rectum. Carcinoma of the stomach is the most frequent site of the disease and is followed in frequency by carcinoma of the colon and rectum. Cancer of the uterus and breast are third and fourth, respectively. Carcinoma of the colon and rectum is more common in males than in females. The incidence is highest in the sixth decade but a little earlier for women than men. The site of the growth in a combined survey of statistics from large clinics throughout the United States is as follows: the cecum, 6 to 8 per cent; the ascending colon, 4 per cent; the hepatic flexure, 2 to 3 per cent; the transverse colon, 4 to 5 per cent; the splenic flexure, 2 to 3 per cent; the descending colon, 3 to 4 per cent; the sigmoid, 13 to 14 per cent; the rectal sigmoid and rectum, 62 to 64 per cent. It would perhaps be better to speak in terms of the iliac and pelvic colon and pelvirectal juncture rather than the rectosigmoid. However, this is a rough estimate of the frequency of the site of the growth.

spread to the regional lymph nodes. Therefore, very often we are faced with the fact that an innocuous-appearing cancer may be removed completely, and the pathologist may report that there is no involvement of the adjacent lymph nodes, yet in such cases the growth may appear later in the liver from metastases which were present at the time of operation. Of course, there is no way of proving this unless the venous channels are carefully inspected by microscopic examination. Even here this may be impossible because the spread may be by embolism. In this way carcinoma of the colon resemble staphylococcic or streptococcic infection. The streptococcus creates very little local tissue reaction but invades the blood stream. The staphylococcus creates a great deal of local reaction and is therefore stopped by the local tissue response and the lymph channels. So it is with carcinoma of the colon. The innocuous-looking carcinoma very often is the invasive type which involves venous blood channels, whereas the large ulcerating type is one which is stopped by regional lymph nodes.

The Lymphatic Spread of Carcinoma.—The importance of this is well known and has been carefully worked up. The lymphatic spread of carcinoma of the colon is primarily embolic. The nodes where the emboli lodge will prevent further spread until they are overwhelmed. Further embolic spread is through collateral channels, each new node involved tending to make a longer and more difficult channel for the embolus to travel. The spread from node to node does not seem to be a common method of dissemination. Thus, the finding of a group of involved nodes within the field of surgery does not mean the case is hopeless, although it does mean that the chance for producing a cure following surgery is one-half as good as if the lymph nodes were not involved. The spread is primarily upward. However, in about 4 or 5 per cent retrograde metastases to nodes, anywhere from 1 to 5 cm., do occur. We have occasionally encountered metastases in the perineal wound and in the lymphatics extending downward into the perineum. The rectum has a lymphatic spread which may be divided roughly into the three areas supplied by the inferior, middle, and superior hemorrhoidal arteries. The inferior region is the 2½ cm. of anus proper, terminating superiorly at the pectinate line. The middle extends upward from the pectinate line to just above the insertions of the levatores ani muscles, and the superior extends from the point of the sigmoid colon and terminates approximately at the level of the third sacral vertebra. The lymphatics originate from a network of tiny lymph spaces which extend throughout the mucosa, submucosa, and the intramuscular layers. From the bowel wall the lymph spread is at right angles to the bowel, and from here into collecting trunks which proceed to the following areas: the inferior node regions may spread upward, joining the pathways of the superior area; occasionally it may go downward or caudally into the adipose tissue of the ischiorectal fossa. Therefore, the inferior and middle regions may spread upward or laterally or downward. The superior region is drained

tumor cells breaking through the muscularis. Many forms of polyps of the colon remain benign for years, but they cannot be trusted because most of them ultimately will become malignant. Thus it makes little difference whether the polyp was originally an adenoma or the result of an inflammatory change due to chronic ulcerative colitis or even diverticulitis. The fact remains that when the mucosa is thrown up into a polypoid formation, the danger of carcinoma is inherent.

Pathology.—Grossly three types of carcinoma are seen: polypoid, infiltrating or ulceratvie, and stenosing. These have been previously discussed under different captions as the well-differentiated adenocarcinoma, and these will vary to the undifferentiated carcinoma simplex. The medullary types of adenocarcinoma are present in 5 to 10 per cent. The scirrhous type causes a stenosis and has given rise to the name of the "napkin ring" deformity of the large bowel. The pathological type of carcinoma is important not only because of its tendencies to growth, but also because of the symptoms and signs. For example, the encephaloid or medullary type of carcinoma, which is a fungating mass, is infected very early and produces ulceration, thereby causing an inflammatory reaction of the lymph nodes. This may be mistaken for involved nodes with carcinoma which may not be the case. This type of growth also is apt to produce bleeding, and gross hemorrhage may occur. Contrariwise the scirrhous type of carcinoma is apt to produce very few symptoms except a change in habit time. Later the symptoms may be chiefly obstructive and no bleeding will occur at any time. Carcinoma may spread primarily in one of three ways or in a combination of these ways: (1) by local extension from its site of origin, (2) by invasion of venous channels, and (3) through the lymphatic system. Most of the growths are low grade, and there will be considerable local growth before widespread metastases has occurred. However, local extension is frequently a cause for inoperability. It may include contiguous organs such as the bladder, the uterus, the tubes, the ovaries, the broad ligaments, the peritoneum, and the contiguous loops of bowel. In many cases in which we have thought that involvement of contiguous organs was present we have found that it was really an inflammatory process rather than a neoplastic one. This is particularly true of the bladder and the uterus due to the ulceration which occurs at the rectosigmoid. Inflammatory changes are common. Perforation may have occurred and the growth may have become densely adherent to the uterus in front or of the bladder in the male. Very often combined resection of the colon, including a portion of the bladder or the uterus, will reveal at examination that the adhesion has been duo to inflammatory change and that the new growth has not actually extended into the adjacent organ.

Venous Spread of the Disease.—Venous spread makes operation impossible for complete extirpation of the growth. It has been noted that when vascular invasion takes place that this occurs before the disease has

conservative operations upon the rectum and the sigmoid with preservation of the sphincter. Since lateral dissemination does occur, the segmental resection of low carcinoma is extremely hazardous in that it may not remove all of the carcinomatous tissue. By lateral dissemination we mean that which spreads along the levatores ani muscles, the coccygii, the base of the bladder, the cervix, or the base of the broad ligaments, to terminate in the internal iliac nodes. This discussion is practical because it deals with the applicability of so-called sphincteric preservation operations. Lesions which are partially or completely below the peritoneal reflexion have a high incidence of local and liver recurrence and, therefore, pull-through or sleeve resections may not produce a cure. Such operations are justified only if the bowel and lymphatic tissue are resected at least 4 to 5 cm. above and below the growth.

The grading of carcinoma of the bowel is based upon several factors:

1. Broder's classification which has been described in Chapter 15 deals with the type of cell and the number of cells which are of an abnormal nature. In grade 1 carcinomas the cells are columnar and the nuclei are not prominent and are smaller than in grade 2. In grade 2 the cells are less columnar and the nucleus assumes a more prominent part in the cell. The nuclei are larger. In grade 3 the cells are larger and round, and the nucleus takes nearly all of the cell. In general, the cells in grade 4 lesions tend to be large, hyperchromatic, and round and have little resemblance to normal cells.

2. Duke's classification is based upon three factors which were originally described by Lockhart-Mummery which he grades as follows: Class A, by which he meant small movable lesions which do not appear to involve the muscular coat or the lymph nodes; Class B, lesions which appear to involve the muscular coat but are not fixed and the lymphatic involvement is not extensive; and Class C, large growths which are fixed and which have extensive lymphatic involvement. Duke's classification is modified so that in Class A are the lesions which were definitely limited to the wall of the rectum without extrarectal extension or metastases to lymph nodes; class B, growths which have spread by direct extension to extrarectal tissues but have not apparently invaded the lymph nodes; and Class C, all carcinomas in which metastases are present to the regional lymph nodes. By grading carcinomas in Broder and Duke's classification a more accurate idea as to prognosis may be obtained. For example, it is apparent that a grade 4 carcinoma has a very poor prognosis and will usually also be a grade C Duke's classification. However, if it is a grade 4 Broder's and a grade A Duke's, the prognosis is better than if it is a Broder's grade 4, grade C Duke's. And the reverse is true. Namely, a Broder's grade 1 which has already extended beyond the confines of the rectum has a poorer prognosis than a grade 4 which is still localized. The presence or absence of mucus is not in itself a guide to prognosis, although mucin, which is produced by the cells, in general,

into nodes which roughly follow the branches of the superior hemorrhoidal artery. After perforating the rectum, they run obliquely upward and backward to reach the nodes in the mesorectum. They traverse several small nodes placed on the muscular layer and covered by the fibrous coat of the rectum on their way. These are known as the pararectal nodes of Gerota. These nodes are found especially in the region of the ampulla. The lowest one is immediately above the levator ani. Normally the lymphatic drainage of the superior region is only upward, although, as has been said, occasionally in blocked lymphatics a retrograde spread

Fig. 316.—Carcinoma of the rectum (polypoid type).

may occur. Carcinoma from the anus or rectum may spread up to the sigmoid by intramural extension and invasion of the small lymph nodes within the bowel wall. Marginal extension may also occur, around the bowel as well as *within the bowel. However,* extension is limited, and, as a rule, intramural dispersion is not of great importance. But in the eradication of the carcinoma, a liberal margin should be *taken* with the growth proximally and distally, say at least 3 to 4 cm.

By far the most important manner of spread is that of extramural dissemination. *Recently the study of extramural spread* has been subjected to close scrutiny because of the revival of conservative or so-called

conservative operations upon the rectum and the sigmoid with tion of the sphincter. Since lateral dissemination does occur mental resection of low carcinoma is extremely hazardous in th not remove all of the carcinomatous tissue. By lateral dissemi mean that which spreads along the levatores ani muscles, the the base of the bladder, the cervix, or the base of the broad lig terminate in the internal iliac nodes. This discussion is practic it deals with the applicability of so-called sphincteric preservati tions. Lesions which are partially or completely below the reflexion have a high incidence of local and liver recurrence a fore, pull-through or sleeve resections may not produce a cu operations are justified only if the bowel and lymphatic tiss sected at least 4 to 5 cm. above and below the growth.

Namely, a Broder's grade 1 which has already extended beyond the confines of the rectum has a poorer prognosis than a grade 4 which is still localized. The presence or absence of mucus is not in itself a guide to prognosis, although mucin, which is produced by the cells, in general,

gives them a primitive function which would tend to imply that the growth was of a lesser degree of malignancy than one which had no *function at all.* Since, however, many carcinomas have a mucoid degeneration and since the cells may be highly malignant and may have spread the presence of mucus, this loses its importance in prognosis.

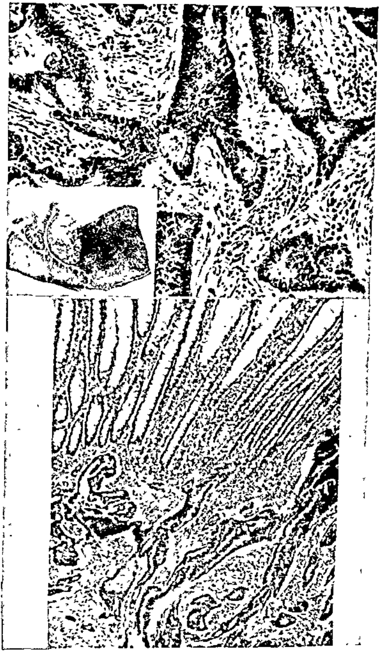

Fig. 317.—Carcinoma of the rectum. *A.* The low power shows the abrupt transition of the normal gland structure into malignant distortion. The high power shows the downgrowth of cylindrical cells. Some contain colloid. *B.* Medium power, showing the tubular downgrowths of atypical epithelium into the submucosa.

Tumors of the higher grade are more rapid in growth and their metastases are apt to cause the death of the person earlier than those of the lower grade. It is perhaps well to grade carcinoma of the rectum in

both classifications when attempting to evaluate it from the prognostic point of view. Carcinomas of the large intestine may be multiple. Many cases have been reported in which the carcinoma has been removed only to have growths appear in other parts of the large intestine. Obviously the immediate deduction in such cases is that the original carcinoma was not completely removed. However, a sufficient number of cases have been reported in which a growth arose in a different location from the primary growth and which was responsible for its own metastases and which had different pathological pattern. Often pólypi which have been overlooked are responsible. Also, it is remarkable the number of cases in which multiple carcinoma may arise from different organs. We have recently encountered a woman who had a carcinoma of the iliac colon. This was resected and an end-to-end anastomosis was done. It was grade 3 Broder's, grade B Duke's classification. The prognosis was not good. In six months the patient returned to the hospital with a large tumor in the abdomen. At operation a proliferating papillary cystadenocarcinoma of the left ovary was responsible for the condition of the patient. This had metastasized over the entire visceral and parietal peritoneum. Multicentric carcinoma then may occur within the organ itself as in the colon or may occur in various other organs. There seems to be no explanation for this observed fact.

Symptoms and Signs of Carcinoma of the Colon.—The complications of carcinoma such as ulceration, hemorrhage, and stenosis of the intestine bring the growth to light rather than the symptoms of the growth itself. In either right or left colon, carcinoma usually gives rise to some abdominal distress and a change in bowel habits, and sometimes a mass may be felt in the abdomen. There may be a weight loss, although this may not be present until extremely late. Blood in the stools is present in approximately one-third of the patients, but since the most common cause for blood in the stools is internal hemorrhoids, this is often not considered seriously. The two sides of the bowel give different sets of symptoms. On the *right* side, the chief finding may be a slight change in bowel habit, some abdominal distress, extreme weakness, and a severe anemia with mild systolic murmur, probably anemic in origin. Very much later a tumor may be discovered. On the *left* side the carcinoma is apt to cause an early type of obstructive symptoms, and therefore the change in the habit time is most important. There may be blood in the stools. The diagnosis is frequently made by the palpation of a tumor or by discovering the growth by digital rectal examination. The fact that in practically one-third of the carcinomas of the lower bowel the neoplasm may be palpated by the examining finger makes it mandatory for every patient to have a routine digital examination of the rectum. There may be some tenderness which will lead to the suspicion, although this is also true of diverticulitis, and this cannot be relied upon. The same thing is true of occult blood, although it lends support to the diagnosis. Barium enemas are

excellent except that the segments where the growths usually occur are in the lower sigmoid, and here the x-ray will miss 10 to 15 per cent of the carcinomas. Proctoscopic examination with biopsy is the method of choice. Any change in the bowel habits of a patient (whether increasing constipation or alternating constipation and diarrhea) or the occurrence of persistent, marked gurgling sounds makes the physician suspicious of new growth.

Vomiting does not occur until very late due to the fact that the ileocecal valve withstands great pressure. The blood supply of the large bowel is different from that of the small bowel in that the vessels almost encircle it before entering its walls. In the small bowel the vessels dip in between the muscularis and submucous coats nearer the mesenteric border; consequently the large bowel may become greatly distended without gangrene or perforation. This is not true of the small intestine.

Carcinoma of the cecum produces toxic symptoms and profound anemia rather than mechanical symptoms. This anemia has been attributed to (1) bleeding; (2) injury of the mucous membrane, with loss of its selective absorption powers, leading to toxemia; (3) increase in the normal retrograde waves, favoring increased absorption; (4) the large size of the growths on the right side, due to the larger space for growth, and the ulcerating character of these growths.

If, in addition, there is blood in the stool, the physician thinks of carcinoma of the rectosigmoid or rectum. The diagnosis is made by digital examination (for the low type), proctoscopic examination, and barium enema with x-ray plate. The last is the most important.

Prognosis of Carcinoma of the Colon.—Theoretically the prognosis of carcinoma of the colon should be good. This is true because (1) the development is slow, (2) invasion of the lymphatics is delayed, (3) generalized metastasis is rare, and (4) mucoid degeneration rather than rapid cell proliferation is the usual course. However, this latter point is determined by the type of cell rather than the presence or absence of mucus. The lymph nodes lie close to the colon, as has been shown, forming a first line of defense. Injections of the lymph vessels by Gerota show that they follow the larger blood vessels. Therefore, an operation to be adequate must include not only the lymph vessels but contiguous tissue and approximately three inches on each side of the growth as well in order that a complete extirpation be achieved. If this is done and if the lymph nodes are not involved, a five- to ten-year survival rate of over 70 per cent is feasible. However, where the lymph nodes have been involved, this survival rate drops to approximately 35 per cent. On the right side, however, even with the lymph node involvement the prognosis is much better. In general, it may be stated that nowhere in the body may carcinoma offer such a good prognosis as in the colon, particularly on the right side. However, here, as elsewhere, the growth must be diagnosed early enough so that all contiguous tissue and lymph node basins may be removed.

Treatment of Carcinoma of the Colon.—The treatment of carcinoma of the colon depends upon its location and complicating factors plus the general condition of the patient. First, the uncomplicated carcinoma in patients whose condition is good demands careful preoperative preparation and resection of an adequate amount of the large bowel. The preparation includes the following: attention to water balance, blood volume restoration, the use of Sulfasuxidine or Sulfathalidine for a period of eight days to reduce the flora of coliform bacteria, the use of vitamin K which is not synthesized with the use of Sulfasuxidine, proper food which is low in residue, high carbohydrate, high protein diet, attention to vitamin requirements, and, last, careful cleansing of the bowel prior to operation.

If the carcinoma is in the *cecum*, then the cecum, ascending colon, and the hepatic flexure should be removed and ileotransversostomy done. In the *transverse colon* this portion of the bowel is removed from the hepatic to the splenic flexure. The *splenic flexure* requires removal of the transverse colon for a distance of approximately three inches proximal and the same distance distal to the growth. The *descending colon* requires removal of the sigmoid as well and anastomosis between the splenic flexure and the pelvic colon just above the reflexion of the peritoneum. The *rectosigmoid* may, under certain conditions, be segmentally resected with an end-to-end anastomosis. If, however, there are any complicating factors or extensions, *abdominoperineal* resection may be necessary. This will be discussed later. The growths which lie above 10 cm. from the pectinate line are usually resectable by segmental resection with end-to-end anastomosis. The normal rectum in the adult is anywhere from 13 to 15 cm. in length. However, the peritoneal reflexion varies, and this is an important consideration in primary healing because resections done below the 10 cm. level require extensive mobilization, and there may be a sloughing of the suture line—this, in addition to the fact that the rectum does not have a serosa. The consideration, however, is not whether a sphincter may be preserved or whether segmental resection may be done; the important fact to decide is whether or not it may be adequately performed so that all of the carcinoma and the involved lymph nodes may be removed. Certainly in grade C and even in grade B growths, segmental resection below the 10 cm. level are dangerous and probably will not give the greatest number of five- to ten-year survivals. Recently there has been a revival of the old Hochenegg or pull-through operation, also known in German as the Durchzug operation. This operation is done by mobilizing the bowel proximal and distal to the growth, removing it, and bringing the upper segment down through the lower segment in an effort to preserve sphincteric action. This is often successful. Also, another method recently described is a combination of the Whitehead and the pull-through operation. With this method the sphincter is dissected away, the entire lower bowel is removed, including the carcinoma, and the upper segment is brought out through

excellent except that the segments where the growths usually occur are in the lower sigmoid, and here the x-ray will miss 10 to 15 per cent of the carcinomas. Proctoscopic examination with biopsy is the method of choice. Any change in the bowel habits of a patient (whether increasing constipation or alternating constipation and diarrhea) or the occurrence of persistent, marked gurgling sounds makes the physician suspicious of new growth.

Vomiting does not occur until very late due to the fact that the ileocecal valve withstands great pressure. The blood supply of the large bowel is different from that of the small bowel in that the vessels almost encircle it before entering its walls. In the small bowel the vessels dip in between the muscularis and submucous coats nearer the mesenteric border; consequently the large bowel may become greatly distended without gangrene or perforation. This is not true of the small intestine.

Carcinoma of the cecum produces toxic symptoms and profound anemia rather than mechanical symptoms. This anemia has been attributed to (1) bleeding; (2) injury of the mucous membrane, with loss of its selective absorption powers, leading to toxemia; (3) increase in the normal retrograde waves, favoring increased absorption; (4) the large size of the growths on the right side, due to the larger space for growth, and the ulcerating character of these growths.

If, in addition, there is blood in the stool, the physician thinks of carcinoma of the rectosigmoid or rectum. The diagnosis is made by digital examination (for the low type), proctoscopic examination, and barium enema with x-ray plate. The last is the most important.

Prognosis of Carcinoma of the Colon.—Theoretically the prognosis of carcinoma of the colon should be good. This is true because (1) the development is slow, (2) invasion of the lymphatics is delayed, (3) generalized metastasis is rare, and (4) mucoid degeneration rather than rapid cell proliferation is the usual course. However, this latter point is determined by the type of cell rather than the presence or absence of mucus. The lymph nodes lie close to the colon, as has been shown, forming a first line of defense. Injections of the lymph vessels by Gerota show that they follow the larger blood vessels. Therefore, an operation to be adequate must include not only the lymph vessels but contiguous tissue and approximately three inches on each side of the growth as well in order that a complete extirpation be achieved. If this is done and if the lymph nodes are not involved, a five- to ten-year survival rate of over 70 per cent is feasible. However, where the lymph nodes have been involved, this survival rate drops to approximately 35 per cent. On the right side, however, even with the lymph node involvement the prognosis is much better. In general, it may be stated that nowhere in the body may carcinoma offer such a good prognosis as in the colon, particularly on the right side. However, here, as elsewhere, the growth must be diagnosed early enough so that all contiguous tissue and lymph node basins may be removed.

Fig. 318.—Intraabdominal types of operations for carcinoma of the rectum and rectosigmoid. *A*. The Mikulicz operation. The involved sigmoid is exteriorized, A^1, and later it is removed, A^2; then crushing clamps are applied through the spur which had been made, converting the double-barrel colostomy into a single opening, A^3. Later, the opening is closed, re-establishing the continuity of the bowel. *B*. An obstructive type of intraabdominal operation developed by Rankin. Here the bowel is exteriorized, clamps are applied, and the carcinoma is removed at once. B^1. The two loops have been anchored together, forming a spur. The clamps are removed after forty-eight to seventy-two hours. The spur is then crushed, thereby restoring the continuity of the colon. Later the protruding end of the bowel is closed. *C*. Sleeve resection. If the carcinoma is high in the pelvic colon, it may be completely removed with sufficient bowel below for side-to-end or end-to-end anastomosis. The latter may be safely accomplished by dividing the colon obliquely, to provide an adequate lumen, C^1. The peritoneum is then brought down above the suture line, C^2.

resections of the rectosigmoid, anastomosis is made to the rectum which does not have a serous coat. Therefore the peritoneum is attached above the suture line, and a Penrose soft rubber tube is placed anterior to the coccyx to drain the perirectal space. Occasionally this will be followed by a fistula for a short period of time. If the patient is maintained on Sulfasuxidine, this will soon close spontaneously. We have not as yet had to excise such a fistula. Drainage is required also because the perirectal tissues lying below the pelvic perirenal floor are highly susceptible to infection, and also sometimes much trauma is induced in gaining access to this region. Therefore, drainage is routine procedure and may require resection of the coccyx to obtain better drainage. In this region end-to-end anastomosis is usually practiced and may be done safely. We have not encountered a stricture at this area. However, if the bowel is small, it may be better to close the proximal end and do a side-to-end anastomosis between the side of the upper segment and the end of the lower. This will prevent any tendency toward stricture formation. These operations may be done by the open technique because of the careful preparation which may be attained by Sulfasuxidine and Sulfathalidine. Complimentary cecostomy is not necessary but is useful in very low resection and primary anastomosis. This is particularly true in the old, in whom it is undesirable to limit food and fluid by mouth for long periods of time. (See Fig. 318.)

Posterior resections may be done by removing the coccyx and a portion of the sacrum. In this operation the coccyx and the fifth and half of the fourth sacral bodies are removed. The pelvic fascia is divided and the dissection is carried around the circumference of the rectum outside the perirectal fascia. The peritoneum is opened on the anterior surface, and sufficient sigmoid is drawn down with which to do a repair. Then the peritoneum is reattached by sutures and the bowel further mobilized, and an end-to-end anastomosis is done. The area is then drained with a soft rubber tube, and no colostomy is required in these cases. The operation has some strong advocates but is usually frowned upon because again there is the danger of not getting all of the growth and not being able to do a thorough abdominal exploration. (See Fig. 319.)

The most widely employed operation for the lower portion of the pelvic colon and the rectal ampulla is the so-called Miles operation, or the one-stage abdominoperineal resection. This procedure is carried out through a left oblique incision. The bowel is inspected carefully and then mobilized by incising the lateral margins of the mesosigmoid. Wide areas may be resected, including the superior hemorrhoidal lymph channels and nodes as well as the middle and inferior hemorrhoidals. The entire sacral region and the lateral perirectal tissues may be removed after the ureters have been identified and pushed aside. The proximal end of the bowel is then brought out through the upper margin of the oblique incision or through a separate wound. The pelvic peritoneum is sutured. Then the abdomen is closed. The patient is then put up in the lithotomy position and the entire anus, including the sphincters and all perirectal tissues, are

the preserved sphincter. The special features of this procedure include a dissection of the sphincter as is done in the Whitehead operation for hemorrhoids; then the sphincter muscle is divided posteriorly, and the mobilized bowel which has been freed from above, preserving the blood supply, is brought down through the divided sphincter. Later the sphincter may be closed. The desirability of preserving the sphincter is admitted by all, but not at the expense of complete eradication of the growth. Therefore, we may say that in the lower sigmoid above 10 cm., segmental resection anteriorly done is a feasible and very logical operation in the class A types of carcinoma. It may also be feasible in carcinomas at lower levels. However, to employ this method in all types is feasible surgically but is not to be regarded as giving the best results insofar as five- to ten-year survivals are concerned. (See Fig. 320.)

The *complicating factors* of *carcinoma* include obstruction, fixation, and infection. Carcinoma with obstruction, fixation, or infection (that is, infection within the growth) makes immediate resection undesirable. If carcinoma is producing obstruction, often after the administration of large doses of sulfasuxidine the infection may subside to such a degree that the normal channel will become patent enough to permit the normal fecal current to drain. In acute obstruction, however, it may be necessary to do a temporary cecostomy or appendicocecostomy, or if the obstruction is at the cecum, an ileostomy may be necessary. If the obstruction is not complete and usually it will not be on the right side, a preliminary ileotransversostomy should be done, and then at a second stage the growth may be removed together with the terminal ileum, ascending colon, and a portion of the transverse colon. This will not often be necessary, particularly if a preliminary ileostomy has been done. In such cases after adequate drainage and preparation with sulfasuxidine, second stage operation usually includes resection and anastomosis.

Carcinoma of the *transverse colon* with obstruction may be treated by *a preliminary cecostomy. In doing a cecostomy, a word of warning should* be sounded. The tube introduced should be large, being approximately one-half inch in diameter. We have frequently failed to obtain the proper drainage by using small tubes through an appendicocecostomy. The colon may then be washed out by using a balloon type or Miller-Abbott tube type for irrigation which makes it possible not only to irrigate the proximal portion of the bowel but also to introduce Sulfasuxidine, thereby partially degerminizing it. Then at a second stage the transverse colon may be resected as previously indicated. In obstruction of the splenic flexure it is perhaps best to do a transverse colostomy. Then at a second stage resection is done. It is probably true that the closer to the obstructed portion that the colostomy is made, the more complete will be the emptying of the proximal loop. Therefore, a transverse colostomy is useful in the presence of an obstructing lesion of the splenic flexure. The same may be said for an obstruction in the descending or sigmoid. The reason that the colostomy is not made lower is that it interferes with the secondary operation. In

Fig. 319.—Diagram illustrating various types of operations for carcinoma of the rectum and rectosigmoid. This diagram and the two which follow show the various types of operations. This figure depicts the perineal and sacral operations. *A*. Perineal excision with anastomosis. *A^1*. Lines of excision. The coccyx and a portion of the sacrum have been removed. *A^2*. End-to-end anastomosis. *B*. Preliminary colostomy. *B^1*. Perineal excision with closure of the distal segment. *B^2* The distal segment is brought out through the perineum to prevent a blind pouch accumulation. *C*. Kraske type of perineal excision. *C^1*. A portion of the sacrum as well as the coccyx is removed, and through a perineal approach the carcinoma is excised and the remaining bowel anastomosed as shown in *A^1*. *C^2*. In the Kraske operation the proximal end of the rectosigmoid may be brought out as a perineal anus—an undesirable procedure.

surgery. The suture lines are carefully placed without tension and with preservation of blood supply and careful approximation of serosa to serosa wherever this is possible, and, if impossible, then the peritoneum is attached above the suture line. In order to avoid obstruction, openings in and around mesenteries are carefully closed, particularly the area between the extruded proximal colon and the lateral pelvic wall. Also, all raw surfaces must be covered. Loops of small bowel will become adherent to the reconstructed pelvic floor if the serosa is not sutured to serosa, producing a smooth suture line. Other complications which are not specific for this type of operation include embolism which does occur in a limited number of patients. Bladder complications are more common, but since the introduction of early mobilization so that patients may empty the bladder without the aid of catheters, this has been greatly lessened. (See Fig. 320.)

The Mikulicz type of resection has a limited place in surgery of the colon for cancer. It is useful in badly infected colons in which the diagnosis is more or less by surprise. The carcinomatous area of the bowel is mobilized and brought outside the abdomen through a separate incision or through the incision which has been made to do the exploration. This may be left on the oustide and removed at a later date, or the proximal and distal ends of the bowel may be sutured together, forming a spur, and then an obstructive resection may be done; that is, clamps are placed on the proximal and distal parts of the bowel and the carcinoma removed. At a later date a clamp is placed between the two loops which have now formed a double barrel shotgun type of colostomy, and then at a third stage the bowel is closed. This type of procedure has not given good results but was an important step in the treatment of infected carcinomas before the era of chemotherapy and antibiotics. It still is useful in so-called surprise cases, where the element of obstruction is present and where the carcinoma has already caused a perforation and the whole part must be extruded. The dangers of the operation are the local infection and, most important, the transplantation of the carcinoma into the skin at the site of the colostomy. Therefore, at present, if operation is contemplated, this type of procedure is not employed as commonly as was formerly the case. It was even employed in dealing with carcinomas of the right side at one time. In all cases of carcinoma the postoperative management consists of the use of a Levine tube to delimit the amount of gas in the upper intestine unless a preliminary colostomy or complimentary colostomy has been done. The use of Sulfasuxidine is not usually continued after surgery. Penicillin is given in fairly large doses, 100,000 units every three hours. Streptomycin is employed in a dose of .2 to .5 Gm. every six hours, giving a total of .8 to 2 Gm. per day. This is thought to reduce the incidence of coliform infection. Attention is also given to water balance and plasma and blood volume, and then a careful dietary management is maintained until healing has occurred. This consists of a high protein, high carbohydrate, low residue diet. In the Miles operation or the abdominoperineal resection the colostomy sometimes requires correction in that the loop of bowel may

completely excised and the loop is brought out from below. The lower margin is left open with a few soft Penrose drains. Packs are not employed because the gauze is apt to adhere to the suture line of the peritoneum, and in removing them this may be torn, producing hernia or peritonitis. Within ten days to two weeks these patients are up and around, and they are permitted to sit up on the second day. The perineal wound heals slowly but completely. In the hands of most surgeons this operation has given the most satisfactory result. Its objection is, of course, the use of the abdominal anus or the permanent colostomy. However, with proper education and careful dietary management the stool may be regulated so that it will be loose or hard, depending upon the type of food that is eaten. Furthermore, colostomy bags are available which are not too unsightly and which may be cleansed without much trouble. Most patients learn to regulate their dietary habits so that the stool is kept formed and so that by using a syringe to irrigate the colostomy once or twice a day they do not require a colostomy bag during the day. Instead they wear a pad and have very little trouble.

The operation of abdominoperineal resection may be combined with resection of the uterus including the posterior vaginal wall. Also, a portion of the bladder may be resected, and, if necessary, the entire bladder, performing a preliminary ureterostomy. This is a very extensive procedure and may not result in a cure but may be done in the extreme case where it seems indicated. Also, in a few instances a single nodule in the liver may be resected, doing even a lobectomy of the liver if that is necessary. These radical resections may not result in many cures. However, they will prolong life and ameliorate suffering, and in that sense they are to be advocated in selected cases. Usually, however, where there is extensive invasion of the bladder, particularly low down in the prostate, cure is almost impossible and, therefore, a palliative colostomy is done. In all massive resection of this nature in which a portion of the bladder is removed a suprapubic cystotomy is done. Also, a complimentary transverse colostomy is performed to relieve the tension on the suture line. End-to-end anastomosis may be accomplished in connection with this operation, but as a rule it will be an abdominoperineal type of resection. One may question these heroic methods of excision. However, if the surgeon is worthy of his tradition he will do as radical a procedure as is commensurate with the patient's ability to stand the surgery with the hope of producing a cure or an arrestment of the disease. If he can save only 1 or 2 per cent of such hopeless cases, he is better off than if he did not try at all. If the operation is carried out properly, there will be only a few complications. However, there are inherent dangers in the operation and the most formidable of these is peritonitis, or obstruction. Peritonitis has been greatly reduced due to the advent of the sulfonamides and careful aseptic technique; that is, as near aseptic as possible. Surgeons have learned that they cannot depend upon drugs as a substitute for careful atraumatic

surgery. The suture lines are carefully placed without tension and with preservation of blood supply and careful approximation of serosa to serosa wherever this is possible, and, if impossible, then the peritoneum is attached above the suture line. In order to avoid obstruction, openings in and around mesenteries are carefully closed, particularly the area between the extruded proximal colon and the lateral pelvic wall. Also, all raw surfaces must be covered. Loops of small bowel will become adherent to the reconstructed pelvic floor if the serosa is not sutured to serosa, producing a smooth suture line. Other complications which are not specific for this type of operation include embolism which does occur in a limited number of patients. Bladder complications are more common, but since the introduction of early mobilization so that patients may empty the bladder without the aid of catheters, this has been greatly lessened. (See Fig. 320.)

The Mikulicz type of resection has a limited place in surgery of the colon for cancer. It is useful in badly infected colons in which the diagnosis is more or less by surprise. The carcinomatous area of the bowel is mobilized and brought outside the abdomen through a separate incision or through the incision which has been made to do the exploration. This may be left on the oustide and removed at a later date, or the proximal and distal ends of the bowel may be sutured together, forming a spur, and then an obstructive resection may be done; that is, clamps are placed on the proximal and distal parts of the bowel and the carcinoma removed. At a later date a clamp is placed between the two loops which have now formed a double barrel shotgun type of colostomy, and then at a third stage the bowel is closed. This type of procedure has not given good results but was an important step in the treatment of infected carcinomas before the era of chemotherapy and antibiotics. It still is useful in so-called surprise cases, where the element of obstruction is present and where the carcinoma has already caused a perforation and the whole part must be extruded. The dangers of the operation are the local infection and, most important, the transplantation of the carcinoma into the skin at the site of the colostomy. Therefore, at present, if operation is contemplated, this type of procedure is not employed as commonly as was formerly the case. It was even employed in dealing with carcinomas of the right side at one time. In all cases of carcinoma the postoperative management consists of the use of a Levine tube to delimit the amount of gas in the upper intestine unless a preliminary colostomy or complimentary colostomy has been done. The use of Sulfasuxidine is not usually continued after surgery. Penicillin is given in fairly large doses, 100,000 units every three hours. Streptomycin is employed in a dose of .2 to .5 Gm. every six hours, giving a total of .8 to 2 Gm. per day. This is thought to reduce the incidence of coliform infection. Attention is also given to water balance and plasma and blood volume, and then a careful dietary management is maintained until healing has occurred. This consists of a high protein, high carbohydrate, low residue diet. In the Miles operation or the abdominoperineal resection the colostomy sometimes requires correction in that the loop of bowel may

be too long. It is desirable to have this the case rather than too little exteriorized bowel with ultimate retraction of the permanent colostomy. This latter may require further operation. *Carcinomas below the peritoneal* reflection recur more frequently than those above. This recurrence manifests itself with a persistent progressive pain described as "bursting pain" by the patient.

THE RECTUM AND ANUS

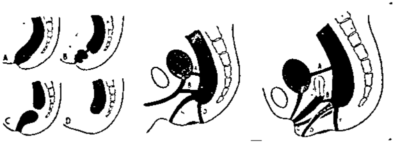
The rectum extends from the dentate margin to the peritoneal reflexion. The anus extends from the skin to the dentate margin. The anus varies in length from 1½ to 3 cm. Its superior border is the dentate margin which comprises the anal semilunar valves and the anal papillae together with the *anal clefts or Morgagni*. The dentate margin is also known as the pectinate line or the anal rectal line and the muco *cutaneous line or border. The term white line of Hilton* has been used to refer to the intersphincteric line and is not synonymous with dentate margin. The anal canal is lined by skin and not by mucous membrane. The anal papilli form the ridges in the anal clefts or valleys which appear at the dentate margin. The rectum is, of course, lined by mucous membrane and, therefore, the dentate margin has been called the mucocutaneous line or border.

The hind gut in the early embryo ends in a blind pouch which is later joined by an invagination of the proctodeum (anus). As a result of this embryological arrangement, many congenital anomalies occur. Then, too, the urogenital tract in the embryo is part of the common cloaca which is separated later into an anterior urogenital sinus and a posterior rectum by a saddlelike partition (urogenital septum). Should this fail to close completely, various fistulae may occur. These fistulae may be between the rectum and the vagina, or the rectum and the bladder, or the rectum and the urethra. The anomalies include an imperforate anus in which a thin membrane covers the anal *opening, congenital absence of the anus or rectum, persistence of a blind hind-gut*, and various strictures and fistulae.

Anomalies are discovered first by a careful inspection of the child at birth. In the congenital absence of the anus, this is apparent and *if, in* addition, it is seen that there is meconium coming from the urethra, a *fistula is, of course, suspected. In all cases where there is distention* in the absence of flatus or meconium a scout film of the abdomen *should be made*. This may be facilitated by taking a picture of the baby in the upside down position to determine the lowest level of gas.

The operation for the relief of the condition is planned *according to* the position of the blind pouch. If the hind-gut is within approximately a centimeter of the skin margin, it may be brought down by an operation done entirely from below. In such cases, particularly *when there is a* sphincter present, an incision is made through the sphincter in the midline, dividing the upper half of the sphincter. The blind hind-gut is mobilized and brought down and sutured to *the skin. If, however*, there is only a persistent anal membrane, no mobilization is necessary and division of this membrane is all that need be done. When the hind-gut is high, it may be better *to wait twenty-four hours or* more to allow gas to come down to its lowest level. In this way the x-ray examination will be more accurate and will reveal the true level of the blind hind-gut. *If the hind-gut is*

high, that is, more than a centimeter or a centimeter and a half from the anus, then it is, perhaps, best to do a colostomy. The colostomy should be done in the transverse colon and it should be an exclusion type; that is, the two loops should be separated by a bridge of skin. If this is not done, the distal loop or the blind loop will fill with fecal matter spilling over and fistulae will remain, or if they have been potential, they will open up. There is one warning about the transverse colon in the newborn. It may upset water balance to such a degree that a long period of time cannot be allowed to elapse before the second operation is done and, therefore, when a transverse colostomy is done, preparation should be made to do the combined abdominal perineal mobilization technique within a relatively short time; namely, within a week or two or sooner if there is difficulty in maintaining water balance. If the child is in a very precarious condition and if the blind loop is extremely large, it is perhaps best to bring the loop up to the skin and make an opening, using a catheter, and suturing the catheter by purse-string suture. It is very hazardous to attempt to bring the descending colon which is greatly dilated out through the abdominal opening to make a loop colostomy because the hind-gut is too thin and it will



I. *II* *III.*

Fig. 321.—Diagram illustrating types of congenital anomalies of the rectum and anus. *I.* Four common types of anomalies. *A*, occlusion by anal membrane or skin; *B*, narrowing at the anal margin or higher; *C*, anus and anal pouch normal but hindgut ends blindly; *D*, absence of anus with blind hindgut. *II.* Fistulas in the male with or without anomaly of the rectum or anus: *A*, rectovesical; *B*, rectourethral; *C* and *D*, rectoperineal. *III.* Fistulas in the female: *A*, rectovesical; *B*, rectovaginal; *C*, recto-fossanavicularis; *D* and *E*, rectoperineal. (After Berman. Surg., Gynec. & Obst. 66: 11, 1938.)

tear and it is too large to be mobilized. The combined abdominal and perineal technique should not be attempted without a preliminary colostomy in most cases. Rarely there will be so little distention that it will be safe to attempt this without preliminary colostomy. Fistulae may be closed at the time that the combined operation is done. At a later date the colostomy may be closed.

Prolapse of the rectum may affect the mucous membrane alone or the entire wall. The term *procidentia* has been applied to the latter condition. In the young infant a prolapse of the mucous membrane is not uncommon, particularly in association with congenital anomalies of the spinal cord or with extrophy of the bladder. The condition may be troublesome but usually responds to replacement and strapping of the buttocks together with adhesive tape between defecations. Within a few weeks the mucous

be too long. It is desirable to have this the case rather than too little exteriorized bowel with ultimate retraction of the permanent colostomy. This latter may require further operation. Carcinomas below the peritoneal reflection recur more frequently than those above. This recurrence manifests itself with a persistent progressive pain described as "bursting pain" by the patient.

THE RECTUM AND ANUS

The rectum extends from the dentate margin to the peritoneal reflexion. The anus extends from the skin to the dentate margin. The anus varies in length from 1½ to 3 cm. Its superior border is the dentate margin which comprises the anal semilunar valves and the anal papillae together with the anal clefts or Morgagni. The dentate margin is also known as the pectinate line or the anal rectal line and the mucocutaneous line or border. The term white line of Hilton has been used to refer to the intersphincteric line and is not synonymous with dentate margin. The anal canal is lined by skin and not by mucous membrane. The anal papilli form the ridges in the anal clefts or valleys which appear at the dentate margin. The rectum is, of course, lined by mucous membrane and, therefore, the dentate margin has been called the mucocutaneous line or border.

The hind gut in the early embryo ends in a blind pouch which is later joined by an invagination of the proctodeum (anus). As a result of this embryological arrangement, many congenital anomalies occur. Then, too, the urogenital tract in the embryo is part of the common cloaca which is separated later into an anterior urogenital sinus and a posterior rectum by a saddlelike partition (urogenital septum). Should this fail to close completely, various fistulae may occur. These fistulae may be between the rectum and the vagina, or the rectum and the bladder, or the rectum and the urethra. The anomalies include an imperforate anus in which a thin membrane covers the anal opening, congenital absence of the anus or rectum, persistence of a blind hind-gut, and various strictures and fistulae.

Anomalies are discovered first by a careful inspection of the child at birth. In the congenital absence of the anus, this is apparent and if, in addition, it is seen that there is meconium coming from the urethra, a fistula is, of course, suspected. In all cases where there is distention in the absence of flatus or meconium a scout film of the abdomen should be made. This may be facilitated by taking a picture of the baby in the upside down position to determine the lowest level of gas.

The operation for the relief of the condition is planned according to the position of the blind pouch. If the hind-gut is within approximately a centimeter of the skin margin, it may be brought down by an operation done entirely from below. In such cases, particularly when there is a sphincter present, an incision is made through the sphincter in the midline, dividing the upper half of the sphincter. The blind hind-gut is mobilized and brought down and sutured to the skin. If, however, there is only a persistent anal membrane, no mobilization is necessary and division of this membrane is all that need be done. When the hind-gut is high, it may be better to wait twenty-four hours or more to allow gas to come down to its lowest level. In this way the x-ray examination will be more accurate and will reveal the true level of the blind hind-gut. If the hind-gut is

The patient tried his best to push the sigmoid out but was not successful and the operation to date has held. However, in cases where the sigmoid has been out for some time and the viability is questionable or if recurrences take place, resection of the sigmoid and then formation of a temporary iliac anus with fixation may be the operation of choice.

Fissure is a small crack or break in the mucous membrane, due to dragging by hemorrhoids and pinching by irritable sphincter, or secondary to cryptitis (inflammation of crypts of Morgagni) or papillitis (inflammation of rectal papillae) which also produces an irritation of the sphincter and may cause a fissure by burrowing under the anal skin. For this reason the offending crypts or papillae should be removed. The lesion causes much pain, itching, and sphincteric spasm. The treatment is thorough dilatation of the sphincter, allowing the fissure a better blood supply; in intractable cases, removal of the fissure is necessary, and, in addition, the hemorrhoids should be removed.

Hemorrhoids are simply dilated veins of the rectum with fibrosis about them. They may be *external* (outside the external sphincter and arising from the inferior hemorrhoidal vein), in which case they are covered by skin, or *internal* (above the external sphincter and arising from the middle hemorrhoidal veins), or both external and internal. They cause many symptoms which are a source of discomfort to the patient. Internal hemorrhoids may cause bleeding, or, if ulcerated, they may be painful, protruding outside the sphincter on defecation. External hemorrhoids may become thrombosed, causing severe pain, or they may cause fissures and intense itching. The permanent cure is removal. Palliative treatment includes a nonresidue diet, bland suppositories, and witch hazel and anesthetic ointments for itching; for thrombosis, incision and evacuation of the clot.

Pruritus ani may be so severe and persistent as to demand more than palliative treatment. The cause may be local due to hemorrhoids, cryptitis, proctitis, enlarged papillae, fungus infection, and vaginal discharge in which it is associated with pruritis vulvae; or general due to neurasthenia, diabetes, jaundice, allergic states. The treatment in addition to local soothing application includes the treatment of the cause, and the injection of alcohol (95 per cent) is sometimes practiced. Other symptoms of anorectal disease are pain, hemorrhage, protrusion or prolapse, and discharge of pus.

Ischiorectal abscess occurs in the space named and is due to infection passing through the rectal wall into this area of loose areolar tissue. The infection may go through an infected crypt of Morgagni, a fissure, a punctured wound made by a foreign body, or, in rare cases, through a carcinomatous area. Anal ducts lined with transitional epithelium course downward from the crypts, often penetrating the internal anal sphincter, and may carry the infection into the ischiorectal space. There are fever, severe pain, especially on defecation, and, later, swelling externally. The

membrane becomes adherent and does not prolapse. In cases where there is perineal paralysis and loss of sphincter tone, the prolapse may become engorged and gangrenous and surgery may be necessary. Such cases frequently require amputation from below and suture of the mucous membrane. Great care must be exercised, however, because the prolapse may be a true one and, if so, it may permit loops of small bowel to enter into the prolapsed bowel. In the adult the prolapse of the mucous membrane is usually the result of hemorrhoids. These become thrombosed and literally pull the membrane outward after each defecation Then the mucous membrane is replaced. Such cases improve greatly after hemorrhoidectomy and are helped by sutures placed longitudinally in the mucous membrane to decrease the circumference of the bowel. Sometimes even after this procedure the mucous membrane still protrudes, and in such cases linear cauterization may be indicated.

The more troublesome type, however, is a true prolapse of the entire rectum. In true prolapse there is a hole several centimeters deep which may be felt with the finger between the anus and the prolapse. This is not present in a simple prolapse of the anal mucosa. The treatment for true prolapse consists of, first, the perineal operation and, second, the abdominal operation. Perineal operations include narrowing of the anal ring, fixation of the rectum to the sacrum or coccyx, and resection of the entire prolapse (Mikulicz operation). These operations may be employed for anal prolapse, although they are not practical for rectal prolapse, which should be handled through a laparotomy incision. In most instances the perineal type of operation for true prolapse is not indicated, and the results are not as good as those from the abdominal operation. However, if the extruded mucosa is gangrenous, it should be excised, leaving the muscle and connective tissue coats and the ends sutured together (Delorme operation). The abdominal operations are of three types: (1) obliteration of the pouch of Douglas, alone. Since the prolapse is more common in women than in men, the sagging pouch of Douglas is the offending mechanism. (2) Obliteration of the pouch with fixation of the pelvic colon. (3) Obliteration of the pouch with resection of the sigmoid flexure and temporary colostomy. We have encountered several prolapses of the rectum. One was in a man who was an inmate of the Central Hospital for the Insane. The other was a woman who was of low mental caliber. The rectal sphincters were so large and patulous that the entire hand could be introduced easily. The man was a dementia praecox and insisted on pushing the rectum out. In the woman we employed the operation of obliteration of the pouch of Douglas and in addition a ventral fixation of the uterus was done, fixing the uterus to the anterior wall of the abdomen. In the man, we obliterated the rectovesical fossa with interrupted sutures, then made a flap of the mesosigmoid, anchored the sigmoid to the psoas muscle, and then overlapped the peritoneal flap on top of the sigmoid to further anchor it. We did not do a resection nor did we do a complimentary ileostomy.

rectal carcinoma is not painful, whereas anal carcinoma is accompanied by pain. In fact, pain is usually due to anal rather than rectal disease (fissure, thrombosed or strangulated hemorrhoids, ulceration, perineal abscess, etc.) It is squamous in type as a rule but in rare instances may be basal-cell carcinoma. The lesion begins as an ulcer usually but may originate in papillomatous growths. The cancer grows rapidly and soon invades the perirectal fat or vagina and spreads by continuity. The superficial lymph nodes of the vaginal region are involved first, and later the deep nodes of this basin are involved. The hemorrhoidal venous flexures may be invaded and transport tumor cells to the liver as well as to the lungs. Treatment consists of early and complete removal by the abdominoperineal resection or colostomy with posterior resection. In late cases or those inoperable for other reasons, radium should be used. The results are almost as good as surgery.

Strictures of the rectum are caused by (1) syphilis, (2) tuberculosis, (3) new growth, (4) lymphogranuloma inguinale, (5) gonorrhea, (6) chronic ulcerative colitis, and (7) congenital defects. The symptoms are those of obstruction. Diagnosis is made by digital examination and by biopsy through the proctoscope. The treatment consists in removing the causative factor, plus repeated dilatations. Sometimes colostomy is necessary for temporary or permanent diversion of the fecal current. Resection may be necessary. See previous discussions under respective subjects.

treatment consists of early incision and drainage as close to the anus as possible so that if a fistula results it will be short. Since it is an anatomically localized space and since it will spread around the anus, waiting invites a fistula.

Fistula in ano is a common sequel to the preceding. It is seen often in chronic ulcerative colitis and proctitis. Usually the infection descends from the anal crypt by way of the anal ducts and is carried into the surrounding tissues by way of the lymphatics. The loose fatty areolar tissue breaks down into an abscess. When it is opened or breaks, a fistula with its inner opening in an anal crypt is formed. The outer opening may be perianal, through an abscess cavity or by a direct line, or pelvirectal or retrorectal. Also, any of these potential spaces (two ischiorectals below the levators, two pelvirectal and one retrorectal above the levators) may harbor an abscess. This is an opening from the rectum to the outside which discharges pus. About 10 per cent are tuberculous and are secondary to tuberculosis elsewhere, and some are due to actinomycosis. Sometimes the fistula burrows around the sphincter in various directions. Since it is lined by epithelium, it will not heal unless it is laid open and its wall destroyed, so that granulations can form from the bottom up.

New growths may be benign (polypi) or malignant (carcinoma). The former are usually adenomas and hang in grapelike fashion from the mucosa. They are freely movable because of their pedicle, and are extruded with every act of defecation. Their relation to carcinoma has been discussed and they should therefore be removed. Their removal is easily accomplished by the cautery. *Carcinomas* may be of the soft medullary or of the hard scirrhus type. The symptoms of carcinoma of the rectum are bleeding and change in bowel habit. The diagnosis is easily made by digital and proctoscopic examination. Since internal hemorrhoids are a usual cause of bleeding, the patient is apt to ascribe the bloody stool to these. Both conditions are relatively painless at first, and valuable time may be lost. Bleeding from the rectum demands investigation by the physician. The treatment is surgical and consists of what is known as the combined abdominoperineal operation. The sigmoid is divided above the growth, and its proximal end is brought out through the left lower abdominal wall. The distal end, including the growth, is freed down to the levator ani muscles if possible; then the patient is placed in the lithotomy position, and the anus and lower rectum are freed until the entire lower bowel is removed. Variations are two-stage operations and Kraske types (removal of the sacrum and rectum from below only). Sarcoma of the colon and rectum is rarely seen. When it does occur, it is usually lymphosarcoma. Melanoma as a primary or secondary growth may occur, the former from misplaced skin elements (in the rectum) and from chromatophore cells around the anus.

Anal carcinoma occurs at the mucocutaneous border. Very few tactile corpuscles are present above the mucocutaneous junction. Therefore,

Muscles contain about 8 mg. per 100 grams, and blood plasma 9 to 11.5 mg. per cent. Small amounts are present in the red blood cells, the lymph, the aqueous humor, and the cerebrospinal fluid. Some is found in ascitic and edema fluids.

Calcium is thus absorbed and is constantly being deposited in bone. It is also used or mobilized as needed. The level of the calcium in the blood is kept more or less constant in normal individuals through the aid of the parathyroids. McLean and Hastings state that the organism is protected against too sudden changes in the concentration of ionized calcium by the reserve supply in the blood (bound to protein) and also by the reserve in bone. *Nondiffusible* calcium is bound to serum protein. The *diffusible* calcium of the serum is in an ionized form. The calcium balance (that is, the difference between the quantity ingested and excreted) is positive (calcium retention) during growth, pregnancy, acromegaly, or after a period of calcium starvation. It is negative in infantile rickets, celiac and renal rickets, sprue, osteomalacia, hyperparathyroidism, hyperthyroidism, and starvation (calcium deficiency) and during lactation.

Fig. 322.—Osteomyelitis The dark area is the sequestrum, which has become separated and is surrounded by pus.

Bones undergo hypertrophy when subjected to strong muscular demands over long periods. Conversely, atrophy is common in disuse (immobilization for injuries, amputation stumps which are not carrying artificial limbs, paralyzed extremities). Sometimes the atrophy is out of all proportion to the disuse as in suppurative joint disease. Here it occurs early probably due to nutritional insufficiency or toxic effects. In children atrophy causes a decrease in the growth of bones both in length and thickness. In fact the skeleton like the muscles which make it work, reflect the physical efforts of the individual. Therefore the difference in skeletal development is not all a matter of heredity but in environmental requirements as well. This may be the key to the treatment of bone and joint disease.

The long bones are formed from cartilage. The *epiphysis* is the cartilaginous end of the bone where growth occurs. The shaft of the bone is called the *diaphysis*. Here growth in circumference only occurs. Adjacent to the epiphysis is the *metaphysis*, the very vascular end of the diaphysis where most infections arise. The bone is composed of a hard cortex, made of compact bone, and a loose *medulla*

Chapter 21

THE SKELETAL SYSTEM

The great mesenchymal framework of the body is necessary to house its vital organs. Nature delays the formation of the skeletal system until the later months of fetal life. Unlike the housebuilder, she forms the vital organs first, then surrounds them with the exterior. This framework has many other functions besides protection and locomotion. The bone marrow and cortex are essential to hematopoiesis, antibody formation, and calcium metabolism, whereas the muscular system, which constitutes about 40 per cent of the weight of the healthy adult body and contains 100,000 miles of capillaries, plays a vital role not only in locomotion but also in glycogen metabolism, heat regulation, circulation, antibody formation, protein metabolism, elimination of fatigue products (lactic acid), maintenance of the pH of the blood, the blood volume, water storage, etc. It may be readily seen, then, that bone and muscle constitute organs of great importance to anabolism, catabolism, and metabolic equilibrium. Health and the cure of disease are dependent in no small measure upon these organs.

BONES

The embryologial development, anatomy, and repair of bones has been described in Chapter 3. In this discussion the role of mesenchymal cells was mentioned. However, it is well to emphasize that mesenchymal cells and reticulum cells are closely related and that they give rise to bone marrow cells, fibroblasts, chondroblasts, and osteoblasts. Therefore, injuries or disease of bone may be repaired by any or all of these cells, or the cells may be transformed from one to another, even reverting back to their embryological types in some instances of neoplasia.

The chief constituent of bone is calcium. This substance must be ingested in sufficient amount, absorbed, and metabolized and must reach the skeleton in order to maintain positive calcium balance. Furthermore, it must not be dissipated faster than it can be assimilated in order that a positive balance may persist.

Bone calcium exists as calcium carbonate and tricalcium phosphate. Other minerals present in small quantities are phosphorus, magnesium, potassium, sodium, chlorine, fluorine, and iron. Organic matter in bone (aside from marrow) is chiefly protein, ossein with small amounts of osseomucoid, and albuminoid.

Calcium is needed in (1) coagulation of blood, (2) formation of bone, (3) cardiac rhythmicity, (4) maintenance of neuromuscular excitability, (5) milk production, and (6) membrane permeability.

Calcium is present in the ingested food in organic and inorganic forms. It is absorbed in the small intestine and is excreted into the colon through the bowel wall and, in small amounts, in the urine. Calcium constitutes about 2 per cent of the weight of the adult body, and 97 per cent of the total quantity is contained in the skeleton.

Outline of Bone Diseases

A. Congenital anomalies
B. Injuries
   1. Fractures
C. Diseases of bone due to defective mesenchymal framework
   1. Osteogenesis imperfecta
   2. Achondroplasia
   3. Fibrous dysplasia
D. Infections and inflammations of bone
   1. Osteomyelitis
   2. Syphilitic osteitis
   3. Tuberculous osteitis
   4. Pulmonary osteoarthropathy (?)
   5. Echinococcus cyst
   6. Eosinophilic granuloma
E. Circulatory disorders of bone (epiphysitis)
   1. Legg-Perthes' disease
   2. Osgood Schlatter's disease
   3. Köhler's disease
   4. Freiberg's infraction
   5. Scurvy (vitamin C deficiency)
F. Defective assimilation or utilization of calcium due to vitamin D deficiency
   1. Rickets (in children)
   2. Osteomalacia (in adults)
G. Diseases of bone due to hyperparathyroidism
   1. Osteitis fibrosa cystica (von Recklinghausen's disease of bone)
   2. Paget's disease of bone
H. Changes due to excessive excretion of calcium (osteoporosis)
   1. Cushing's disease
   2. Hyperthyroidism
   3. Diabetes
I. Neoplasms of bone
   1. Metastatic growths
   2. Multiple myeloma
   3. Hand-Schüller-Christian's disease (xanthomatosis)—lipoid storage diseases
   4. Multiple chondral exostosis and osteoma, hemangioma, neurofibroma
   5. Osteogenic sarcoma
   6. Benign giant-cell tumor
   7. Unicamerate cyst
   8. Adamantinoma, liposarcoma, lymphoblastoma, hemangioendothelioma, hemangiosarcoma, fibrosarcoma, chondrosarcoma
J. Disorders of the vertebral column
   1. Injuries
   2. Infections (tuberculous spondylitis)
   3. New growths

Congenital Anomalies of Bones and Joints

Deformities of the skeleton may occur in the earliest embryonic stage or may be due to intrauterine constrictions, amputations, or interference with development in other ways. The following is a list of some of the more common anomalies: congenital clubfeet (talipes equinovarus), adduction of forefoot (metatarsus varus), eversion and dorsiflex-

(marrow), made of cancellous bone. Surrounding the cortex is a thin osteogenetic membrane in two layers known as the *periosteum*. Its outer layer carries the blood and nerve supply, while its inner layer is filled with osteoblasts. Lining the cancellous bone is another membrane, the *endosteum*, filled with bone-forming cells. Since bone is formed on a connective tissue framework, its calcium deposits occur along trabeculae and in lamellar fashion. These are seen in all directions and surround the Haversian canals which carry blood into the compact bone and medulla (Haversian lamellae). The principal artery to a long bone in the upper extremity runs toward the elbow; in the lower extremity, away from the knee. Flat bones are formed directly from membrane and are called membranous bones. They heal with connective tissue. In the skull the diploe corresponds to the marrow cavity.

Fig. 323.—Extensive chronic osteomyelitis of the humerus. The x-ray picture shows the sequestrum, which occupies the entire shaft partially surrounded by involucrum.

In the diagnosis and treatment of injuries and diseases of bones, it must be remembered that muscles, tendons, and ligaments are attached to the bones and that between the bones are the joints, which make locomotion possible. If a bone deviates from its normal weight-bearing or stress direction, all other bones and joints along this line of force may be affected (Wolff's law), although there is a tendency on the part of nature to correct deformities insofar as possible to prevent changes in stress upon joints.

rhage, or through nerves, severing them. Should a fragment break through the skin, a simple fracture would be converted into a compound one. For immobilization, any board or hard cardboard will do. A few rules to follow are:

1. Pad the splint well with cotton, cloth, or pillows.
2. Extend the splint above and below adjacent joints.
3. Tie the splint tight. This is absolutely necessary to prevent movement of the fragments and to alleviate suffering. A loose splint is worse than none at all.
4. Two splints (anterior and posterior) are better than one.

Fig. 325.—Garré's sclerosing osteomyelitis. The low power shows the involvement of compact and cancellous bone. The high power shows the absence of suppuration, much connective tissue, and many lymphocytes. The large cells seen in the upper right section are osteoblasts.

Fractures are usually due to external violence or strong muscular action. However, pathological fractures occur in diseased bone with very little exciting cause.

The treatment of fractures is designed to obtain good union of the fragments in a good functional position. The restoration of movements in joints and power in the muscles is desired in the shortest possible time. Some general observations in the treatment of fractures are as follows: (1) The earlier the reduction of the fracture, the easier and safer, and better the result. (2) Anesthesia is necessary—general in children and in adults with extensive fractures where the condition permits; local in less extensive fractures in adults. (3) Closed reduction is preferable to open reduction if possible. Traction is advisable in severe

ion of ankle (talipes calcaneovalgus), flat feet (pes planus or valgus), imperfectly formed limbs (ectromelia), extra digits (polydactylism), webbed fingers and toes (syndactylism), overgrowth of digits (macrodactylism), clubhand (manus vara), radioulnar synostosis, asymmetrical development (hemihypertrophy, hemimacrosomia), partial fibrous ankylosis of many joints (arthrogryposis multiplex congenita, amyoplasia congenita), absence of part or all or both clavicles with increased diameter of cranium and abnormal dentition (cleidocranial dysostosis), elevation of the scapula (Sprengel's deformity), congenital synostosis of the cervical spine (Klippel-Feil syndrome), congenital dislocation of the hip, knee, patella, ankle, shoulder, elbow, wrist, congenital absence of the radius, tibia, or fibula, progressive dislocation of the radioulnar joint (*Madelung's deformity*), *acute angling of femoral neck* (*congenital coxa vara*), obtuse angling of the neck of femur (congenital coxa valga). Treatment should be in early infancy and consists of mechanical appliances or surgical maneuvers, depending on the type encountered.

Fig. 324.—Chronic osteomyelitis with draining sinus. The low power shows the skin densely adherent to the bone, and the epithelium-lined sinus tract. The high power reveals the extent of epithelial penetration. To cure the sinus, all of the epithelial lining must be removed.

Fractures

The repair of bone is discussed in Chapter 3. In bone injuries, as in other injuries, bleeding, if present, must be controlled first. Then the patient is treated for shock (see Chapter 14). *A patient should not be moved until the fractured part is immobilized.* If this is not done, the broken bone may tear through blood vessels, starting a severe hemor-

rhage, or through nerves, severing them. Should a fragment break through the skin, a simple fracture would be converted into a compound one. For immobilization, any board or hard cardboard will do. A few rules to follow are:

1. Pad the splint well with cotton, cloth, or pillows.
2. Extend the splint above and below adjacent joints.
3. Tie the splint tight. This is absolutely necessary to prevent movement of the fragments and to alleviate suffering. A loose splint is worse than none at all.
4. Two splints (anterior and posterior) are better than one.

Fig. 325.—Garré's sclerosing osteomyelitis. The low power shows the involvement of compact and cancellous bone. The high power shows the absence of suppuration, much connective tissue, and many lymphocytes. The large cells seen in the upper right section are osteoblasts.

Fractures are usually due to external violence or strong muscular action. However, pathological fractures occur in diseased bone with very little exciting cause.

The treatment of fractures is designed to obtain good union of the fragments in a good functional position. The restoration of movements in joints and power in the muscles is desired in the shortest possible time. Some general observations in the treatment of fractures are as follows: (1) The earlier the reduction of the fracture, the easier and safer, and better the result. (2) Anesthesia is necessary—general in children and in adults with extensive fractures where the condition permits; local in less extensive fractures in adults. (3) Closed reduction is preferable to open reduction if possible. Traction is advisable in severe

compound fractures and in oblique and comminuted fractures of the shafts of long bones, especially the humerus and femur, where thick muscles cover the bone and maintenance of reduction is difficult to maintain. Open operation is done when reduction or maintenance cannot be secured by other methods; also in cases where large lengths of bone have been devitalized and bone graft is necessary. (4) Immobilization is secured by recumbency, bandages, slings, traction, splints, plaster of Paris, wires (Kirschner), pins, screws, nails, flanged nails, bands (Parham), plates (Sherman), ivory pegs, plates, and bone. Unabsorbable foreign bodies in fractures, like the same material in soft tissue wounds, should not be used in contaminated or potentially contaminated fractures (compound fractures, badly contused wounds, hematoma of large size, etc.).

Fig. 326.—Tuberculosis of the wrist. There are generalized osteoporosis and disintegration of the joint as well as bone destruction.

Infection is more apt to occur, and the foreign body will have to be removed or will slough out due to osteomyelitis. Immobilization should be maintained with the finest material possible. The porosity of the bone and its size and position will be determining factors. However, large heavy spikes, bands which encircle bones, and plates which produce ischemia all interfere with blood supply and therefore will delay healing (see Chapter 3). (5) The general condition of the patient is important in obtaining good healing and good function; therefore, any form of immobilization which will allow early movement of the patient as a whole is desirable. This is especially true in the aged. (6) Compound

fractures are treated as open contaminated wounds (see Chapter 16) and are débrided and then immobilized and protected by chemotherapeutic agents and antibiotics.

Diseases of Bone Due to Defective Mesenchymal Framework

Osteogenesis imperfecta, also called *fragilitas ossium* and *osteopsathyrosis*, is congenital in origin and consists of an atrophic, brittle type of bone which gives rise to multiple fractures early in life. They heal slowly. The child may outgrow the condition. Vitamins D and K in early life help.

Achondroplasia is another congenital bone defect consisting of a failure of the epiphyseal cartilage to ossify. Longitudinal growth is interrupted and the child fails to grow, becoming a dwarf.

Fibrous dysplasia is also called fibrosa cystica disseminata, osteodystrophia fibrosa, fibrocystic disease of bone, and Albright's disease. It may involve one or many bones. The cortex is expanded and thin over the defects in the bone. These areas are filled with gelatinous grayish-white tissue, which contains thin-walled capillaries, foreign body giant cells, trabeculae of new bone, hyaline cartilage, and some nests of foam cells. The symptoms are swelling and pain. Very often a pathological fracture is the first symptom. Blood calcium and phosphorus are normal. In early life the disease is accompanied by pigmentation of the skin, precocity in females, premature skeletal growth, abnormalities of the heart and kidneys, and multiple lesions and deformities of bones (Albright's disease). Treatment consists of curettage of the bone defects and filling in with bone chips. If polyostotic, this must be done in stages.

Infections and Inflammations

Infections in bone are not as common as in the era before antibiotics and chemotherapeutic agents. In fact, acute hematogenous osteomyelitis is now extremely rare. Or, if it does occur, then penicillin and the sulfonamides used in the treatment of the primary conditions eradicate the bone infection before recognizable destruction occurs. Nongranulomatous inflammations are hematogenous and exogenous osteomyelitis, Brodie's abscess, and echinococcus cyst. Granulomatous lesions are syphilis, tuberculosis, eosinophilic granuloma, coccidioidal granulomas, Boeck's sarcoid, actinomycosis, blastomycosis, leprosy, and granuloma inguinale.

Osteomyelitis is an infection of the medulla of bone which spreads through the cortex and medulla, sometimes causing widespread destruction. Its cause is usually hematogenous, although in adults it usually occurs as a result of direct trauma such as compound fracture or infection following the use of bands or plates. A child may have a series of boils or otitis media, and bacteria from the acute focus may be carried to the metaphysis of a bone. Trauma may influence the site affected.

The mechanism of infection has been studied extensively. Cultures of staphylococci which are injected into bone through a drill hole fail to produce osteomyelitis unless under pressure. Sterile water injected under pressure produces necrosis but no infection (compact bone and can-

Fig. 327.—*A*. Legg-Perthes disease (osteochondritis *deformans juvenilis*). *Note the fragmentation of the head of the femur*, and the shortening and broadening of the neck on the left side. *B*. Osgood-Schlatter disease, showing the fragmentation of the epiphyses of the tibial tuberosities.

cellous bone in the metaphysis are normally sterile). Staphylococci injected into the nutrient artery of a bone in experimental animals do not produce osteomyelitis. If acacia or sodium morrhuate is added, or if the culture is injected under great pressure, osteomyelitis develops. Some experimenters have produced the disease in animals following the intra-

Fig. 329.—*A*. Rickets. X-ray showing the beading at the costochondral junction (rachitic rosary). *B*. Coxa vara deformity on the left. *C*. X-ray showing the irregularity and cupping of the epiphyseal lines.

venous injection of *Staphylococcus aureus*. The experimental work, though conflicting, tends to establish the same laws of infection in bone as elsewhere; *namely*, if the local resistance of the metaphysis is decreased by local factors (trauma, deficient blood supply) *or by general disease* (septicemia, avitaminosis), infection occurs when bacteria are injected locally or systemically.

The compact or cortical bone is almost absent at the metaphysis. The adult is not susceptible to hematogenous osteomyelitis because when the epiphysis becomes ossified and fuses, the metaphysis has a more adequate blood supply (being supplied by the epiphyseal, juxtaepiphyseal, periosteal, and nutrient arteries).

Fig. 329.—Osteomalacia. There is decalcification of the vertebrae and the pelvic bones. *The vertebral bodies appear as mere outlines.* The patient is a woman aged 61 years. The complaint was "general pains in legs and abdomen." Physical examination and all laboratory tests normal.

An interesting clinical observation is the rarity of involvement of other organs and tissues in multiple osteomyelitis unless a general bacteriemia is present. Better stated, the spread of the infection from the acute focus seems to *be limited to bones. Various explanations* of this have been suggested: (1) the relatively few macrophages present in the cancellous bone of the metaphysis, which make the local resistance poor;

(2) the slow circulation in the metaphysis due to the many capillaries; (3) the many end arterial twigs; (4) the small size of the capillaries which results in the trapping of the organisms (in the lung, for example, they are larger, permitting the organism to go through and become engulfed by septal or dust cells).

The infection causes destruction of bone and, if unchecked, may burrow through the cortex and strip the periosteum as well as the endosteum. This gives rise to a necrotic piece of bone called a *sequestrum*. Around this, nature forms a sheath of new bone, the *involucrum*. Pus works its way out of a necrotic hole in the cortex (cloaca) which permits draining sinuses to occur in the skin. The early symptoms and

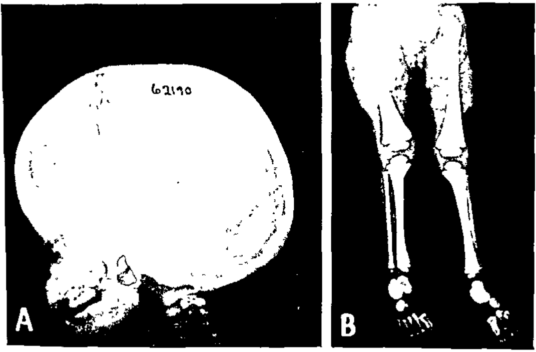

Fig. 330.—*A*. Marble bones (Albers-Schönberg disease). There is increased density of the bones of the base of the skull. *B*. Marble bones of the lower skeleton. Note the chalky appearance of the bones. The disease is also called osteosclerosis fragilis. Pathologic fractures are common.

signs are severe pain and tenderness over the affected bone near the epiphyseal line, high fever and leucocytosis (the result of pus under pressure), great prostration, and, in infants, convulsions. The diagnosis is not always easy because *x-ray does not help in the early stages.* The history, clinical symptoms and signs, and exploratory trephining establish the diagnosis.

The treatment consists of large doses of penicillin with sulfadiazine and rest in bed unless a subcutaneous abscess forms, then incision and drainage. Sequestra are extremely rare now, especially in very young children. This is due to the fact that the thin porous cortex surrounding the metaphysis allows exit of the pus. In older children and adults

the same treatment is now employed by most surgeons: rest in bed and immobilization of the affected leg until localization occurs; then simple drainage of the localized abscess. Exploratory trephining is no longer practiced. Late and neglected cases with sequestration require a "gutter" operation on the bone, with removal of sequestra (sequestrectomy), followed by infrequent dressings to allow the cavity to heal from the bottom up. The affected leg is immobilized for protection against fracture and to encourage healing.

The treatment of chronic osteomyelitis differs little from the treatment of an abscess elsewhere and may be dogmatically outlined as follows:

1. *Wait for localization* (complete separation of the sequestrum).

2. Provide ample drainage (a long gutter should be made over the involved area, through the involucrum).

3. Remove all dead bone gently and carefully but not healthy granulation tissue.

4. Obliterate the dead space. (The area will then fill in with granulation tissue, which is changed to osteoid tissue and bone.)

5. Secure rest to the part by cast or splint.

6. Change the dressing infrequently just as in the case of other wounds. The Orr treatment consists of packing the cavity with petrolatum gauze, putting on a cast, and letting the bone severely alone for six to eight weeks. Results have been good. Open casts, with occasional irrigations with normal saline, eliminate the absorption of toxic products and are used by many surgeons.

Maggot therapy is used by some to aid in "cleaning up" the cavity. Others use allantoin, which is thought to be the healing substance supplied by the maggots. Pectin-agar mixtures, as described by Haynes and co-workers, have given good results.

7. Give attention to the general care of the patient. This includes rest, attention to water balance, and blood transfusion.

8. Staphylococcic toxoid or vaccine still have advocates in the treatment of chronic lesions. Usually this is unnecessary if all sequestra have been removed.

Brodie's abscess is an illustration of a so-called nonspecific infection which behaves clinically like tuberculosis. It is caused usually by the same organisms as acute hematogenous osteomyelitis but is very insidious in onset. The center of the abscess is filled with granulation tissue which later changes in part to connective tissue with the formation of pockets and cysts filled with serous or purulent material. The treatment consists of wide open drainage and saucerization to allow for healing from the bottom up.

Echinococcus cysts occasionally occur in bone and are discovered by x-ray examination. The patient may feel a tumor, or soft tissues may

be involved due to leakage. The lesion is polycystic and sharply defined. Treatment consists of excision and marsupialization.

Syphilitic Osteitis.—The "aching bones" of persons with syphilis were known to the early physicians. The bone involvement in secondary syphilis is a *periostitis;* in tertiary syphilis, *hyperostosis* ("saber tibia") and *necrosis,* due to gumma. The x-ray and serological tests, together with the history and general symptoms, confirm the diagnosis. The treat-

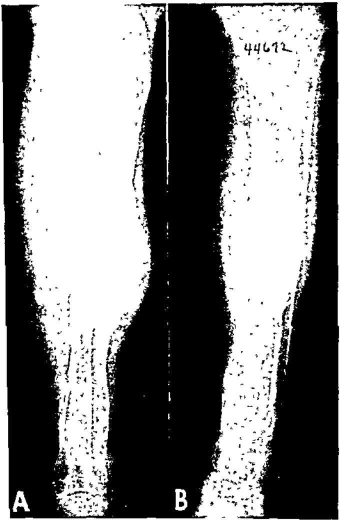

Fig. 331.—Osteitis fibrosa cystica (von Recklinghausen's disease). This was due to a parathyroid adenoma, with hyperparathyroidism. *A.* Lateral view. *B.* Anteroposterior view.

ment is limited to antisyphilitic treatment, including large doses of penicillin unless sequestration takes place. This demands the removal of the dead bone (sequestrectomy). (Chapter 9.)

Tuberculous Osteitis.—Tuberculosis of bones is an important problem since it usually affects children. The behavior of tuberculosis in bone is similar to its behavior elsewhere: There are destruction of bone,

caseation, *and cold abscess formation. The bacillus lodges in the metaphysis* and extends into the epiphyseal cartilage, frequently involving the joint. Tuberculosis infects bone through the blood stream or by way of contiguous joints. *It is almost impossible to induce tuberculosis in a* bone by injecting tubercle bacilli either into the blood stream or directly into the bone. If previous tuberculosis has been present, a gelatinous de*generation, with fibromyxomatous change, occurs, making the bones sus*ceptible *because of a tuberculous endarteritis of the nutrient and metaphyseal vessels.* The diaphysis of a bone is occasionally affected, especially *in small bones* (tuberculous dactylitis), *due to the fact that the* small vessels break up immediately upon entering the bone. Tuberculosis in a long bone is due to a tuberculous endarteritis of the nutrient artery *at its entrance.*

Fig. 332.—Multiple myeloma of bone. Note the punched-out appearance of the areas in the skull. Other portions of the skeleton were similarly affected.

The epiphysis may be involved (1) from the metaphysis, (2) directly, *from the joint, or* (3) *indirectly, if the synovial* membrane is related to the epiphysis without extending to the diaphysis. *Diagnosis is made from* a history of a slowly evolved, "cold" process, "night cries" due to muscular *contraction of the spastic muscles,* a positive von Pirquet test, evidence of tuberculosis elsewhere, and characteristic x-ray findings. The treatment consists of immobilization and the general treatment *of the* disease. Ultraviolet light and sunshine aid in the arrestment. Streptomycin is extremely *valuable. In adults* fusion or surgical fixation of the involved joint is indicated (arthrodesis, spinal fusion).

Pulmonary osteoarthropathy (acropachy) is a thickening of the distal phalanges of the hands and feet, nonpitting edema of the distal portions of the extremities and subperiosteal proliferation of the bones of the arms and legs, rarely synovitis of the joints associated with chronic pulmonary or cardiac disease (lung abscess, chronic empyema, tuberculosis, congenital and valvular heart disease). The fingers become clubbed and the nails curve. The cause is unknown, although the associated cyanosis makes one think of a vascular as well as a nutritional (and perhaps infectious) process. Great improvement follows the eradication of the chronic focus.

Eosinophilic granuloma is probably not due to an infection, virus or bacterial. It is a granulomatous lesion causing destruction of one or more bones usually in young males. Some observers state that it is related to Hand-Schüller-Christian disease or to Letterer-Siwe disease

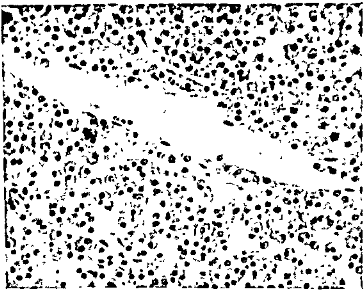

Fig. 333.—Plasma-cell myeloma of bone Note invasion of cells into the blood vessel This permits widespread dissemination.

(generalized reticulo-endothelial disease occurring in infants and rapidly fatal). The symptoms and signs are those of infection: fever, leucocytosis, anorexia, and malaise, and, locally, pain, swelling, and tenderness. Pathological studies of the tissue early show necrosis and hemorrhage with various cells (eosinophils, neutrophils, lymphocytes, plasma cells, foreign body giant cells); later the predominating cells are the round or polyhedral foam cells with small nuclei and reticulated cytoplasm. Diagnosis is made by the x-ray and biopsy. Treatment consists of excision.

Circulatory Disorders of Bone

In growing children the epiphysis may become inflamed due to some local circulatory disturbance, brought on often by a trifling injury

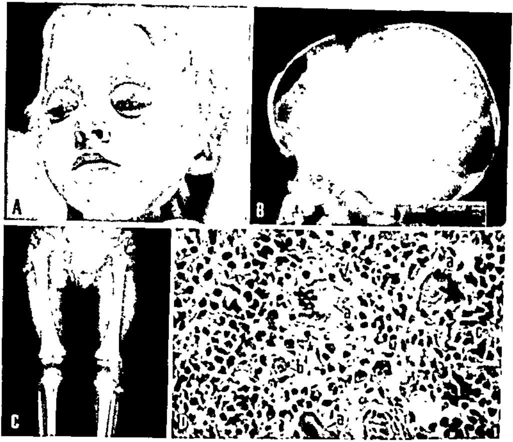

Fig. 334.—Hand-Schüller-Christian's disease. *A.* Clinical photograph of a 6-year-old child with Hand-Schüller-Christian's disease. He is pale and emaciated with bilateral exophthalmos, an enlarged skull, soft, bulging swelling beside the right ear, and bilateral choked discs. The child's father stated that he had been drinking three gallons of water a day and that he had passed "enormous" quantities of urine. *B.* Lateral x-ray photograph of the skull. The lateral examination of the skull shows a sharply circumscribed defect in the right frontal bone and several smaller defects of a similar type in the parietal region. One of the characteristic findings in lesions of this type (xanthomatosis) is the absence of any sclerotic reaction at the margins of the sharply circumscribed lesions. *C.* Examination of the long bones of the lower extremities shows areas of decreased density in the upper ends of the femurs, more numerous on the right, and a single lesion in the upper end of the left tibia. These lesions are typical of those seen in Hand-Schüller-Christian's disease. *D.* High-power photomicrograph of tissue taken from the area of defect in the previous case showing the usual findings of Hand-Schüller-Christian's disease (xanthomatosis of bone). *a,* Giant cells, some of which show fatty vacuoles in cytoplasm (fat stains show a large amount of lipoid usually thought to be cholesterol in this particular tissue); *b,* cells containing large granules of hemoglobin pigment; *c,* large mononuclear and epithelioid cells. Eosinophiles which are often seen in these cases are not plain enough in this picture to be identified.

Hand-Schüller-Christian's disease belongs to the group known as lipoidoses. It is also known as generalized visceral xanthomatosis. The usual characteristics of the disease are unilateral exophthalmos, diabetes insipidus, retarded development and defects in the bones, chiefly the skull, pelvic girdle, and the vertebrae.

Abnormal lipoids, chiefly cholesterol esters, accumulate in the cells of the reticulo-endothelial system. X-ray therapy over the affected bones is efficacious. However, relapses are common. The other two diseases which belong in this group and which show an enlarged spleen are (1) Gaucher's disease (which is also known as essential lipoid histiocytosis, cerebroside lipoidosis, and large cell splenomegaly), which will be discussed in Chapter 22, and (2) Niemann-Pick disease (also known as lipoid histiocytosis, phosphatide lipoidosis), which is characterized by splenomegaly, hepatomegaly, retarded development, emaciation, gastrointestinal symptoms, and lymphocytosis. Gaucher's disease and Niemann-Pick disease are usually fatal.

Hand-Schüller-Christian's snydrome offers a more favorable prognosis. The latter is the only one of the three that shows characteristic bone changes. This patient was improved by x-ray therapy. However, he returned later in a state of coma. He had mumps at this time. He recovered from this and was released from the hospital greatly improved.

(epiphysitis, osteochondritis, subchondral necrosis, aseptic necrosis). This causes pain and deformity of the part, somewhat resembling the effects of tuberculosis. In the hip, a flattened femoral head occurs. This is known as Legg-Perthes' disease. Inflammation of the tibial tubercle epiphysis gives rise to Osgood-Schlatter's disease; of the tarsal scaphoid, to Köhler's disease; of the second metatarsal head, to Freiberg's infraction. Other bones which may be involved are vertebral bodies, femur, patella, astrogalus, clavicle, humerus, radius, ulna, iliac crests, symphysis pubis. Diagnosis is made by x-ray and by ruling out tuberculosis. The part is immobilized and protected from injury, with resulting cure and perhaps some deformity.

In *scurvy,* while the bone is not directly affected, hemorrhages occur beneath the periosteum, giving rise to bone pain. The disease is caused by lack of vitamin C (ascorbic, or cevitamic, acid), the vitamin which preserves the normal consistency of the intercellular ground substance of various tissues (notably the dentine of the teeth, connective tissue, and the capillary endothelium). The first symptom of scurvy in children is irritability; in adults, various psychoses. The treatment is administration of vitamin C, either in the diet (citrus fruits) or as cevitamic acid.

Diseases Due to Deficiencies of Calcium or Vitamin D

Rickets.—Vitamin D, which occurs in cod-liver oil and is synthesized by sunshine in the body, aids in the assimilation and utilization of calcium. In children its absence or deficiency gives rise to *rickets (rachitis).* The disease appears between the sixth and eighteenth months of life and is characterized by a bony softening, with enlarged epiphyses, deformity of the skull ("square head"), delayed dentition, bowlegs or knock-knees, "pigeon" breast, and enlarged costochondral articulations ("rachitic rosary"). Sunshine, proper diet (mother's milk in infancy, if possible), and cod-liver oil prevent it. Cod-liver oil cures the disease but bony changes may persist.

Osteomalacia occurs in adults—usually in pregnant women, though it may occur in any undernourished person. It is due to lack of mineral salts or deficiency of Vitamin D and in its pathology resembles rickets. The treatment is good and proper food, sunshine, and cod-liver oil.

Diseases of Bone Due to Hyperparathyroidism

We shall learn in Chapter 23 that the parathyroids are intimately related to calcium metabolism. As a result of an adenoma or more obscure causes, the parathyroids may secrete an excess of their hormone. This causes decalcification of bone, hypercalcemia, and excessive excretion of calcium in the urine, with, perhaps, a formation of renal calculi. There may result multiple bone cysts throughout the skeleton, *osteitis fibrosa cystica* (von Recklinghausen's disease). The disease is diagnosed

by x-ray examination, and attention is often first called to it by a pathological fracture. Added to this, the high blood calcium with low blood phosphorus and other symptoms establish the diagnosis. Single cysts are probably not related to parathyroid disease. In the aged, Paget's disease, or osteitis deformans, causes softening and overgrowth of bone, bowing of the extremities, and enlargement of the head. The disease is rare and thought to be related to parathyroid dysfunction. Sarcoma may be a complication of this disease.

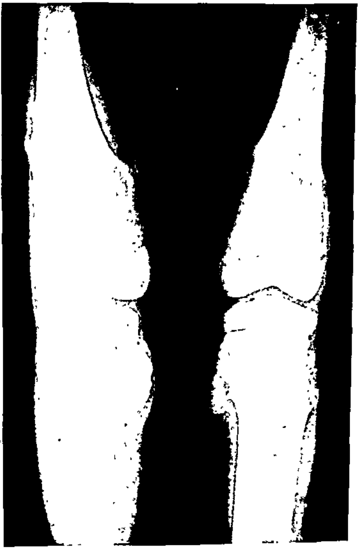

Fig. 335.—Multiple exostoses of the femur, tibia, and fibula (benign). Anteroposterior and lateral views.

Osteoporosis is not a disease, and it is not a disorder of calcium metabolism. It is a deficiency in laying down of osteoid tissue. It is a generalized atrophy of bone matrix when prolonged immobilization has produced bone atrophy.

Adult bone is continually being formed and resorbed. Bone may be deficient because resorption is too great (hyperparathyroidism with

Fig. 336.—Osteochondroma of the femur (benign)

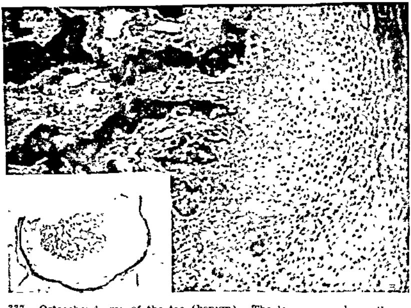

Fig 337—Osteochondroma of the toe (benign). The low power shows the cancellous bone capped by cartilage which in turn is covered with skin; the high power, cancellous bone on the left and cartilage on the right.

osteitis fibrosa cystica generalisata) or because formation is too little (osteoporosis or osteomalacia). If the osteoblasts do not lay down sufficient matrix or osteoid tissue, there is osteoporosis. If, however, the matrix is laid down but not calcified, there is rickets or osteomalacia. Factors which may be responsible for osteoporosis are disuse, dietary deficiency, gastric hypoacidity, repeated pregnancies, senescence, postmenopausal period. Also, in Cushing's disease, hyperthyroidism, and diabetes, a thinning of bone is seen. Control of the underlying disorder results in redeposition of matrix and calcium. Fractures are apt to occur in these brittle bones.

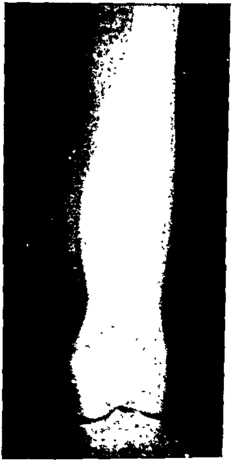

Fig. 338.—Osteogenic sarcoma of the femur. The shaft is broadened due to bone production. This is the periosteal type (osteogenetic).

Sudeck's atrophy (posttraumatic painful dystrophy of the extremities, acute atrophy of bone, posttraumatic osteoporosis, traumatic angiospasm, chronic traumatic edema, peripheral trophoneurosis, reflex nervous dystrophy) has been discussed in Chapter 6. The osteoporosis is a late phenomenon and probably results from a combination of factors; namely, disuse and deficient blood supply. It is greatly improved by sympathetic ganglionectomy, neuropsychiatric treatment, and mobilization.

Neoplasms of Bone

Neoplasms of bone are many and varied. Ewing's classification of sarcoma of bone and bone marrow is given in Table XXIV.

TABLE XXIV

EWING'S CLASSIFICATION OF SARCOMA OF BONE AND BONE MARROW

MALIGNANT	BENIGN
I. Osteogenic series	
Osteogenic sarcoma	
1. Medullary and subperiosteal	1. Exostosis
2. Telangiectatic	2. Osteoma
3. Sclerosing	
4. Periosteal	
5. Fibrosarcoma	
(a) Medullary	
(b) Periosteal	
6. Parosteal, capsular	
II. Chondroma series	
1. Chondrosarcoma	1. Chondroma
2. Myxosarcoma	
III. Giant-cell tumor series	
1. Malignant	1. Epiphyseal giant cell tumor
IV. Angioma series—Ewing's tumor	
1. Angioendothelioma	1. Cavernous angioma
2. Diffuse endothelioma	2. Plexiform angioma
V. Myeloma series	
1. Plasma cell—plasmacytoma	
2. Myelocytoma	
3. Erythroblastoma	
4. Lymphocytoma	
VI. Reticulum-cell lymphosarcoma	
VII. Liposarcoma	

Secondary Bone Tumors.—Secondary tumors of bone are common, especially when the primary carcinoma is in the breast, prostate, ovaries, kidney, and adrenal and thyroid glands. Thus cancer of the breast may invade the spine where it may cause a collapse of the vertebra; also the ribs, sternum, humarus and, rarely, the upper femur. The prostate usually is responsible for metastases to the pelvic bones and lower spine. Any bone may be involved, and the reaction in the bone is not always osteolytic. At times there is increased density around the metastatic area, and rarely osteogenesis is stimulated. Treatment is that of the primary lesion and x-ray therapy to the bones which are involved. In addition, castration and stilbestrol cause amelioration of bone lesions in carcinoma of the prostate (see Chapter 23). Testosterone proprionate alleviates pain in metastatic cancer from breast and ovaries but does not materially change the bone picture (see Chapter 16). Radioactive iodine may be used to discover early thyroid metastases (with the aid of the Geiger counter) and to cause recession in the bone and thyroid lesion (see Chapter 22). Radioactive phosphorus and other elements may prove helpful in other forms of metastatic cancer.

Primary Bone Tumors.—*Multiple myeloma* is a fatal disease in adults, consisting of an infiltration of bones, usually with plasma cells. Soft tissue

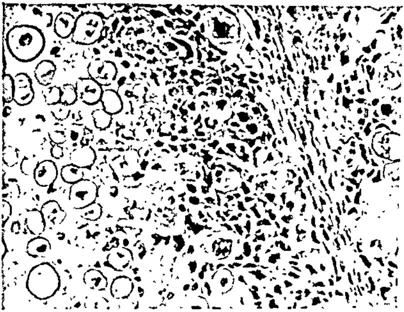

Fig. 339.—Osteogenic sarcoma. On the left are chondroblasts; in the center, tumor cells, and on the extreme right, osteoid tissue. The tumor cells are polyhedral and spindle-shaped. A few malignant giant cells are seen.

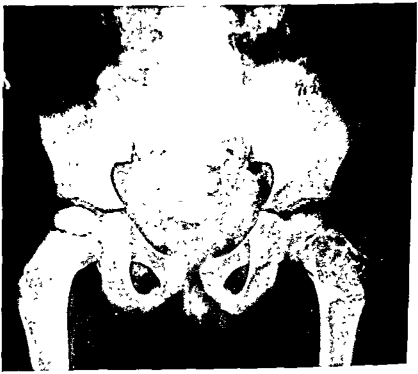

Fig. 340.—X-ray photograph of benign giant-cell tumor of the femur, showing expansion of the bone, with thinning of the cortex.

Fig. 341.—Benign giant-cell tumor of the clavicle. The giant cells are seen to arise from the capillary endothelium. There is no bone production. The fibrous stroma, filled with spindle-shaped cells, makes up the bulk of the tumor.

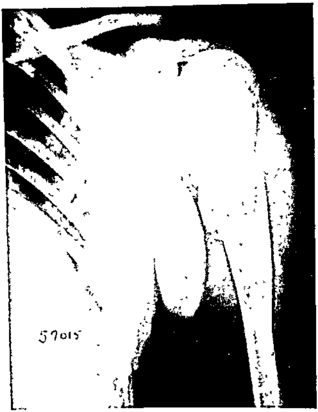

Fig. 342.—Pathologic fracture of the humerus directly through a bone cyst. Note thinning of bone and cystic appearance.

Fig. 343.—Adamantinoma. J. G., a woman aged 52 years, was admitted to the hospital complaining of a draining sinus in the left gingiva. This was in 1932. In 1933 a cyst was curetted from the left mandible. She had subsequent recurrences at frequent intervals and in 1937 took x-ray treatment over a period of four years consisting of treatments approximately once a month. In 1940 she came to the hospital with a tumor mass measuring approximately 3 by 4 inches. At this time she had severe pain in the left mandibular area and an operation was deemed advisable. Accordingly, a hemiresection of the mandible was done on the left side. The external carotid artery was ligated first, and then the entire left mandible was removed together with the submaxillary gland and the lymph nodes in the left anterior triangle of the neck. The growth proved to be an adamantinoma.

The patient came back to the hospital in July, 1949, for treatment for hypertension. At this time it was found that there was no recurrence and that the right half of the mandible was functioning in a satisfactory manner. *A*, Clinical photograph of the woman as she appeared in July, 1949. *B*, Photograph of the gross specimen showing the lesion and *C*, Longitudinal section of the mandible and its tumor mass. It will be noted that the growth is partially solid and partially cystic. *D*, Low-power photomicrograph. Note layer of columnar cells (enameloblasts) at periphery and loose stroma in the interior of irregular tumor masses. (Specimen prepared by Dr. Harold C. Thornton, pathologist.)

metastases occur. Sometimes plasma cell leucemia is the terminal picture with 30,000 to 40,000 cells per cubic millimeter. Diagnosis is made by x-ray examination, together with the occurrence of Bence Jones protein in the urine, which is present in about 50 per cent of the cases, and biopsy. The treatment is by x-ray which may temporarily alleviate but will not cure this disease. *Lipoid storage diseases of bone include xanthomatosis* (Hand-Schüller-Christian disease), Niemann-Pick's disease, and Gaucher's disease (see Chapters 16 and 22). *Xanthomatosis* causes a thinning of bones in children due to the deposit of fat cells. X-ray examination and the finding of an increase in the blood cholesterol and biopsy make the diagnosis. Restriction of fat in the diet and x-ray treatment may bring about its remission. In Gaucher's disease splenectomy may help. *Multiple chondral exostosis* and *osteoma* are benign cartilaginous and bony tumors, often congenital in origin. They occur near the epiphysis or the adductor tubercle and under the big toenail (subungual). Diagnosis is made by x-ray. The treatment consists of removal.

Fig. 344.—Endothelial myeloma of bone (Ewing's tumor). There is a monotonous appearance of large cells with ovoid nuclei and scanty protoplasm. Broad bands of connective tissue traverse the masses of cells.

Multiple cartilaginous exostosis (hereditary multiple exostosis; diaphyseal aclasis, hereditary deforming chondrodysplasia, and dyschondroplasia) is also a disease of benign, bony, and cartilaginous growths which are multiple, bilateral, or symmetrical and may involve any bone in the body except the membranous bones and the tarsal and carpal bones. The lesions are common at the epiphyseal end in the cartilaginous plates. Treatment is indicated if the lesions interfere with function. Chondrosarcoma sometimes occurs.

Hemangiomas are benign growths which may affect the vertebra, skull, pelvis, or long bones. They may cause pain and deformity. Diagnosis is made by x-ray. Treatment consists of excision.

Neurofibromatosis of bone occurs rarely and may arise from nerve fibers in the periosteum, cortex, or medulla. If near the epiphysis, they may stimulate or retard growth. Pseudoarthrosis, spontaneous fractures, and scoliosis may result from their presence. They should be removed.

Osteogenic sarcoma, as its name implies, arises in bone. Some authors use the term to include osteosarcoma, chondrosarcoma, and fibrosarcoma of bone. It may be osteogenetic (bone-forming) or osteolytic (bone-destroying). It may be very malignant, the latter variety more than the former. It usually occurs in children or young adults. Osteosarcoma is a term used to denote a primary osseous tumor arising from osteoblasts or their forebears. Osteoblastic osteosarcoma usually arises from the diaphyseal periosteum. Osteolytic osteosarcoma arises in the metaphyseal medulla and has been called a malignant bone aneurysm or cyst.

Fig. 345.—Clinical photograph (J. B.) showing large carcinoma of right hand. There had been previous attempts at removal. Axillary metastases were present. The entire upper extremity was removed by the interscapulothoracic *disarticulation technique* described in Figs 340, 341, 342, 343, and 344. (From Berman, J. K., Surgery 18: 256, 1945)

Osteosarcoma spreads by direct extension and by the blood stream. Diagnosis is made by x-ray and by biopsy, with tourniquet immediately proximal to the growth. Amputation is done if the condition is diagnosed early. This may necessitate disarticulation of an extremity or the entire extremity and its attachments: in the arm, interscapulothoracic disarticulation, and in the leg, hemipelvectomy, exarticulation, sacroiliac disarticulation. If metastasis has occurred (by the blood stream to the lungs), x-ray treatment may be tried but is usually unavailing.

Benign giant-cell tumor resembles an area of granulation tissue, filled with giant cells of the foreign body type, which has pushed the cortex of the bone aside, thinning it. There may be some fibroblastic connective

Diagram illustrating the antomy of the subcutaneous structures 1, Incision in the periosteum of the clavicle; 2, division of sternomastoid muscle from its clavicular origin; 3, subperiosteal removal of the lateral two-thirds of the clavicle; 4, separation of the pectoralis major muscle from the clavicles, 5, severance and lateral reflection of the subclavius and its overlying periosteum in line with medial edge of divided clavicle. (From Berman, J. K.: Surgery 18, 256, 1945.)

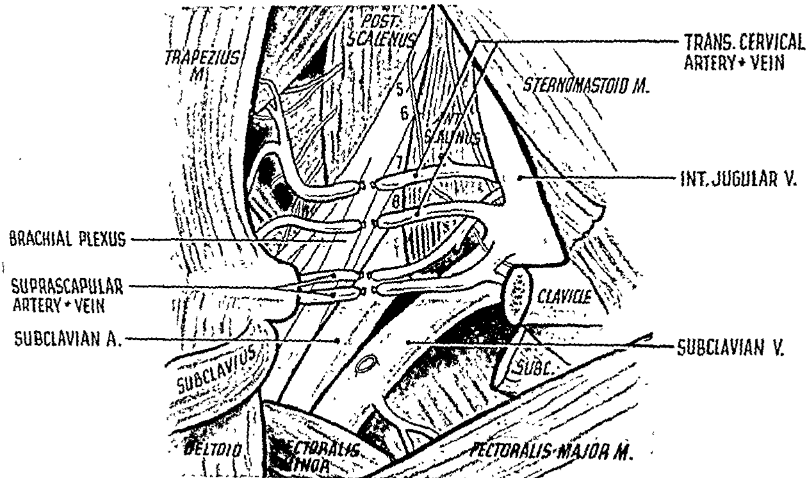

Fig. 348.—Interscapulothoracic disarticulation of the arm (continued). Diagram of the deep anatomy. The transverse cervical and transverse scapular arteries and veins have been divided between ligatures. (From Berman, J. K.: Surgery 18: 256, 1945.)

tissue and some spicules in the later stages of the tumor. Geschicter has published a chart for x-ray use showing sites of bone disease and tumors.

Although it may be difficult to distinguish different types of giant cells in histological sections, due to the manner in which they are cut or distorted, yet three main types are encountered: the foreign body type seen in infections as a rule, the Langhans' type (seen in tuberculosis and less often in syphilis), and the malignant type seen in osteogenic and other sarcomas. Some believe the so-called Langhans' type is an artifact due to a cross section of a capillary and that the peripherally placed nuclei are simply the nuclei of the endothelial cells of the capillary wall. The giant-cell tumor usually occurs near the epiphysis in young people.

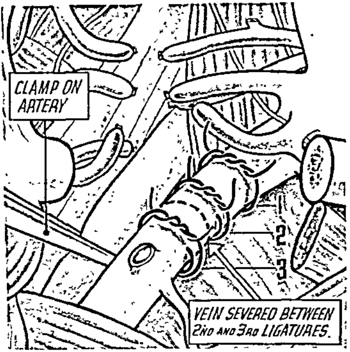

Fig. 349.—Interscapulothoracic disarticulation of the arm (continued). Method of vascular control; the subclavian artery has been clamped, the vein is tied with large silk ligatures. *1*, A simple tie; *2* and *3*, transfixed ligatures. The subclavian artery is then handled in a similar manner. (From Berman, J. K.: Surgery 18: 256, 1945.)

The tumor has been called osteoclastoma because it is thought that the giant cells are forms of osteoclasts. Two main varieties are encountered: (1) The so-called *cystic type* which has been described. It is probably a process of repair and is seen in (a) solitary bone cysts on the metaphyseal side of the epiphysis; (b) in the acute bone cyst which is found in a similar position; (c) sometimes in osteitis fibrosa cystica. The neoplasm tends to heal with x-ray treatment, after a fracture, or following curettement. (2) The *solid* or *noncystic type* is rare and is seen more often in adults in the lower epiphysis of the femur, radius, and upper epiphyseal end of the tibia. It may occur in the vertebrae, skull, and

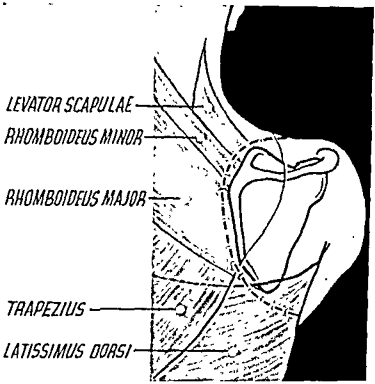

Fig. 350.—Interscapulothoracic disarticulation of the arm (continued). Line of posterior incision. The arm has been moved across the chest, displacing the scapula laterally. (From Berman, J. K.: Surgery 18: 256, 1945.)

Fig. 351.—Clinical photograph (J. B. same case as in Fig. 345) showing scar ten days after interscapulothoracic disarticulation. The wound has healed by first intention. (From Berman, J. K.: Surgery 18: 256, 1945.)

facial bones. Microscopically there are more giant cells and less fibrous tissue and very little new bone. This type tends to recur after removal. The treatment is conservative: that is, x-ray with local curettage. Should it recur, sarcoma must be suspected, although this is uncommon. The growth is related to fibrous *epulis* in the mouth.

Unicamerate cyst is a solitary bone cyst which is lined with connective tissue, contains straw-colored fluid, and has on its inner surface cholesterol crystals and foam cells. The diagnosis is made by x-ray. The treatment is curettage and filling the cavity with bone chips.

Rarer malignant tumors are adamantinoma (adamantinoblastoma) of long bones like those seen in the jaw, liposarcoma, lymphoblastoma (lymphosarcoma, Hodgkin's disease, reticulum-cell, giant follicular), hemangioendothelioma (hemangiosarcoma), and fibrosarcoma.

Ewing's tumor (angioma series—diffuse endothelioma, endothelial myeloma) probably arises from reticulum cells of the marrow or from lymphoblasts which may arise from the reticulum cells. Grossly the tumor is seen as a large growth which has thinned the cortex to an egg-shell thickness. It is light gray on cut surface and is soft, resembling brain substance. There is no bone within the tumor. The destruction is first in the marrow, then the cortex, and then soft tissue. Sometimes this break-through stimulates new bone formation in layers (onion-peel effect). The microscopic picture is a monotonous sheet of small round cells with scanty cytoplasm and round or oval nuclei that are stained evenly. The growth spreads locally, to other bones, lymph nodes, and by the blood stream to the lungs. The diagnosis is made by x-ray and biopsy. Prognosis is extremely bad. Treatment is by x-ray therapy unless a solitary lesion is found, in which case amputation may be indicated.

The Vertebral Column

The vertebral column is made up of twenty-four movable vertebrae and nine false vertebrae, which are fused to form the sacrum and the coccyx. It supports the head and ribs and, through muscular attachments, makes it possible for man to assume the upright position. Below, it rests upon the sacrum, which in turn is wedged between the pelvic bones (the ilia). The seven cervical vertebrae curve forward, the twelve thoracic backward, and the five lumbar forward again, forming an S. The sacrum is formed by five fused vertebrae which curve posteriorly, and the coccyx is made of four which curve in the same direction. Within the vertebral canal lies the spinal cord and between the individual vertebrae run the nerve roots. The vertebrae are held together by strong ligaments supported by the powerful sacrospinalis muscles. Movement of the vertebrae is made possible by the intervertebral cartilaginous discs. The cervical region possesses the widest range of movement and the dorsal region is relatively fixed except for rotation. Each intervertebral fibrocartilage is composed of a peripheral portion (annulus fibrosus) and a pulpy central portion (nucleus pulposus). The laminae are bound together by yellow elastic fibers (ligamenta flava).

Sometimes the vertebrae do not fuse posteriorly, and in extremely rare cases there is an anterior defect. This congenital defect is called *spina bifida.* If the meninges alone protrude, a *meningocele* results. This is amenable to treatment. If the cord is in the sac, a *myelocele* results and is difficult to treat. A meningocele may be

obliterated and frequently remains cured; however, a hydrocephalus may follow. *Spina bifida occulta* is a defect in which there is a failure of fusion of spinal laminae but no sac in the lower lumbar vertebrae and is often accompanied by bladder symptoms and other symptoms. The treatment consists of division of fibrous adhesions to the cord.

Many *tumors* and *cysts* occur about the sacrum and the coccyx (which is a vestigial tail). This is due to the fact that all three germ layers are represented at this site. Thus we see meningoceles, dermoids, teratomas, neurenteric cysts, pilonidal sinus (nidus of hair), adventitious bursae, glomus tumor, and osteomas. The treatment is removal of the growth if feasible.

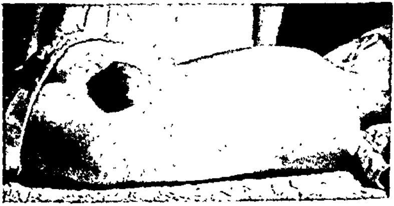

Fig. 352.—Spina bifida, with meningocele.

Fig. 353.—Sacrococcygeal tumor (teratoma) in a 2-month-old infant. Surgical removal and recovery.

The spine sometimes deviates in its curves from the normal. A large backward curve (*kyphosis*) in the thoracic region may be compensated by an exaggerated forward curve (*lordosis*) in the lumbar region. Sometimes the spine deviates and twists laterally. This is known as a rotary lateral curvature (scoliosis). These malalignments are due to postural defects in the legs or abdomen, or to structural change in the ver-

tebrae themselves, such as occur in Pott's disease (tuberculosis), or in the muscle or bony support, as in infantile paralysis, empyema, or following thoracoplasty or other chest-collapsing operations.

The side to which the convex portion extends is not always predictable due to the action of abdominal and other muscles. Following thoracoplasty in adults, the convex portion usually but not invariably points toward the operated side. This is possibly due to the fact that the musculature is disturbed and that the muscles on the opposite side, being normal, contract. Also, the support for the operated side is lost, permitting the convex portion to protrude into that direction. If the musculature is suddenly paralyzed as in poliomyelitis, the concave portion may point to the paralyzed side due to the support on the unaffected side and the lack of support on the paralyzed side. However, in children, this is entirely unpredictable due to the fact that the spine is growing; thus the convex portion may point to the paralyzed side. Also, the variables which occur as a result of groups of muscles which may remain intact renders the entire problem unpredictable. In chronic inflammatory disease of the chest, such as chronic empyema, there will be a tendency for the entire half of the chest to contract down on the affected side. The concave portion, therefore, will face the affected side.

The treatment of the functional types is support by brace or cast and special corrective exercises. Structural types may require spinal fusion operations (of the Albee or Hibbs type).

Fractures and dislocations of the vertebrae occur as a result of severe trauma. As in skull fractures, the seriousness of the injury lies not so much in the fracture or dislocation of the bone as in the damage which may have been done to the cord. This was especially true during World War II when high velocity bullets literally tore gutters in the backward curves (thoracic and sacral) of the spine as soldiers crawled on their bellies. Here the heat of the missiles burned the cord, destroyed large sections and producing paraplegias (see Chapter 18). The treatment is immobilization in a plaster shell, with head traction by tongs if necessary. The slightest movement may impinge a section of the cord and cause paralysis or even death (if the fracture is in the cervical region). Therefore, the patient must be moved with extreme caution. War injuries were treated with greater success by open operation.

Lesser injuries, such as sacroiliac or lumbosacral strain or sprain, produced so-called *chronic backache.* Outlines of the types of pain associated with the various pathological conditions and their causes are given in Tables XXV and XXVI.

Slipping forward of the fifth lumbar vertebra is known as spondylolisthesis. Prespondylolisthesis (spondylolysis, rachischisis, spondyloschisis) is a separation of the neural arch and may be associated with protrusion of the intervertebral disc. Either of these lesions may cause backache. Herniation of fascial fat, traumatic spondylitis (Kümmell's disease); vertebral epiphysitis, and other types of spondylitis may also cause pain. The treatment is by supports and x-ray and surgery where indicated (fusion in spondylolisthesis, removal of disc, or fascial fat herniation).

Spondylitis (hypertrophic, osteoarthritis, degenerating, nonankylosing) may produce pain not only in the back but in the abdomen as well. This is due to irritations of the nerve trunks. Gall bladder, kidney, appendiceal, and pelvic disease may be mimicked. However, in spondylitis rest in bed ameliorates the symptoms. Furthermore, the area of skin innervated by the affected nerves shows changes (becoming moist, cyanotic,

TABLE XXV

PARTICULAR TYPES OF PAIN ASSOCIATED WITH BACKACHE

(From Ghormley, R. K.: Backache. Examination and Differential Diagnosis, J. A. M. A. 125: 412, 1944.)

	TYPE OF PAIN PRESENT			
	STATIC, RELIEVED BY REST	MORNING, WITH OR WITHOUT "JELLING"	NOCTURNAL	CONSTANT
Probable pathological condition present	Traumatic spondylitis Spondylolisthesis Spondylolysis Old fractures of vertebrae Fractures of facets and pedicles Perivertebral traumatic changes	Usually inflammatory lesions Myositis Spondylitis deformans Fibrositis Traumatic injuries with superimposed inflammation	Associated with neurological conditions Tumors of the spinal cord Lesions of discs Obscure types, no demonstrable lesion May be forerunner of spondylitis	Malignant lesions, primary or secondary Other tumors of spinal cord Some lesions of discs Acute infection, such as osteomyelitis or infection of intervertebral disc

TABLE XXVI

LESIONS WHICH OFTEN UNDERLIE PAIN IN LOWER PART OF THE BACK

(From Ghormley, R. K.: Backache. Examination and Differential Diagnosis, J. A. M. A. 125: 412, 1944.)

	GENERAL TYPE OF LESION PRESENT					
	POSTURAL STRAIN	STATIC OR POST-TRAUMATIC	RHEUMATIC	INFECTIOUS (OTHER TYPES)	SENESCENT	NEOPLASTIC
Probable pathological condition present	Abnormal lordosis Adolescent; other types of round back Obesity Faulty body and foot mechanics	Spondylolisthesis Defective pedicles Old fractures (Kümmell's) Fractured facets Fractured pedicles Thin discs; protruded discs Hypertrophic and post-traumatic changes Congenital anomalies	Infectious arthritis Spondylitis deformans Myositis	Tuberculosis—benign osteitis—osteitis deformans Intervertebral discs, inflammatory Brucella abortus Typhoid spine	Senile osteoporosis Senescent and hypertrophic arthritis	A. Malignant myeloma Metastatic malignant lesion Primary sarcoma Ewing's tumor B. Benign osteoma and osteochondroma Giant-cell tumor Hemangioma

and cold) due to sympathetic nerve involvement. In lumbosacral sprain, pain may be referred to the inguinal region or the front of the legs, whereas in sacroiliac sprain, pain is usually referred down the sciatic nerve. The more acute type of spondylitis occurs in the young. It is also known as the rheumatoid type (atrophic, ankylosing, proliferative Marie-Strümpell arthritis, spondylitis rhizomélique). The symptoms are severe and the end result the so-called "poker spine." Treatment is by x-ray therapy and immobilization with braces or supports.

Fig. 354.—Severe degree of rotary lateral curvature of the spine. No bone disease. Condition resulted from anterior poliomyelitis.

Rarely a displaced *nucleus pulposus* (from the primitive notochord) may produce pressure on the spinal cord, causing pain or impaired motor function. This demands removal of the nucleus. Still more rarely, an hypertrophied *ligamentum flavum* may produce symptoms demanding its removal. Tuberculosis of the spinal column (Pott's disease) causes destruction of the vertebral bodies, with collapse, and the formation of a cold (iliopsoas) abscess. The treatment is that of tuberculosis elsewhere (Chapter 8), with support of the spine by casts or braces and sunlight. Occasionally, spinal fusion is required in children, often in adults.

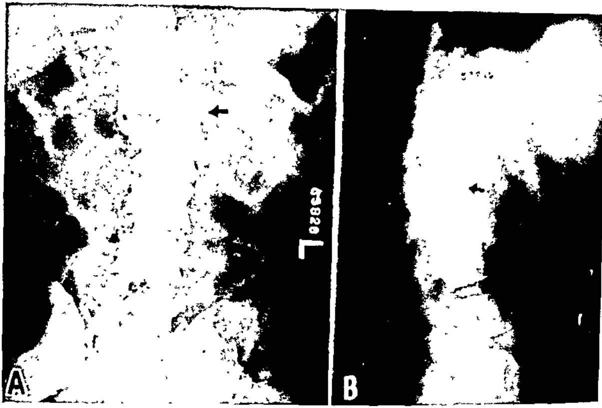

Fig 355.—*A*. Fracture of the first lumbar vertebra, with partial subluxation of the spine anteriorly and laterally. *B*. Lateral view.

Fig. 356.—Kümmell's disease of the spine (traumatic spondylitis). There are rarefaction and partial destruction of the first lumbar vertebra, which has collapsed, producing a local kyphosis.

JOINTS

Embryology, Anatomy, and Physiology

All joints *are mesodermal in origin* and differentiate. Sometimes this differentiation is a temporary stage either as a membrane limiting the extent of adjacent bones (sutura) or as cartilage *as a continuous layer in which* ossification centers occur, and the plane of articulation is marked out by unossified cartilage (synchondrosis).

In *movable joints the development is* not a temporary phase of an ossification process but is permanent. From the start these joints arise from a mass of undifferentiated mesodermic cells *lying between two groups of cells which* have differentiated into cartilage. The mass of cells is disc shaped and is in close proximity above and below with the primitive cartilage. *Around the circumference* the cells are closer together.

Fig. 357.—*Spondylolisthesis.* Note the forward dislocation of the fifth lumbar vertebra on the top of the sacrum. The entire spine is displaced slightly forward.

From this primitive mass of cells all structures of the amphiarthroidal and diarthroidal joints arise. In the latter the following structures take *origin: from the circumference,* investing ligaments and capsule lined with synovial membrane, and from its interior, fibrocartilaginous plates in the articular cavity.

The *synovial* membrane must be close to the blood supply and is, therefore, present everywhere in the joint except the free surface of the articular cartilage. *This is not* due to wear *and tear because* it is found covering the menisci of the knee. Since the epiphyses adjoining the articular cavities are produced in the joint units, the attachments of the capsule *should be limited to the* nonarticular surfaces of the epiphyses. This is true originally, but as growth progresses there are three variations: The epiphyseal line may be (a) extracapsular, (b) intracapsular, or (c) both.

The joints of the body are divided into the *synarthroses*, or immovable joints, best exemplified in the suture lines of the skull (sutura) and the occipitosphenoid articulation (synchondrosis); the *amphiarthroses*, or partially movable joints in the midline of the body, such as the symphysis pubis and the intervertebral and sternoclavicular articulations; and the *diarthroses*, or movable joints.

The diarthroidal joints are equipped for motion and weight-bearing, and the greater the movement and the weight borne, the more likely the joint is to be affected by disease. The cartilaginous caps, which are lined with the secreting synovial membrane, make motion free; and the special locking device, especially in the knee, makes weight-bearing possible. They are well supplied with blood and drain effectively into lymph channels. As in other serous cavities, circulation is not rapid, and the joints may be looked upon as the backwash of the circulation, although immunity is relatively high.

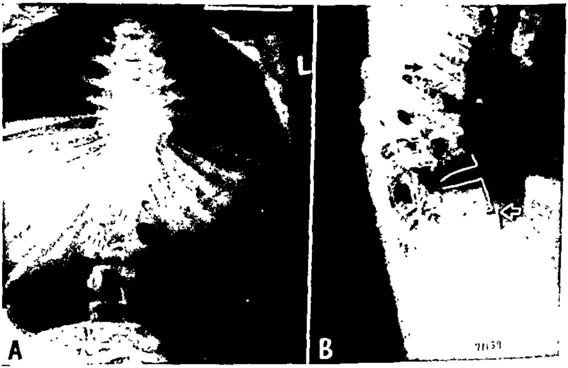

Fig 358.—*A*. Advanced tuberculosis of the spine (Pott's disease). There is collapse of the vertebrae, with calcium deposit in the soft tissues. Note the spider-web appearance of the ribs, due to vertebral collapse. *B*. Lateral view of tuberculosis of the thoracic and lumbar vertebrae. There are destruction of the bodies of the vertebrae and collapse without bone production.

The synovial membrane lines the capsular ligaments and is reflected onto the nonarticular surface of the cartilages in the joint capsule. There is a fibrosis synovial membrane which covers the areas which are subjected to pressure or strain as over the intra articular ligaments and tendons. The areolar synovial membrane lines the parts which move over underlying tissue. The adipose synovial membrane lines the fat pads which project into the joint. The membrane is in two layers: (a) internal, which is compact, cellular, and avascular; (b) external, which is vascular and, except in the fibrous type, is loosely arranged with areolar spaces and has some fat. It contains lymphatics and nerves as in the periosteum. The internal layer is analogous to the articular cartilage and the external is like the cancellous spaces of articular ends of bone.

The synovial membrane is somewhat like the peritoneum. It will absorb crystalloids readily, and colloids by the lymphatics slowly, and very large bodies are surrounded by it.

The membrane can produce osteocartilaginous bodies and is regenerated if dissected off. It may also be the seat of neoplasms (synovioma, chondroma). Due to the fact that it forms from a separate group of mesenchymal cells, it may be much larger than necessary and is thrown into folds, the synovial villi. The blood vessels form a rough circle around each extremity of the joint (circulus vasculosus). They lie opposite the reflection in the deeper connective tissue layer of the synovial membrane, and from each circle there is free inosculation over the deep surface of the membrane. The vessels are intimately connected with those of the underlying bone, especially if the *synovial reflection extends on the diaphyseal side of the epiphyseal cartilage* so as to overlie the metaphysis. In this event, bone infection may easily reach the joint and vice versa. The vessels are known as *juxtaepiphyseal* (Lexer) if they pass into the metaphysis; if not, they are called *epiphyseal*, and their connection with the metaphysis is secondary. The nutrient artery of the bone, periosteal vessels and branches from the muscular vessels, as well as the principal arteries, enter into this articular vascular anastomosis. Lymphatics are plentiful in joints. Absorption is therefore quick and is easily affected as elsewhere by pressure and motion.

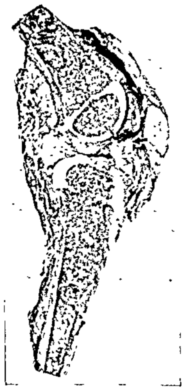

FIG. 359.—Suppurative arthritis of the knee joint. The patient was a 3-year-old boy. Arrow points to the purulent exudate in the joint cavity.

Normally synovial fluid is secreted by the synovial membrane and absorbed by the lymphatics. Trauma increases the amount of synovial fluid secreted. Absorption may be hastened by a tight bandage which increases the intra-articular pressure.

Synovial fluid lubricates joint surfaces, protects the articular cartilage from acid metabolites because it is alkaline, and helps nourish the articular cartilage. Synovial fluid is a secretion but also a transudate. It is alkaline and contains mucin, albumin, fat, inorganic salts. Its specific gravity is about 1.040; viscosity, 10.7 to 20; pH, 8.2 to 8.4; protein content, 1.6 per cent; mucin, 1.95 per cent, bilirubin, 0.5 mg.; glucose, 80 to 120 mg. per 100 c.c.; hemocytes, 50 per cubic millimeter with the following types of cells—mesothelial cells, granulocytes, and monocytes. Some erythrocytes are present.

Diseases and Injuries of Joints

Synovitis.—When the smooth glistening synovial membrane becomes injured or infected, it becomes inflamed as do other tissues, throwing out an excessive amount of synovial fluid for protection (*hydrops*, "water in the joint"). The membrane becomes thickened and rough and is therefore swollen and painful. This is known as *synovitis* and demands rest of the part.

Sprains are injuries which produce a stretching of the capsular ligaments and sometimes a tearing of these structures, resulting in a dislocation which promptly reduces itself. The symptoms are pain, swelling, and disability. For the relief of these, rest is imperative. A sprained joint should be immediately immobilized by a tight bandage, and motion should be limited for seven to ten days. X-ray examination is important because of the possibility of a fracture. A *strain* is an overstretching of muscle with tearing of some of its fibers.

Internal Derangements.—Ligamentous structures are often torn within a joint, and the cartilaginous discs may be fractured, usually as the result of severe injuries brought about from abnormal motions. Such injuries produce much pain and swelling and are exceedingly slow to heal. They are known as *internal derangements* of the joint. The semilunar cartilage has a good peripheral blood supply but a poor central one. The internal cartilage is injured almost nine times as frequently as the external. Conservative treatment leads to healing by connective tissue and should be tried. Immobilization must be maintained for weeks and even months. Often the surgeon must suture the torn ligament or excise the injured cartilage. If excised too early, chronic synovitis may result. Should small fragments of the cartilage or hypertrophied synovial villi break off in the joint, they form loose bodies (joint mice). These interfere with motion and cause the joint to lock. Diagnosis may be facilitated by air injection into the joint. They must be removed through an opening in the joint (arthrotomy).

A tendon ganglion is a cystlike tumor which communicates with the tendon sheath and occasionally with the synovial cavity of a joint. In fact, it may be associated with a low-grade inflammation of the adjacent joint. It is seen usually on the dorsum of the wrist, sometimes on the flexor surface of the wrist, and less commonly in the ankle. It is not painful, as a rule, contains a clear gelatinous substance, and is attributed to tendon injury. The treatment consists of puncture and evacuation, followed by a tight bandage. Should the ganglion recur, excision is indicated.

Classification of the Causes of Arthritis

1. Trauma
   - (a) Direct injury by blunt force
   - (b) Penetrating injuries
   - (c) Muscular action

2. Infections through the blood stream
   (a) Nonspecific infection from an acute focus
   (b) Acute rheumatic fever
   (c) Gonorrhea
   (d) Syphilis
   (e) Acute infectious diseases
       Pneumonia, typhoid, cerebrospinal meningitis
   (f) Tuberculosis
   (g) Brucellosis
3. Infections by contiguity or injury
   (a) Penetrating wounds
   (b) Osteomyelitis
   (c) Cellulitis about the joint
4. Toxins
   Allergy, serum sickness
5. Metabolic
   (a) Gout
   (b) Scurvy
   (c) Rickets
6. Neoplasms
   (a) Synovioma
   (b) Chondroma
7. Diseases of the central nervous system
   (a) Tabes
   (b) Syringomyelia
   (c) Hemiplegia
8. Hemophilia
9. Systemic
   (a) Infections (?)
       Arthritis deformans of the atrophic, ankylosing, rheumatoid, proliferative type; Still's disease; in spine: Marie-Strümpell arthritis, ankylosing spondylitis, spondylitis rhizomélique
   (b) "Wear and tear" (?)
       Arthritis deformans of the hypertrophic, nonankylosing, degenerative, osteoarthritic type
   (c) Arthritis with splenomegaly, leucopenia—Felty's syndrome

Arthritis (Nonspecific Infection Type).—The infection is usually nonspecific and is probably caused by organisms such as the streptococci and staphylococci which gain entrance through the nose or throat. In the acute septic type, a single joint is usually involved. This becomes swollen and exquisitely tender, so that the slightest motion causes excruciating pain. There is a high temperature of the septic type and great prostration. Diagnosis is easily made and confirmed by needle puncture. The fluid may be purulent (less so in streptococcic infections) and should be cultured for the organism. The treatment consists of rest in bed, transfusions if necessary, sulfonamides and penicillin, and immobilization and extension of the affected joint. Repeated aspiration or surgical drainage is often necessary. Early mobilization may minimize the resultant ankylosis.

Suppuration in a joint is governed by the same laws as suppuration elsewhere. Since lymphatic absorption is dependent on increased intra-articular pressure and motion, this can be controlled by rest and aspiration until localization occurs. Then blood capillaries and lymphatics are occluded, local immunity is established, and incision is performed for free drainage. Active motion is then useful, for pressure is relieved and adhesions will be less apt to form.

Gonorrheal arthritis also affects a single joint. It becomes painful and swollen, with less systemic reaction. Chemotherapy, antibiotics, rest, and immobilization result in recovery, as a rule, with some permanent damage. Rarely drainage is necessary.

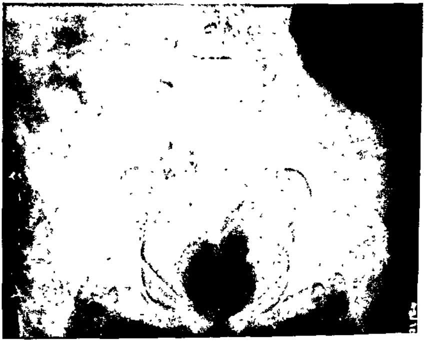

Fig. 360.—Hypertrophic arthritis of the spine (spondylitis), showing lipping of the vertebrae. The same type of arthritis also occurs in the hip joints. Note the narrowing of the joint spaces due to the atrophy of the cartilage.

Tuberculous arthritis is a local manifestation when there is tuberculosis elsewhere. The process usually affects children and is slow and insidious in its development. If left untreated, complete destruction of the joint may result, and a cold abscess will form, with multiple draining sinuses. The disease may spread to the joint by way of the metaphysis or the synovial membrane. If the latter, there may be perichondrial or superficial involvement with pannus formation, or subchondral or deep involvement with destruction of the cartilage; this is the more acute variety. Diagnosis is made by careful history, general examination for evidence of the disease elsewhere in the body, and x-ray. The treatment consists of the general treatment of tuberculosis and immobilization in a plaster cast for months until ankylosis occurs and arrest of the disease has been accomplished. Sometimes in adults it is necessary to remove the articular surfaces of the joint and produce an ankylosis (arthrodesis).

The advisability of immobilization is questioned by some. A cold abscess is thought to contain immune bodies, although these have not been isolated. All are agreed that it should be left alone unless pointing or secondarily infected. The importance of the muscular system is emphasized by Rollier and others. Prolonged immobilization leads to great muscular atrophy and diminished blood supply, with a deficiency in glycogen and immune bodies, as well as to interference with the healthy metabolism of the joints and adjacent bones. Others believe that without ankylosis there can be no arrest of tuberculosis. In general, the disease should be treated conservatively in children, more radically in adults. Streptomycin has been particularly helpful in children before widespread damage has occurred (see Chapter 8).

Syphilis of the joints occurs as a transitory synovitis in the acute secondary phase or in the congenital type. Permanent damage may occur in the tertiary stage. In tabes dorsalis a complication known as Charcot's joint occurs. There are great swelling, accumulation of fluid, overproduction of bone, and abnormal mobility. The joint is painless. The treatment is antisyphilitic therapy, penicillin in large doses, 600,000 units of procaine penicillin in oil three times a week; or, if no improvement, arsenoxide (oxophenarsine hydrochloride, dichlorphenarsine hydrochloride or phenylarsine hydrochloride), with local immobilization (see Chapter 9).

Arthritis Deformans.—A rather large and vaguely understood group of joint affections are grouped under the heading of arthritis deformans. They are divided into two main groups. The one is known as the ankylosing, rheumatoid, proliferative (that is, proliferation of marrow and subchondral and synovial connective tissue) or atrophic type; the other, as the nonankylosing, degenerative, osteoarthritic, hypertrophic, or chronic senescent type. The former occurs in young adults, occasionally in children (Still's disease). The joints are painful and swollen and the synovial membranes look like granulation tissue, and, as the name implies, they are apt to become ankylosed. Formerly, so-called silent and symptomless foci of infection were thought to be the cause. Today ankylosing arthritis deformans is looked upon more as a "system disease" affecting synovial membranes everywhere in the body. There are many examples of system diseases which occur in muscles, bone, lymph nodes, bursae, arteries, and joints. Shall we look upon these as the result of foci of infection? Is there a decreased local resistance, due to previous trauma or infection, with increased capillary permeability at the site, all of which permit an infection to "settle" in a particular type of weakened tissue? Are we confusing foci of infection with atria of infection? Do certain strains of bacteria have a selective affinity for tissues, as Rosenow has pointed out? Is a particular type of tissue susceptible because of constitutional deficiencies or diatheses? Is the disease a psychosomatic problem? These are some of the problems as yet not entirely solved. It is well to remember that the inflamed joints sel-

dom contain bacteria—except in inflammations of the acute suppurative type. The final answer is probably midway between the extremes; in other words, endogenous as well as exogenous factors must play a role. The treatment of this type is varied and includes symptomatic care, attention to vitamins, hydro- and heliotherapy, hormonal therapy (adrenal cortex, pituitary), and early motion. The nonankylosing type occurs in older individuals and leads to spur formation and calcific deposits about the joints. Heberden's nodes are nodular deformities due to small bony outgrowths about the fingers. The disease is slow and discomforting but not excruciatingly painful. Some believe it is due to "wear and tear." The treatment is dietary management, glandular therapy—thyroid and ovarian hormones and perhaps adrenocortical hormone 17-hydroxy-11-dehydrocorticosterone (compound E of Kendall), and hydro- and heliotherapy, combined with rest to the part. Surgery may be helpful. In rheumatoid arthritis the following measure may be tried, depending on the indications: careful manipulation, corrective casts, turnbuckles attached to Kirschner wires (to stretch contracted soft tissues around joints), tendon lengthening, freeing the posterior part of the articular capsule, removal of Baker's cysts (outpouching or herniation of part of articular capsule, or enlarged bursae of popliteal space), excision of rheumatic nodules, aspiration of synovial fluid, osteotomy to provide a better position of function. In osteoarthritis, operation is done usually for relief of pain. This may be accomplished by manipulation of neurectomy (as the obturator nerve in osteoarthritis of the hip) and immobilization.

BURSAE

Bursae are small synovial sacs between muscle and bone, between muscles, and over exposed surfaces. They may develop as a result of chronic irritation (adventitious). They act as hydrostatic bags, making motion free and without friction. They are filled with a small amount of fluid. A sudden tear of a muscle or tendon, or a constant strain on these structures, produces an inflammatory reaction (bursitis), with fluid. Bursae may be affected over the entire body as a result of toxins or infection. This, too, is a "system disease," vaguely understood. Due to fibrinous deposits and roughening of the smooth surfaces, motion of the part is restricted. Such lesions are seen about the shoulder (subdeltoid or subacromial bursitis), the elbow (olecranal bursitis or a "tennis elbow"), the hip (iliopectineal, gluteal, and ischial bursitis), the knee (prepatellar bursitis or "housemaid's knee"), the popliteal space (hamstring bursitis), and the ankle (Achilles bursitis). Sometimes the bursa undergoes calcification, which may be seen in the x-ray plate. The treatment in the acute stage consists of rest to the part, aspiration of fluid, diathermy, and x-ray. Sometimes surgical excision is necessary. Nature then heals the defect with fibrous tissue. Rarely bursitis may be due to tuberculosis. It results in great thickening of the bursa. Sometimes a

cold abscess forms with draining sinuses. Such bursae should be excised. Syphilitic bursitis occurs in the secondary and tertiary stages. Neoplasms of bursae may be benign (giant-cell tumor, lipoma, hemangioma, lymphangioma, fibroma and chondroma) or malignant (synovioma, fibrosarcoma, chondrosarcoma). The treatment is excision of benign growths. This may be adequate for the malignant types also, but amputation may be required.

Nature sometimes forms adventitious bursae to protect an irritated part. They develop in fibrous connective tissue which undergoes mucoid or myxomatous degeneration. They differ from true bursae in that they have no endothelial lining. Such is a *bunion*, which results from *hallux valgus*, or an outward deformity of the big toe. This usually occurs as a result of wearing shoes which are too narrow and too short. The treatment consists of protection by felt pads and proper shoes. In the late stages, excision is demanded.

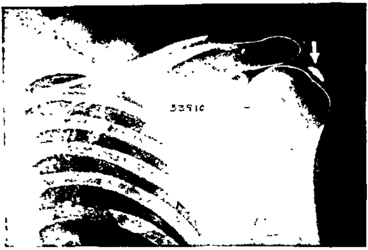

Fig. 361.—X-ray photograph, retouched, showing a calcified subacromial bursa. This disappeared under x-ray treatment.

Metatarsalgia (Morton's disease) is due to a collapse of the transverse arch of the foot. It is painful because of pressure on the plantar nerves and also because of the callus which forms over the collapsed metatarsal heads. This is not a bursa but is an attempt on the part of nature to protect these metatarsal heads. Sometimes these bones hypertrophy. Resection of the heads which are directly over the callus results in great benefit.

MUSCLES AND TENDONS

Physiology

We have noted in Chapter 19 the effects of anoxia on muscle tone. Muscle must have oxygen, not for contraction and relaxation, but for recuperation of its former state. If there is no oxygen, lactic acid accumulates and the muscle enters into rigor. Oxygen dispels lactic acid and enables the muscle to contract. Fatigue is not due to

the exhaustion of glycogen but to the high acidity. This inhibits the enzyme necessary to cause glycogen breakdown. Phosphoric acid also accumulates in muscle if oxygen is inadequate. The great role that muscle plays in the heat production of the body has already been discussed. When muscle contracts isometrically (without shortening), all the energy expended appears as heat. If it lifts a weight, 35 per cent of the energy is expended as mechanical work.

During exercise, lactic acid may appear in amounts of 3 Gm. per second. This is buffered by muscle protein, phosphates, and bicarbonates, but still there is sufficient change in blood reaction to stimulate the respiratory center so that large amounts of CO_2 are given off (Chapter 12). Lactic acid is removed in muscle by oxidation through the oxygen consumption during the recovery phase. The liver, heart, brain, and muscles not engaged in exercise help remove lactic acid which is carried to them by the blood stream. In the liver, heart, and muscles, lactic acid is removed through its conversion to glycogen. Traumatized muscle over wide areas may be a causative factor in "crush syndrome" (Chapter 14). Devitalization of muscles makes this tissue vulnerable to anaerobic infections (Chapter 6).

To test the excitability of tissue, a standard is used known as *chronaxia*. The intensity or voltage of current, which when allowed to flow for an indefinitely long period is just capable of exciting the tissue, is called the *rheobase*. *The chronaxia is the shortest duration of a current necessary for excitation when its strength is twice the rheobase.*

We have already noted in the beginning of this chapter that the muscles have important functions other than aiding in locomotion. However, they are necessary to movement and are attached to bones through their tendinous ends. Muscles undergo *atrophy* from disuse or interference with the nerve supply, or *contracture* from a constant contraction (unopposed by opposite groups of muscles) over long periods. *These are avoided by early mobilization of the arms and legs in bone or joint disease and by fixation in a neutral position.*

Flexion Contractures of the Hand

Flexion contractures of the hand produce a deformity known as "claw hand." This may result from ulnar nerve paralysis (Chapter 18), palmar skin, subcutaneous tissue, palmar fascia, or flexor tendon fibrosis; or all of these structures combined in fibrosis (Dupuytren's contracture), interference with blood supply chiefly to the flexor muscles as a result of interference with arterial supply due to injury of the branchial artery or with venous return (Volkmann's ischemic contracture).

Dupuytren's Contracture.—The cause of the palmar fascia contracture is not definitely known. Such factors as chronic trauma due to manual labor, heredity, the association with spinal cord injuries and disease (tabes dorsalis, syringomyelia, multiple sclerosis) have been mentioned as possible causes. The chief pathological change is in the palmar fascia with inflammation, proliferation of capillaries and fibroblasts, and perivascular lymphocytic infiltration. There is active proliferation of fibroblasts without other signs of inflammation and then deposition of collagen with subsequent cicatrization. Indeed the process resembles keloid formation as seen in the skin. In addition, the skin, subcutaneous tissue, and tendons may be enmeshed in scar. Certain areas may be mistaken for fibrosarcoma, but the cytology is normal. Treatment con-

sists of excision of the palmar fascia and subcutaneous scar, although the operation is difficult and recurrence is likely.

Contractures Due to Interference With Blood Supply.—These may result from arterial injury or venous occlusion. Arterial injury may result in prolonged spasm of the brachial artery with resultant ischemia and muscle degeneration with fibrosis. The pulse is absent and the extremity is cold and pale. The patient complains of severe pain. Such conditions result from fractures especially about the elbow and rarely about the knee. The treatment consists of restoring arterial supply if possible. This may be done as follows: Paravertebral injection of procaine in spasm; release of compression on the artery by blood clot, fractured bone, tight cast; and restoration of continuity of a divided artery by primary suture or venous graft.

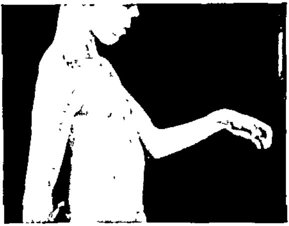

Fig. 362.—Volkmann's contracture. Note the "claw hand," with atrophy of the forearm muscles. This followed fracture of the lower end of the humerus and prolonged immobilization in a plaster cast.

Volkmann's Contracture.—A special form of contracture known as Volkmann's ischemic contracture is seen in the hand and forearm. This usually results from complete venous occlusion over relatively short periods and is seen especially in fractures about the elbow. Extravasation of blood, edema, and tight casts may be exciting factors. If this occlusion persists, rupture of the veins occurs due to extreme passive congestion. Stasis, with local asphyxia, may cause muscles to undergo necrosis, followed by fibrosis and permanent crippling. Severe pain, or discoloration of the hand in fractures about the elbow, is the first sign. Pulsation may be present in the radial artery, and early, when prevention of necrosis is still possible, there is pulsation which may be normal or weak. Regardless of the pulsation, when the pressure in the venule capillary juncture is equal to that of the arteriolar capillary pressure, circulation is impaired and ischemia results. Prior to this, however, the venules rupture and blood extravasates, thus allowing the persistent pulsation in the radial artery. The hand becomes cyanotic, cold, and

the exhaustion of glycogen but to the high acidity. This inhibits the enzyme necessary to cause glycogen breakdown. Phosphoric acid also accumulates in muscle if oxygen is inadequate. The great role that muscle plays in the heat production of the body has already been discussed. When muscle contracts isometrically (without shortening), all the energy expended appears as heat. If it lifts a weight, 35 per cent of the energy is expended as mechanical work.

During exercise, lactic acid may appear in amounts of 3 Gm. per second. This is buffered by muscle protein, phosphates, and bicarbonates, but still there is sufficient change in blood reaction to stimulate the respiratory center so that large amounts of CO_2 are given off (Chapter 12). Lactic acid is removed in muscle by oxidation through the oxygen consumption during the recovery phase. The liver, heart, brain, and muscles not engaged in exercise help remove lactic acid which is carried to them by the blood stream. In the liver, heart, and muscles, lactic acid is removed through its conversion to glycogen. Traumatized muscle over wide areas may be a causative factor in "crush syndrome" (Chapter 14). Devitalization of muscles makes this tissue vulnerable to anaerobic infections (Chapter 6).

To test the excitability of tissue, a standard is used known as *chronaxia*. The intensity or voltage of current, which when allowed to flow for an indefinitely long period is just capable of exciting the tissue, is called the *rheobase*. *The chronaxia is the shortest duration of a current necessary for excitation when its strength is twice the rheobase.*

We have already noted in the beginning of this chapter that the muscles have important functions other than aiding in locomotion. However, they are necessary to movement and are attached to bones through their tendinous ends. Muscles undergo *atrophy* from disuse or interference with the nerve supply, or *contracture* from a constant contraction (unopposed by opposite groups of muscles) over long periods. *These are avoided by early mobilization of the arms and legs in bone or joint disease and by fixation in a neutral position.*

Flexion Contractures of the Hand

Flexion contractures of the hand produce a deformity known as "claw hand." This may result from ulnar nerve paralysis (Chapter 18), palmar skin, subcutaneous tissue, palmar fascia, or flexor tendon fibrosis; or all of these structures combined in fibrosis (Dupuytren's contracture), interference with blood supply chiefly to the flexor muscles as a result of interference with arterial supply due to injury of the branchial artery or with venous return (Volkmann's ischemic contracture).

Dupuytren's Contracture.—The cause of the palmar fascia contracture is not definitely known. Such factors as chronic trauma due to manual labor, heredity, the association with spinal cord injuries and disease (tabes dorsalis, syringomyelia, multiple sclerosis) have been mentioned as possible causes. The chief pathological change is in the palmar fascia with inflammation, proliferation of capillaries and fibroblasts, and perivascular lymphocytic infiltration. There is active proliferation of fibroblasts without other signs of inflammation and then deposition of collagen with subsequent cicatrization. Indeed the process resembles keloid formation as seen in the skin. In addition, the skin, subcutaneous tissue, and tendons may be enmeshed in scar. Certain areas may be mistaken for fibrosarcoma, but the cytology is normal. Treatment con-

with silk (as described in Chapter 3). (6) The fibrous sheath should be reconstructed. (7) The incision in the finger is carefully closed and then after the proximal end of the graft has been sutured, the palmar or wrist incision is closed. (8) The hand is put up in flexion at the wrist (120 degrees) and at the metacarpophalangeal joints (120 degrees) (Koch).

Neuromuscular Disorders

Neuromuscular disorders (myopathies, myelopathies) are diseases and syndromes with muscular weakness and atrophy. The so-called primary muscular atrophies include the *sporadic* and *familial* diseases. The more common sporadic types are progressive muscular atrophy, including bulbar paralyses and amyotrophic lateral sclerosis, and amyotoma congenita (lack of development of muscle fibers and changes in the cortico-

Fig. 363.—Progressive muscular dystrophy. Clinical photograph of a white man (C. P.) aged 27 years who complained of generalized muscular weakness, and atrophy of the muscles of the upper arm and thigh In addition to the atrophy of the muscles of the upper arms and of the quadriceps femoris muscles, there was also some atrophy of the muscles of the back The scapula projected high in the supraclavicular spaces and the patient was unable to raise his arms above the head. His reflexes were absent or greatly diminished in most areas. Two brothers had a similar dystrophy of muscles. This man is said to exhibit a typical myopathic facies. The lips are fleshy, the eyelids tend to droop, and the smile is transverse. The involved muscles showed pseudohypertrophic masses. The patient also presented the typical "loose shoulders" of progressive muscular dystrophy There were no fibrillary tremors in the involved muscles. This particular type has been called the juvenile variety.

moist. Prevention is relatively easy. Cure is difficult, once the condition arises. Sometimes incision in the edematous tissue is necessary to relieve the venous obstruction. Fractures must be closely watched, and when pain is present in the hand, occlusive venous pressure is suspected. Some observers believe that Volkmann's contracture is arterial in origin. We prefer to regard this type as of venous origin and have therefore separated the two types. However, this may be a very difficult task clinically.

Injuries to Muscles and Tendons

Muscles and tendons may be ruptured by a severe strain and by direct trauma. Suture is often demanded. Sound muscle has a good blood supply, and proteolytic substances are minimal. If traumatized, large amounts of such substances as para-aminobenzoic acid are present, making the medium favorable for bacterial growth. In open wounds devitalized muscle makes an excellent culture medium for bacteria, especially of the anaerobic type, causing gas gangrene. Such wounds are treated by careful débridement, antitoxin, and open drainage (see Chapter 6).

Tendon repair requires a good union of the severed ends plus a smooth passageway for the tendon to move. If repair is done immediately after injury and if destruction is not too great, this may be accomplished with good results. If the tendon is badly damaged, normal uninjured tendon may be used to bridge the gap between the ends of the profundus, or one of the long extensor tendons from the the dorsum of the foot may be employed (the long extensor tendons of the lateral four toes may be removed without loss of function of the toes). After repair, the tendon must be held in place when it flexes and must be provided with a covering. The synovial sheath has a visceral layer covering the tendon and a parietal layer lining the fibrous sheath. This arrangement permits gliding movement. Substitutes for this are difficult to obtain, and therefore any part of the sheath should be saved and used as a covering. The fibrous layer may be replaced by a piece of tendon wrapped around the finger. A few rules of tendon repair may be helpful: (1) Incisions should be made so as to avoid scar contractures. The site of the incision is governed by the position of the original wound and the position of the hand at the time of injury. If the tendons are severed in extension, the distal ends will be close to the site of injury, the proximal ends far upward. If the fingers were in flexion, the distal ends of the tendons will retract downward. (2) The fibrous tendon sheath should be preserved, especially its synovial lining. In early injuries it should be opened close to its attachment to bring the tendon down. In late injuries the ventral surface may be saved in part and the dorsal surface in toto. (3) Tendons should be mobilized gently and, if fixed, the adhesions should be divided by sharp dissection. (4) Grafts should be used in widely separated old injuries. (5) Tendons should be sutured

Myotonia congenita (Thomsen's disease) is hereditary and persists throughout life with little muscular atrophy. Good results are reported with quinine.

Progressive Myelopathic Atrophies.—Infantile muscular atrophy, hypertrophic neuritis, peroneal muscular atrophy, and Friedreich's ataxia all are system diseases with changes in the central nervous system. In hypertrophic neuritis there are lesions also in the nerve trunks, and sometimes there is an associated congenital optic atrophy. The causes are unknown and there is no specific treatment.

Inflammations of Muscles and Tendons

Fibrositis.—The occurrence of infections in muscle is debatable. Healthy muscle (that is, muscle that has not been traumatized) is probably *not infected except in trichinosis. Phenomena such as Zenkerian* or hyaline degeneration of muscle fibers and the finding of aerobic bacteria in normal muscle should be mentioned. Perhaps the good blood supply of muscle has much to do with its immunity; it may also account for infections resulting after infarcts from thrombi or emboli. Tendons have a poor blood supply, and sloughing is common. In other infections the inflammation is in the connective tissue septa and should be called a *fibrositis*. Such entities as *acute lumbago* and *torticollis* belong to this group and are treated by rest, heat, massage, injection of procaine in "trigger" points, and vitamin E.

Acute *wry neck* (torticollis) is a very painful spasm of the sternocleidomastoid muscle; the patient carries the head to one side and turns the face to the opposite side from the affected muscle and fascia. The acute spasmodic type is most common. Some babies are born with a short muscle and fascia—a condition which requires surgical aid. The muscles and fascia must be divided and the child placed in a plaster cast. There is a chronic, acquired type, due to injury or infection of the lymph glands, as in tuberculosis. Sometimes tenotomy is done in the traumatic type, but rarely in the type secondary to neighboring infections. Muscular torticollis of early infancy may be due to intrauterine position, trauma at birth, and pre-existing changes within the muscle due to maldevelopment. It is thought that intrauterine torticollis is a factor in causing breech presentation. The muscle contains hard "tumors" which are thought to be hematomas or fibromas. Excision of these fibromas from the sternocleidomastoid muscle in early infancy will usually correct the deformity and thus prevent associated deformities of the head, face, and spine.

Calcification of muscle is seen in tuberculosis, hematomas, cysts, and arteriosclerosis. **Myositis ossificans traumatica** is a rare condition in which calcium is deposited in an injured muscle. It is painful and may require excision of the calcified area. In *progressive ossifying myositis* calcium may be deposited over the entire muscle system. Ammonium chloride has been advised. This condition is invariably fatal.

spinal tract). The familial type is subdivided into two groups: (a) myopathic diseases in which the histopathological changes are limited to muscles themselves or to endocrine glands; (b) inherited diseases of muscle secondary to changes in spinal cord cells—so-called myelopathic diseases.

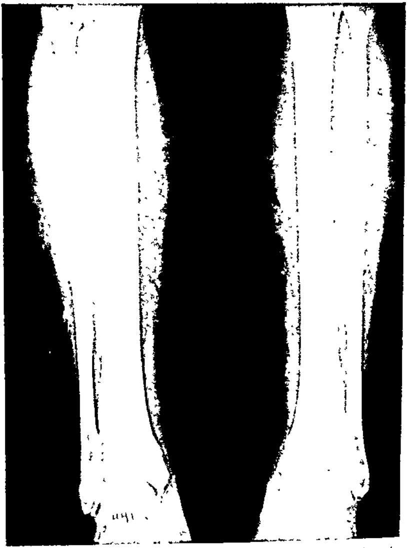

Fig. 364.—Interstitial calcinosis. There is a diffuse deposit of calcium in the muscles and around the vessels. This differs from myositis ossificans, in which there is deposition of calcium in large amounts at the site of an injury. A progressive ossifying myositis is related to this. The latter is invariably fatal.

The Progressive Myopathic Atrophies.—Myasthenia gravis is presumed to be a disorder of the myoneural junction, primarily the cholinesterase and the acetylcholine. The best treatment is neostigmine. Thymectomy may relieve some of the symptoms.

Family periodic paralysis is a hereditary disease associated with low potassium levels in the blood serum. Potassium chloride given orally is helpful.

Progressive muscular dystrophy is little understood. Vitamins are said to be helpful.

Trichinosis has been previously discussed (page 208). Echinococcus disease rarely occurs (pages 214, 741, 1091). Tuberculous myositis may be due to extension from neighboring foci (as in tuberculous spondylitis) or as a primary disease. Syphilis is seen in the secondary stage as a fibrositis and in the tertiary stage as a gumma. New growths of muscle are rare. They may be benign (fibroma, desmoid, angioma) or malignant (fibrosarcoma, rhabdomyosarcoma, angiosarcoma). Secondary carcinoma also occurs.

Tenosynovitis.—Tendons may be infected or irritated, giving rise to painful lesions. Tenosynovitis of the suppurative type may occur as a result of an injury (see Chapter 5). This requires incision and drainage. Another type (traumatic and chronic) may be due to overuse and is treated by immobilization of the part. "Trigger" finger or snapping tendon is due to either a thickening of the tendon or narrowing of the sheath. The sheath may have to be divided longitudinally to produce a cure. Acute tendinitis with calcification may be treated by aspiration and washing of tendon sheath with procaine in physiological saline and with the x-ray.

Tendon ganglions are small cystlike accumulations of jellylike fluid which is clear and white. They probably result from a low-grade inflammation developing within the joint capsule or over the periosteum of small bones about the wrist. They are treated by excision.

Rarely, *tuberculosis* attacks tendon sheaths, giving rise to an accumulation of fluid in the sheath (hydrops), with small flakes of fibrin (rice bodies). These sheaths should be excised.

New growths of tendon sheaths include lipoma, benign giant cell tumor, xanthoma, and sarcoma. Tumors should be completely excised.

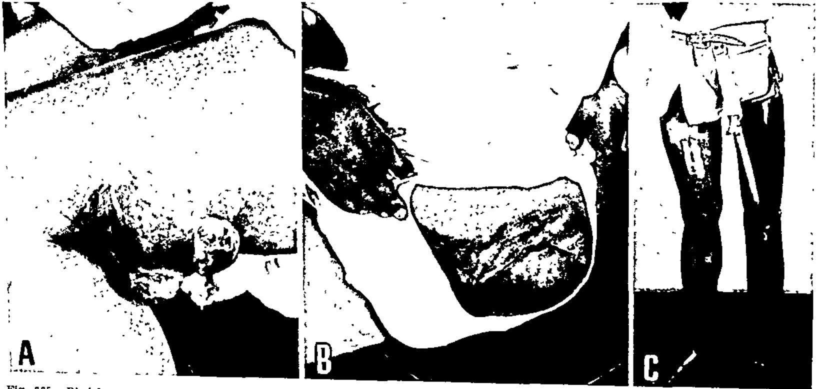

Fig. 365.—Rhabdomyosarcoma of the left thigh. The patient was a colored male aged 37 years. The growth was noted about one year before admission and had increased rapidly in size since that time. Biopsy showed the neoplasm to be a rhabdomyosarcoma. A radical amputation was done, including a disarticulation of the hip and the acetabulum. However, the interilial or hind quarter disarticulation was not deemed necessary after sampling the inguinal nodes. *A*. Clinical photograph of the neoplasm before surgery. *B*. Photograph showing the healed stump. *C*. Photograph showing the prosthesis. A special platform was built and this patient has been able to carry on his work on the artificial leg. At the end of two years the patient was still alive without metastases or recurrence.

Chapter 22

GLANDS

There are many structures, widely diff[illegible] their anatomy, physiology, and development, known as glands. [illegible] includes the following structures under the term *glands:*

1. Glands producing a visible fluid or semifluid secretion, which is discharged from the cells of the gland, either directly or by a [illegible] on a free surface, on which it is useful chemically or mechanically or by which it is [illegible].

2. The so-called *ductless glands,* which possess no [illegible] or secrete substances which are directly and gradually transmitted from the cells of the gland to the blood or lymph stream and are of use in the general metabolism of the body.

3. Cytogenic or cell producing glands, not always epithelial and usually with no distinct duct, which consist of aggregations of special cells enclosed in a more or less definite framework of connective tissue and freely supplied with blood and lymph vessels. Glands of this type are concerned in the production, from the cells in the glands, of special cells, which are liberated from the gland tissue and pass away from it. Such glands are lymph glands, bone marrow, and the reproductive glands (testes and ovaries).

Glands differ widely in structure. According to their development, they are as follows: (1) Epithelial (developed from epithelial cells with or without ducts). This group includes most of the glands of the body. The epithelium is simple, variable in structure (columnar, cuboidal), also in origin, and from time to time its morphology varies with its functions. Practically all substances which are absorbed from the outside, modified, secreted, or excreted must pass through epithelium. (2) Vascular (developed in connection with vessels, as, for example, the lymph glands, the tonsils, the thymus, and the spleen). Glands are further classified into:

1. Simple glands (duct undivided)
   a. Simple tubular—undilated at end (such as the intestinal glands)
   b. Simple alveolar—dilated at end (these do not occur in mammals)
2. Compound glands (duct divided)
   a. Compound tubular glands—branched elongated tubes with no acini (such as the cardiac glands of the stomach, Brunner's glands, the bulbourethral and vestibular glands, and the kidney)
   b. Compound acinous (grapelike) or alveolar (racemose) glands—branched duct, or ducts with saccular acini on terminal branches (which include most of the glands of the body: namely, the salivary glands, the lacrimal glands, the mammary glands, etc.)
3. Actinotubular glands—branched duct with elongated, narrow acini on terminal branches (such as the pancreas)

Glands may also be divided into *exocrine* (with epithelium lining the glandular cavities, demarcated by basement membrane from the connective tissue and blood vessels); *endocrine* (not so demarcated); and *mixed* exocrine and endocrine. *Merocrine* glands (from *mero,* a part of) secrete but do not lose cells or parts of their cells in so doing. Salivary glands and pancreatic glands are examples of this group. *Eccrine* (to expel) glands are merocrine glands with ducts.

Holocrine glands (from *holo,* entirely) secrete but lose their cells by death and sloughing in the process. The sebaceous glands belong to this type.

grown to a large and complex state and have multiple functions in addition to the production of a secretion or excretion which is carried by ducts to the alimentary canal, or to a reservoir (such as the gall bladder or urinary bladder). This group has been designated as duct glands (exocrine) to distinguish them from the ductless gland or glands of internal secretion (endocrine), which pour their products directly into the blood stream. Some glands have both exocrine and endocrine functions. The relationship of exocrine glands to immunity (the reticulo-endothelial system) and their detoxifying function are important. Moreover, they are important in blood formation, destruction, clotting, and blood volume. Their relation to general body metabolism makes of these independent organs a large system of simple epithelial and endothelial structures which usually act as independent units. None of the secretory work is done by the capillary endothelium. "We have the gland cells for that, large robust cells with a complicated protoplasmic structure"—Krogh. The capillary endothelium is permeable to the substances required by glands. However, they may act in a concerted fashion to preserve and sustain life. The endocrine and exocrine systems are certainly capable of disengaging its units into individual parts, so far as function is concerned, but each unit is influenced by, and in turn influences, other units. Examples of this are the thyroid and pituitary, liver and kidney, pancreas and liver (these are a single unit in certain fish), the parotid, sublingual, submaxillary, and lachrymal glands which are affected in Mikulicz's disease and the lymph nodes too in the syndrome, the parotid, testes or ovaries, mammary glands, and pancreas which may be involved in mumps, and the spleen, liver, and bone marrow in Banti's syndrome. Moreover, this is definitely a system which in turn is related to the autonomic nervous system.

Therefore, we shall consider in this chapter the salivary glands and their ducts, the liver with the gall bladder and the bile ducts, the pancreas and its ducts, and the spleen; also the great endocrine system, beginning with the master pituitary, and including the pineal, the thyroid, the parathyroids, the thymus, the adrenals, the ovaries, and the testes.

EXOCRINE GLANDS

The Salivary Glands

The salivary glands include the *parotid, submaxillary,* and *sublingual* glands. Smaller glands found in the lips, cheek, palate, and tongue are similar in nature, secreting a protective mucin. There are two types of salivary cells, serous and mucous. The parotid is composed entirely of serous cells, the submaxillary contains both types of cell, and the sublingual is composed mostly of mucous cells but has some serous cells. Saliva is secreted through the stimulation of the nerves of the mouth or of some sense organ other than taste. The functions of saliva are: (1) digestive, the ptyalin of the saliva acting upon the starch molecule and splitting it into molecules of disaccharide, maltose; (2) solvent action (making possible the operation of the sense of taste); (3) preparation of food for swallowing by altering its consistency; (4) cleansing action; (5) moistening and lubricating action; (6) excretory. Many organic and inorganic substances are excreted in the saliva—drugs such as mercury, potassium iodide, lead; urea in chronic nephritis; sugar, sometimes, in diabetes; calcium in parathyroid overdosage. The viruses of hydrophobia and anterior poliomyeiltis are excreted in the saliva.

The saliva plays a role in water balance. It is secreted continuously, and the amount secreted in the course of twenty-four hours may equal 1500 c.c. In dehydration states salivary secretion, along with other secretions, is suppressed. This gives a sensation of thirst and is therefore a part of the conservative mechanism designed to maintain the water balance

The *parotid gland* lies on the masseter muscle in front of the ear and extends down to the inferior angle of the mandible. It empties its secretion into the mouth through the parotid (Stensen's) duct opposite the second upper molar. The *submax-*

Apocrine glands (from *apo*, away or separation) secrete but lose a part of the cell's cytoplasm in producing the secretion. The mammary glands and certain sweat glands belong to this group (see Chapter 5). The latter are found in the axilla, around the vulva, and in the perianal region and give off a characteristic odor. The secretion accumulates in the free end of the cell. After a time this portion of the cytoplasm is sloughed but the nucleus and the rest of the cytoplasm remain intact. Soon the cell recovers and the entire process is repeated.

In this chapter will be found examples of the various types of glands. The sebaceous, sweat, and mammary glands are considered in the chapter on skin (Chapter 16). Brunner's glands, the gastric glands, and the intestinal glands are discussed in Chapter 20, the Alimentary System. The kidneys are discussed under the Excretory System, while the vulvovaginal Bartholin's glands and the corresponding Cowper's glands in the male are discussed under the Reproductive System, Chapter 23. There remains now to be described a large group of glands with special functions that are indispensable to the body economy. Other glands can only be mentioned. For example, the mucous membrane are endowed with special glands, such as the apical in the mouth, the glands of Naboth in the cervix, the periurethral glands, etc., which lubricate and protect these linings by their smooth, slightly antiseptic viscid fluid. Some glands in the body have

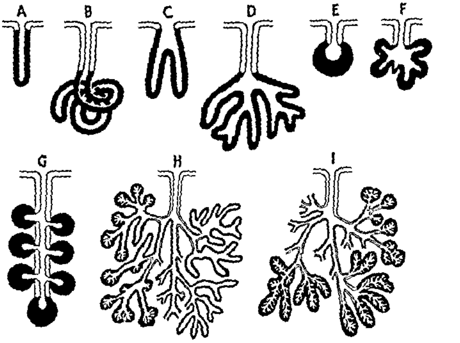

Fig. 366.—Diagram illustrating *simple* and *compound* exocrine glands (after Maximow and Bloom). The black portion is the secretory part of the gland.

A. Simple tubular gland, as found in the crypts of Lieberkuhn in the intestine.

B. Simple coiled tubular gland, as seen in the sweat glands.

C. and *D.* Simple *branched* tubular *glands*, such *as those* of the mucous membrane of the stomach and uterus (without excretory ducts), the small glands of the oral cavity, the tongue, and the esophagus, and some of the glands of *Brunner*.

E. Simple acinous or alveolar gland (*not found in mammals*).

F. and G. Simple *branched* acinous gland, as seen in the sebaceous glands of the skin and the meibomian glands of the eyelids.

H. Compound tubular gland, such as the pure mucous glands *of the oral cavity*, the cardiac glands *of the stomach*, *Brunner's glands*, the bulbourethral and vestibular glands, and the kidney.

I. Compound acinous or alveolar gland, as seen in most of the *larger exocrine* glands—albuminous and *mixed glands of the oral* cavity and respiratory passages, the pancreas, the lacrimal glands, the mammary glands, and the prostate gland.

A *secretion is* the changed *product* elaborated by the gland from *materials* brought to it; an excretion, the *separation of unchanged* waste material. It may be *difficult* to decide whether the product is the *former* or the latter or both.

the salivary flow is the normal way of cleaning the salivary ducts and the mouth. (3) Parotitis may be due to obstruction of the duct by foreign bodies such as calculi. If any of the salivary ducts are obstructed by calculi, infection may occur and will persist, leading to possible abscess formation and subsequent fistula unless the calculi are removed. (4) Parotitis from contiguous infections such as lymphadenitis, peritonsillar abscess, retropharyngeal abscess, actinomycosis, and tuberculosis of the face is secondary and will usually resolve when the primary cause is relieved. (5) Parotitis may follow injuries with or without lacerations on the outside. If the duct is torn, it must be approximated. A small cannula may be used over which the anastomosis is accomplished; then it is removed. Stenosis or atresias will result in a parotid fistula. If the duct's function cannot be restored (see Chapter V, law of fistula), the gland may be inactivated by x-ray therapy, thereby relieving an annoying fistulous discharge of saliva. (6) Parotid swelling occurs from the excretion of drugs and viruses even though a definite parotitis is not present (see discussion on functions of saliva), Chapter 20.

Tumors and Cysts of the Salivary Glands

The Parotid Gland.—*Mixed tumors* (chondrofibromyxomas) of the parotid gland might arise in at least three different ways: (1) From epithelial cells in the salivary gland which undergo mucoid degeneration into a soft jellylike substance with subsequent condensation and chemical transformation into cartilage (Ehrich); (2) from embryonal glandular rudiments (Cohnheim); (3) from remnants of the branchial arches (Virchow thought the cartilage came from Meckel's and Reichert's cartilage). The histological picture is extremely variable, so much so that pathologists have labelled mixed tumors benign and malignant. This is due to the fact that they are usually encapsulated and rarely infiltrative; they do not cause tissue destruction except for the overlying skin, and thus differ from carcinomas which involve the facial nerve; they do recur after removal, but rarely metastasize; they do not often interfere with function unless they reach a very large size. In addition, they may be composed mostly of interstitial or parenchymatous tissue, or both kinds may be present in equal amounts. Lastly, such tumors as angiomas, onchocytomas (Hürthle-cell tumors), and schwannomas may be mixed into the picture with more confusion. In the light of all available facts, it is best to regard mixed tumors as usually malignant although of low grade. Clinically they manifest themselves as painless, hard swellings. *Treatment consists of complete removal.* Formerly it was thought that it was better to wait until the tumor reached at least 3 to 4 cm. before removal so that a false capsule would form by compressing the surrounding glandular tissue. This would afford a line of cleavage, minimize injury to the facial nerve, and ensure complete enucleation. It is perhaps safer

illary gland lies under the mandible and empties its secretion through the submaxillary (Wharton's) duct on either side of the frenum, along with the ducts of the sublingual gland, which is found in this area.

Infections of Salivary Glands

Parotitis.—(1) The epidemic type known as mumps is probably due to a filtrable virus and is infectious. It may be associated with mastitis, orchitis or oophoritis, or pancreatitis (abdominal mumps). (2) Postoperative parotitis due to an ascending infection by way of Stensen's duct from the mouth and is preventable. It is usually seen in badly debilitated or severely sick patients from whom water and food by mouth are withheld. This fact and the edema occurring at the opening of the duct lead to the deduction that it is the obstruction of the duct which causes the parotitis rather than an ascending infection. The same is true in other ducts (bile duct, ureter). Formerly, when typhoid fever was

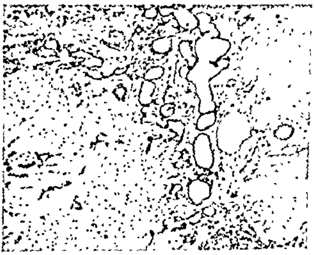

Fig. 367.—Mixed tumor of the parotid gland, showing cartilage and gland tissue.

common, the dry, dirty mouths with sores, the dehydration, and starvation which were a part of the course of the disease were often associated with this type of parotitis. Occasionally suppuration occurs, which demands incision and drainage. The patients become very ill with high temperature. The use of the duodenal suction apparatus permits the free intake of fluids after stomach and intestinal operations, although they are immediately aspirated. In addition, lemon juice and glycerine stimulate a free flow of saliva, which keeps the ducts clean. Local antiseptic solutions used as mouthwashes are useless. Attention to water and protein balance is important as a prophylactic measure. Formerly iodides were used because they are excreted in part through the salivary glands and act as an antiseptic agent. Now penicillin and streptomycin are employed. Close attention to the mouth is important in pre- and postoperative patients: cleanliness should be maintained by gentle brushing rather than by strong antiseptics, which wash out the protective mucus. Stimulation of

cylindroma type; malignant mucoepidermoid tumors, and squamous-cell carcinoma. Clinically malignant tumors are found as hard nodular painless fixed growths. Sometimes there is facial nerve paralysis early. It is impossible to be sure of the nature of a parotid tumor by palpation unless there is early facial nerve involvement. The treatment of malignant growths may be divided into three types: (1) Local excision. In early stages, when the growths are small, local excision with a wide margin is all that is necessary. Here the diagnosis is made by the pathologist as a rule. (2) Complete removal. The moderately advanced cases can be diagnosed clinically and require complete removal of the parotid gland with excision of the facial nerve if involved and a radical dissection of the neck nodes. (3) Palliative measures. In late cases with wide local involvement and distant metastases, palliative measures are indicated. These include local excision of a foul necrotic area, x-ray, and radium therapy.

The Submaxillary Gland.—This is frequently the site of secondary carcinoma from the mouth and tongue due to the close proximity of the submaxillary lymph nodes. In removing the latter, the submaxillary gland is usually taken also. Tumors which are found in the parotid also affect the submaxillary gland, requiring its removal. Retention cysts as well as cystadenomas are found, requiring removal of the gland.

The Sublingual Gland.—This is sometimes cystic and produces a swelling at the side of the frenum. This is known as a *ranula* and should be excised, for it interferes with speech and mastication.

A very rare disease, which involves all of the salivary as well as the lachrymal glands, is known as *Mikulicz's disease.* It may occur as a distinct entity with no patholgical change except round-cell infiltration, or as part of a leucemic syndrome. Treatment is x-ray.

The Liver, Gall Bladder, and Bile Ducts

The liver is developed from the entoderm of the fore gut and grows rapidly, weighing 2 grams at two months, 75 grams at birth, and 1,500 grams at maturity. The liver develops from the entoderm of the fore-gut as a median ventral growth (hepatic diverticulum). Its thick walls surround a cavity which is continuous with that of the gut. Solid cords of cells proliferate from the liver anlage and anastomose, forming the glandular portion of the liver. The duct system develops from the hollow hepatic diverticulum. This is connected with the liver by a single cord of cells which later becomes the hepatic duct. The gall bladder is at first a solid outgrowth of the caudal region of the hepatic diverticulum, which also forms the cystic and common ducts. The duct system then grows into the liver parenchyma from the hepatic diverticulum, forming the larger intrahepatic bile ducts. Gross anomalies of the external ducts are often associated with absence of internal bile capillaries. Since at first the biliary pas sages tend to be solid, a congenitally narrowed or solid state of the gall bladder and ducts is seen. Absence of the gall bladder (as seen normally in the horse and elephant) is not too rare. As a result of early splitting of ducts and gall bladder, these structures are subject to duplication. Bile is secreted in fetuses of three months; therefore babies with obstructions to the biliary tree will be jaundiced at birth. Although no main ductal connections have been demonstrated between the right and left lobes of the liver, there are undoubtedly connections between the smaller ducts of all lobes. The liver lies under the diaphragm and is held in place by its ligaments. Spaces occur be-

to remove the growth as soon as discovered, with complete removal of the tumor and surrounding gland after identification of the facial nerve so that it may be left uninjured.

Benign tumors such as adenomas and fibromas, mucoepidermoid tumors, papillary cystadenoma, and adenoma lymphomatosum should be excised. Dermoid cysts and branchial cleft cysts are sometimes found.

Malignant tumors include carcinomas, sarcomas, and miscellaneous growths such as malignant adenolymphoma (adenocarcinoma lymphomatosum; squamous carcinoma lymphomatosum), adenocarcinoma of the

Fig. 368.—Mixed tumor of the right parotid gland with malignant change and metastasis to the cervical lymph nodes. The patient, I. S., was a woman 69 years of age who had had a growth in the right parotid gland since 1918. At that time it was approximately one inch in diameter. It had enlarged steadily, but within the last two years it had grown very rapidly. At the time of admission she was unable to open her jaw and had severe pain in the right ear.

The patient was prepared for surgery and an incision was made along the inferior angle of the right mandible extending in front of the right ear. The external carotid artery was ligated just proximal to the superior thyroid artery. The right cervical and the submental nodes were removed and found to contain metastatic carcinoma from the parotid gland. The submaxillary salivary gland was also removed, but this showed no invasion. The entire right parotid gland was excised en masse and the facial nerve was preserved.

A, Clinical photograph prior to operation made from a snapshot. *B*, High-power photomicrograph of the lesion showing loose mucoid stroma with masses of fairly uniform-sized epithelial cells. Some of the strands of cells suggest a tendency to gland formation. *C*, Postoperative photograph. (Referred by Dr. D. Faris.)

as a rule. In the lungs the capillaries are compressed between epithelial plates or are without covering (see Chapter 10), allowing for a free exchange of gases. Sinusoids are not connections between arteries and veins (as capillaries are). They are subdivisions of veins. Thus, in the liver, the portal vein enters the organ and is subdivided by cords of hepatic cells into sinusoids. "The sinusoids have therefore been described as formed by the intercrescence of vascular endothelium and hepatic parenchyma." (Cunningham.) This same type of circulation is present in the Wolffian body and is probably a primitive type of vascularization, since a single vessel passing by or through an organ provides it with both afferent and efferent vessels, whereas in arteriovenous circulation there must be two vessels, the currents of which flow in opposite directions.

The portal vein carries about 75 per cent of the blood entering the liver. In this blood is insulin from the pancreas and nutrient material from the alimentary canal to be changed, detoxified, synthesized, and utilized by the liver. There are no valves in the portal vein (see Chapter 19), and normally the pressure equals about 8 to 12 mm. of Hg (108 to 162 mm. H_2O) as compared with 40 to 110 mm. H_2O in the median basilic vein. The great variations in pressure in the systemic circulation is due to the fact that the pressure as measured is the algebraic sum of the positive pressure transmitted from the arterial side and the negative pressure exerted upon the blood column by the thoracic cavity. In the portal circulation the variation is due to the enormous storage function in the operation of liver circulation. This varies as needs arise, and the outflow is controlled by a variable sluice mechanism at the hepatic venous side which is closed by histamine or opened by epinephrine or sympathetic stimulation in the experimental animal. About 1,200 to 1,900 c.c. of blood (average, 1,500 c.c.) go through the liver per minute; since the average weight of the liver is 1,500 grams, flows of 100 c.c. per 100 grams per minute occur.

Although the portal vein carries some oxygen, most of it comes from the hepatic artery which carries about 25 per cent of the blood entering the liver. The pressure in the hepatic artery is about 1200 mm. Hg. Thus, there is in the hepatic artery a small volume of circulation with a high pressure and in the portal vein a large volume of circulation with a low pressure—between the two, a freely expansible tissue framework and a common channel of exit, the hepatic vein. Both sets of vessels are under vasomotor control, and they may influence each other by direct communication or by lateral pressure. Lastly, there is an equalization of these pressures at the junction of the interlobular and intralobular venules of the liver lobules, which occurs through the communications between the veins coming from the capillaries bringing arterial blood and the portal venules. Herrick found that the rise in portal pressure was 1 mm. for every 40 mm. of arterial pressure. In the cirrhotic liver it is 1 mm. for every 6 mm. of arterial pressure. This would vary with the degree of collateral circulation, which occurs at four principal sites:

1. The veins at the site of the obliterated fetal circulation, the paraumbilical veins of the round ligament of the liver.

2. The veins at the cardiac end of the stomach which provide an outlet by way of the esophageal plexus and azygos veins to the superior vena cava.

3. Veins at the anus which connect the portal with the systemic system through the middle hemorrhoidals to the inferior vena cava.

4. Veins at sites within the abdomen where the gastrointestinal tract, or organs arising from it developed retroperitoneally. Also veins which form as a result of adhesions to the abdominal wall due to some pathological process or resulting from a previous nonspecific abdominal operation or one which is purposeful as in omentopexy (Talma) operation.

Since the liver retains such a primitive arrangement, it is easy to understand how it carries on its many functions which necessitate a free communication with the blood stream. This also explains the greater permeability of the liver capillaries to protein.

tween its superior surface and the diaphragm. The falciform ligament is a fold of peritoneum which runs from the anterior abdominal wall to the inferior margin of the liver and covers the round ligament, which is attached to the umbilicus. On the right of this is the right lobe of the liver, and on the left is the left lobe. There are also the caudate and quadrate lobes, and occasionally an extraprolongation off the right lobe, known as Riedel's lobe. The somewhat mottled appearance of the liver is due to its many lobules (about 480,000 in the dog), made of the liver cells which are arranged in cords around a central vein. In between the lobules may be seen the portal canals, which contain branches of the portal vein, the bile duct, and the hepatic artery. The liver has a double blood supply (by the hepatic artery from the celiac axis and by the portal vein from the gastrointestinal tract and the spleen, pancreas, and gall bladder). The venous blood which enters the liver has already passed through one capillary bed and in the liver passes through a second. There are two sets of capillaries within the liver itself through which its blood must go before returning to the systemic veins; the hepatic artery leads to one set of capillaries, the portal vein to another.

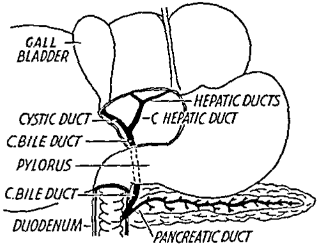

Fig. 369.—Diagram illustrating the relation of the common bile duct and the main pancreatic duct. If there is a spasm or occlusion of the ampulla of Vater, bile may flow into the main pancreatic duct, and if under sufficient pressure, may *be the cause* of acute hemorrhagic pancreatitis. Conversely, pancreatic juice may be regurgitated into the gall bladder, giving rise to acute cholecystitis. Although pancreatic juice *has been found in* the calculous gall bladder, *there is no proof* that it is the cause of gallstones.

Blood flows from the portal veins (in the portal canals) into the interlobular branches, which anastomose freely, then through the capilliform sinusoids to the central veins (intralobular veins), thence through the sublobular veins into the hepatic veins, which empty into the inferior vena cava. The arteries divide into capillaries, which empty into the capilliform sinusoids adjacent to the portal canals, thus ending in the branches of the portal vein. The arteries play a small role in hepatic circulation, supplying blood to the connective tissue about the portal canals and the surface of the liver. However, sudden occlusion of the hepatic artery is fatal in over 50 per cent of experimental animals. If penicillin is given immediately after ligation, the dogs live (Markowitz, Rappaport, and Scott). Since the liver is thought to be the source of hypertensinogen (together with the kidney), a reduction in arterial and portal vein flow reduces experimentally produced hypertension. It is not known whether this is due to a decrease in hypertensinogen or an increase in the vasodepressor substance (Davis, Tanturi, and Tarkington). The liver sinusoids (like the lacunar vessels or parasinoidal sinuses of the dura) have as thin walls as ordinary capillaries, but their diameter is greater. The close apposition of the endothelium to the cells of the liver allows a free interchange of fluids. The capillaries in general have some connective tissue about them

3. *Cardiac output and renal blood flow.* Cardiac output and renal blood flow measured by methods utilizing similar principles show that about 25 per cent of the basal cardiac output passes through the splanchnic circulation. The kidneys receive about 1,200 c.c. of blood per minute, and the brain about 800 c.c. per minute. We have noted in Chapter 18 that the cerebral circulation must be kept constant. Therefore, vascular regulation must fall upon the liver and kidneys.

4. *Variations in blood flow.* A variation of from 40 to 160 c.c. per minute per gram of liver tissue has been observed in animals. In the human being the range of blood flow is large, and all evidence points to the fact that these variations are due to general rather than to focal alterations in vasomotor activity. Moreover, this vasomotor activity affects the splanchnic arterioles also, since vasoconstriction in the liver alone would trap blood in this organ. Hepatic vasodilation would do the same thing by raising the pressure in hepatic arterial capillaries with resulting dynamic obstruction to portal outflow.

5. *Effect of exercise on blood flow.* Simultaneous measurements of blood pressure, cardiac output by the direct Fick method (Chapter 13), renal blood flow by the sodium p-aminohippurate clearance (Chapter 23), and hepatic blood flow by the method just described have revealed the following changes: (1) little change in blood pressure, (2) cardiac output almost double, (3) decreased kidney and liver blood flow (that is, the splanchnic vascular bed), with a greater decrease in the liver than the kidneys, (4) increased blood flow to the brain, heart, and muscles during exercise at the expense of the liver and kidneys, while the heart is spared the effort of supplying sufficient blood to meet the total need of exercising muscles.

6. *Effect of standing upright on blood flow.* There is a fall in cardiac output and not much change in mean arterial pressure, but there is a smaller pulse pressure due to diminished stroke volume. Vasoconstriction in the hepatoportal and renal vascular beds forms part of the diminished vascular space and the increased total peripheral resistance, accounting for reduction in local flows despite maintenance of arterial pressure. This mechanism of ischemia in the hepatic and splanchnic areas to provide blood to areas more sensitive to the effects of ischemia is part of the compensatory mechanisms described in shock (Chapter 14), hemorrhage (Chapter 13), dehydration (Chapter 11), and normal physiological variations.

If the upright position results in hepatic ischemia, then in convalescence from inflammations of the liver, especially hepatitis, patients should remain recumbent, because adequate blood flow is necessary to produce resolution (Chapter 4).

7. *Effect of pyrogenic reactions on blood flow.* With chills and fever there is an increased cardiac output, with increased blood flow through the kidney and the liver (see Chapter 4) and an increase in blood pressure. Liver function is diminished. This may be due to the heavy work of the liver in removing toxins or other pyogenic substances, thus slowing its ability to excrete bromsulfalein. These same changes occur even if fever is not present.

8 *Effect of cirrhosis on blood flow.* Atrophic cirrhosis produces a fibrotic change which results in simplification of blood vessels, changing the tortuous complex plexuses (arterial and venous) to simplified, reduced, and distorted vessels, thus reducing blood flow. Perfusion experiments of Herrick showed that the hepatic artery in a cirrhotic liver may be perfused more easily than that in the normal liver, and Dock found a decrease in arterial resistance. Studies of the estimated hepatic blood flow in cirrhosis shows it to be less than normal. Moreover, the hepatic oxygen arteriovenous difference in cirrhotic patients exceeded the normal range. Also, there is a reduction in hepatic venous oxygen saturation. In the kidney, oxygen arteriovenous difference remains about the same despite wide changes in blood flow, indicating that the variation of oxygen consumption by renal tissue is a function of blood flow. Since oxygen excretion rises when blood flow through the liver is decreased during standing, it is probably correct to assume that the increased hepatoportal oxygen excretion in cirrhosis is due to a more sluggish flow of blood through active tissues. Hepatic tissue is one of the most impor-

The liver cells are intimately connected both with the blood capillaries and radicles of bile ducts. From both sets of vessels minute channels pass into the liver cell (intracellular canals). The liver is well supplied with lymphatics, which accompany the portal and hepatic veins: the former empty into the celiac nodes; the latter pierce the diaphragm, pass through the thoracic nodes about the vena cava, and empty into the thoracic duct. A superficial set of lymphatics drains the parietal and visceral surfaces of the liver, and there are communications between the superficial and deep channels and also between the lymphatics of the gall bladder and the superficial lymphatics of the liver—hence the necessity for removing liver parenchyma in cholecystectomy for carcinoma of the gall bladder.

In addition to the polygonal cells which carry on the function of the liver, there are stellate (Kupffer) cells which are found in the sinusoids (small spaces between the liver cells). These cells have a special function which is phagocytic and are part of the *reticulo-endothelial system.* The beginnings of the biliary tract are known as bile *canaliculi* (ductus biliferi). They are small spaces between the cords of hepatic cells, which drain into interlobular ducts, that unite, forming the hepatic ducts (lying in the portal canals), which in turn come together to form the large right and left hepatic ducts. Injected specimens resemble the branches of a tree. The right and left hepatic ducts unite to form the *common hepatic duct,* which is joined by the cystic duct to form the common bile duct. This enters the duodenum at the ampulla of Vater.

The gall bladder is a blind sac which stores bile, concentrates it, and then contracts in response to a hormone (cholecystokinin) which is found in the duodenum. If the gall bladder is removed, the bile ducts dilate to take on its function in part. Although normally the bile capillaries are separated from the blood vessels by hepatic cells, if great distention of the ducts occurs due to obstruction, they may rupture, causing bile to escape into the perivascular tissue, with resulting jaundice.

Physiology of the Liver.—The liver is the largest single organ in the body with important functions. Its extirpation is fatal to animals and man, yet removal of 80 per cent of it leaves enough liver to carry on its function. Moreover, it regenerates so rapidly that within six to eight weeks it regains its normal size. We may look upon it as a large gland strategically placed between the gastrointestinal tract and the blood stream, acting as a selective barrier, metabolizing, detoxifying, and elaborating (for further physiological disposition) various substances that come to it through the portal vein.

Bradley and co-workers have introduced a long radiopaque ureteral catheter in the antecubital vein and have passed it, under fluoroscopic control, through the superior vena cava, the right atrium, the inferior vena cava, and then into one of the right hepatic veins. With this technique the following studies were made:

1. *Hepatic blood flow.* Hepatic blood flow was estimated by the bromsulfalein clearance technique. Since this drug is removed almost exclusively by the liver, the rate of intravenous infusion is equal to the rate of hepatic removal when the bromsulfalein concentration in the blood is kept constant. Dividing the calculated rate of removal by the difference between bromsulfalein concentrations in the hepatic venous and peripheral arterial (or venous) blood will yield a value which is roughly that of hepatic blood flow. There may be three sources of error in this technique: (1) some of the dye is removed by the tissues outside the liver, (2) the concentration in peripheral arterial blood may not equal concentration in the portal vein, (3) blood is sampled from only one hepatic vein and may not be representative of the liver as a whole.

2. *Normal estimated hepatic blood flow.* Normal estimated hepatic blood flow is from 950 to 1,840 c.c. per minute per 1.73 $M.^2$ of body surface. The average is about 1,500 c.c. per minute.

bile is acid (pH 5.0 to 6.0). Organic materials make up 60 per cent of its solids. Gall bladder bile is about seven times more concentrated than liver bile. Bile salts are sodium glycocholate and taurocholate. Bile pigments are derived from hemoglobin and are formed in the reticulo-endothelial cells as well as in the liver, so that the liver excretes bile pigments brought to it as such, and in addition, secretes those which it forms. Before passing through the liver cells, the bilirubin is known as "prehepatic" or reticulo-endothelial bilirubin. On passing through the liver cells, bilirubin is converted from a colloid to a crystalloid by removal of a protein molecule; it then becomes "posthepatic" bilirubin, in which form it is excreted in the feces. Here it undergoes reduction by bacteria to form urobilinogen (stercobilinogen). A part of this is excreted in the stools, and by oxidation it is converted to urobilin (stercobilin). A part of the urobilinogen is absorbed and brought to the liver for re-excretion in the bile. Normally the bilirubin and only traces of urobilin appear in the urine. Bile aids in fat digestion and absorption. It is also said to be antiputrefactive and laxative. If bile is completely excluded from the body, death ultimately results. Lately, it has been shown that bile aids in the absorption of vitamin K from the intestine, thereby facilitating the formation of prothrombin, which is necessary in blood clotting. Other functions: Bile acids promote the formation of bile and aid in the absorption of iron, calcium, and vitamins D, E, and carotene. After bile acids have performed their functions, they are reabsorbed by the intestines (80 to 90 per cent) and returned to the liver by the portal system. Some bile acid is lost by excretion in the feces and urine and still less absorbed by the lymph channels.

7. Vitamin metabolism. (a) Conversion of carotene to vitamin A. (b) Vitamin D is stored to a large extent in the liver. (c) Vitamin K is necessary for the formation of prothrombin. (d) The liver is a storehouse for vitamin B complex. Some of these factors aid in detoxification and are depleted in so-called toxic states (thyrotoxicosis, burns, toxemia of pregnancy). They aid in the oxidation of carbohydrate and the synthesis of fat from carbohydrate and protein by participation in enzyme system.

8. Blood-forming function is present in the embryo, and the liver is a storage depot for the erythrocyte maturing factor.

9. Ascites is associated with liver disease and is not due solely to the increased hydrostatic pressure in the portal system. Other factors causing it are (a) lowering of serum proteins with decrease in osmotic pressure, (b) dietary factors, (c) disturbance of ability of liver to handle water, (d) increased permeability of portal capillaries from toxins or anoxemia and causes unknown, (e) inability of liver to help destroy the antidiuretic hormone of the pituitary. It is because of the intimate relation between hepatic function and the development of ascites in some cases that the disease is listed here.

10. Iron and copper storage, blood volume regulation, and heat production.

Functional Diseases of the Liver

Hepatic Insufficiency.—Bearing these functions in mind, we may understand what is meant by *hepatic insufficiency.* Mann performed hepatectomy (removal of the liver) in dogs. They developed hypoglycemia, or low blood sugar (see 1 above), azotemia, or accumulation of nitrogen metabolites in the blood (see 2), acidosis (see 3), toxemia, high fever, and central nervous symptoms such as stupor, convulsions, and coma (see 4), bleeding from mucous membranes (see 5), and jaundice (see 6). These same symptoms in milder form are seen clinically in hepatic insufficiency.

tant sites of oxygen uptake. Augmented oxygen excretion indicates relative ischemia of hepatic tissue. Hepatic flow is reduced in cirrhosis as a result of increased vascular resistance. This acts to produce a relative ischemia of hepatic tissues in which the excretive (parenchymal) cells figure much less prominently than in the normal organ.

9. *Relation of liver blood flow to cardiovascular dynamics.* The liver plays a role in cardiovascular dynamics since it acts with the kidney as an active reservoir for daily circulatory requirements.

Among the chief functions of the liver are the following:

1. Carbohydrate metabolism. The liver stores ingested carbohydrate as glycogen. Other sources of glycogen are protein, the glyceride of fat, and lactic acid produced in the muscles. Glycogen stores are mobile.

When blood sugar is high after the ingestion of a meal, the liver stores glycogen and then reconverts it to glucose when the body requires it. Livers with adequate stores of glycogen are less susceptible to toxic agents or processes such as chloroform or anoxemia. Excess glucose is converted to fat. When there is too little glucose, fat is mobilized and partly broken down by the liver to ketone bodies. Carbohydrate inhibits this antiketogenic function.

2. Protein metabolism is one of the most important functions of the liver, and when the organ is diseased this is the last function to cease. Among the various protein functions are (a) The synthesis of amino acids into new proteins as needed for the formation of body protein; (b) the elaboration and maintenance of plasma proteins—albumin, globulin, fibrinogen, and prothrombin; the supply of proteins to the tissues is regulated through the plasma proteins; (c) storage of synthesized protein in a labile form so that it may be quickly mobilized; adeqate stores of these proteins protect the liver from the effects of various toxins, albumin, euglobulin, pseudoglobulin; (d) protein is necessary for and accelerates the formation of acholic acid; (e) deaminization; the nitrogenous portion of the amino acid molecule is converted to urea and excreted; the remainder of the molecule is metabolized as de-glucose and fat.

3. Fat metabolism. Fat circulates in the blood as neutral fat (glyceride), cholesterol esters, and phospholipids and is present in the liver in these forms. The fatty acids combined as liver phospholipids and glycerides are more unsaturated than the fatty acids found in other tissues. Liver fat comes from the ingestion of fat, mobilization from fat depots, and synthesis of fat by the liver from carbohydrate and protein.

Normally only 2 to 4 per cent of the liver weight is due to fat. As a result of toxins, excessive amounts of cholesterol and alcohol, or deficiency in choline, the liver stores fat, thereby rendering itself susceptible to the effects of hepatic toxins.

The liver is the principal site of formation of ketone bodies. Lipotrophic factors influence the amount of liver fat by preventing its deposition or increasing its rate of removal. Lecithin was first found to prevent fatty infiltration of the liver in depancreatized dogs. Later choline was shown to be the constituent of lecithin that had this effect. Other lipotropic substances are lipocaiac, inositol, and certain amino acids. Choline acts by promoting synthesis of phospholipid in the liver as well as in the intestine.

4. Detoxification of toxins through stored glycogen and carbohydrate and defense against bacteria through the Kupffer cells.

5. Blood-clotting function through the production of fibrinogen and prothrombin.

6. Production of bile (containing cholesterol, the bile salts, and the bile pigment), bilirubin and its oxidized product biliverdin, and lecithin, inorganic salts (sodium chloride and sodium bicarbonate).

Bile is secreted continuously by the liver cells in amounts varying from 500 to 700 c.c. per day. Besides acting as a vehicle for the elimination of waste products, it has many complex functions. Liver bile is alkaline (pH 8.0 to 8.6); gall bladder

2. The *degree of damage* of liver cells. This is established by the fact that the liver will hold on to some of its functions until almost completely destroyed. The most important functions of the liver and therefore those which are not impaired until there is extensive and *severe* damage are those of protein metabolism. This impairment can be detected by the estimation of serum albumin and globulin and the albumin globulin ratio, and the prothrombin level before and after administration of vitamin K. The total serum protein is not as helpful, although it may be determined quickly and very simply by the copper sulfate gravity method. Since serum globulin may be formed elsewhere than in the liver, a very high globulin and low albumin may give a normal total value. However, a *low* total serum protein is very significant when intake and protein loss are normal. Normal value of serum albumin averages 4.1 and globulin 2.7, with an A-G ratio of 1.51 (see Chapter 15). It is usually normal in hemolytic and obstructive jaundice, high and reversed in hepatocellular jaundice. The prothrombin time is taken twenty-four hours after the administration of 2 mg. menadione intramuscularly. It is prolonged in liver damage. Other tests which are difficult and which are not routinely necessary are alkaline phosphatase, total cholesterol (150 to 220 mg. per cent normal; normal in hemolytic and hepatocellular jaundice, high in obstructive jaundice), and cholesterol esters (60 per cent of total is normal).

3. *The cause of jaundice.* The various causes of jaundice will be described later in this chapter. When one examines these causes it is apparent that the jaundice may be due to: (a) obstruction, partial or complete due to causes in the bile ducts or within the liver; (b) destruction of liver cells or hepatocellular damage, local or diffuse (so-called intrahepatic jaundice); (c) hemolytic diseases; (d) various combinations of the foregoing. The surgeon is vitally interested in trying to diagnose the cause of the jaundice as early as possible so that he may remove the cause and spare the liver. Formerly exploratory operation was resorted to frequently. Now the surgeon is aware that in certain types of infectious hepatitis exploration is not only not innocuous, but dangerous. It is probably correct to assume that in all types of jaundice there is some hepatocellular damage. If this is diffuse and comes on early in the disease, the cause is probably inflammatory and not an organic obstruction. We have already indicated the tests which may be used in such cases. A positive finding is meaningless without a very careful history and physical examination together with a meticulous study of all symptoms and signs. Some of these findings will be discussed later under Jaundice. However, we should state at this time that a careful examination of the stool, the vomitus if any, and the urine can be of great help in making a diagnosis. The nurse must be taught to chart carefully, and she must be instructed as to the meaning of a gray or white or clay-colored (acholic) stool, of dark orange-colored urine, of vomitus without bile, of jaundice with normal urine (acholuric) and stools, because color is at least a clue.

Certain tests are useful in the differential diagnosis between so-called surgical and nonsurgical jaundice, and when these tests are not conclusive, then surgical exploration is the best policy to follow.

We have reviewed earlier in this chapter the physiology of bile pigment metabolism. The significant fact upon which tests are based are as follows: Bilirubin is formed in the reticulo endothelial cells from hemoglobin. As it circulates in the blood stream on its way to the liver, it is bound with a plasma protein. It does not pass into the urine. It is a colloidal compound which is readily oxidized. It is not soluble in water or Ehrlich's solution, but it is soluble in alcohol. It is known as prehepatic or reticulo-endothelial or bilirubin I or A. It is taken to the liver where it is converted into bilirubin II or B or posthepatic bilirubin. It is colloidal but behaves like a crystalloid since it is soluble in water. It is combined with bile salts, oxidizes slowly, and passes readily into the tissues when not excreted. It is soluble in water, alcohol, and Ehrlich's solution. It is supposedly freed of its protein connection. In the intestine the post-

The surgeon is vitally interested in liver function, and he attempts to evaluate this and the function of the kidney, which is intimately associated with it, by various tests. (See Chapter 2.)

Tests for Liver Function

Because of the enormous functional reserve in the liver, tests are apt to be misleading. It has been stated that if the morbid changes are patchy, then more than 80 per cent of the liver may be damaged without any variation in liver function tests. Other factors which may give rise to erroneous results are as follows: (a) Excretory tests are subject to error due to associated kidney damage, failure of the substance to be absorbed due to disease of the bowel, or too rapid excretion of the bowel. (b) Tests based upon metabolic functions of the liver are subject to the same error as in (a), and, in addition, a low or high renal threshold. (c) Urobilinogen is formed by action of bacteria in the bowel, yet this action may take place by bacteria in the bile ducts and by bacteria acting on collections of bood as in hemorrhagic cysts of the ovary. (d) There may be technical errors in executing and reading the tests. It is wise to consider the tests in the light of the history and all of the physical findings, remembering always that any laboratory test is but a symptom, and a transient one at that. Therefore, no single test, just as no single symptom, is pathognomonic of a specific liver disease. Moreover, several pathological states may be present at the same time.

Much has been written recently about "screening tests" for liver disease. While this is an excellent method of scientific investigation, the cost to a private patient for all the tests necessary to produce screening would be prohibitive. Therefore, a practical approach to the problem is the selection of such tests as are absolutely necessary to supplement the clinical findings so that a proper diagnosis may be made and prognosis given. In the following paragraphs we shall mention many of the available tests, and discuss those which we have found to be most useful.

Tests often help in three ways:

1. The *extent* of the damage. This may be revealed by a test based on a failure of one of the less important functions of the liver and which would be apparent only if the lesion were extensive. In jaundiced patients some hepatocellular damage is usually present and it will be widespread. However, the duration of symptoms must be correlated with the findings. If the illness has been brief and the test indicates a widespread injury (35 per cent retention after one hour), infectious hepatitis may be the cause, or poisons causing extensive damage. If the history indicates a longer duration, the pathology is more apt to be patchy as in obstructive types of jaundice. For this, the *bromsulfalein test* is useful. In normal persons bromsulfalein is excreted almost entirely by the liver. Five milligrams per kilogram of body weight are injected, and there should be practically no retention after thirty minutes. In hemolytic jaundice the test is normal. In hepatocellular jaundice it is elevated; also in obstructive jaundice. In this group of laboratory aids belongs the hippuric acid test. Sodium benzoate is normally detoxified by the liver by conjugating it with aminoacetic acid to hippuric acid which is excreted in the urine. Sodium benzoate, 5.9 Gm., is given by mouth, and the quantity of hippuric acid excreted in the urine is determined by hourly examination for four hours. Normally 3 to 3.5 Gm. are excreted. This test assumes normal kidney function, and therefore a phenolsulfonphthalein test should be done at the same time. *Other* tests which are used to show the extent of the liver damage are: thymol turbidity (abnormal lipoglobulin) (0 to 3 units normal; normal in hemolytic and obstructive jaundice before liver damage occurs, positive in hepatocellular jaundice), galactose tolerance, cephalin flocculation (failure of protection of gamma globulin by albumin) (0 to + normal; normal in hemolytic and obstructive jaundice, positive in hepatocellular types), and blood sugar determination (hypoglycemia).

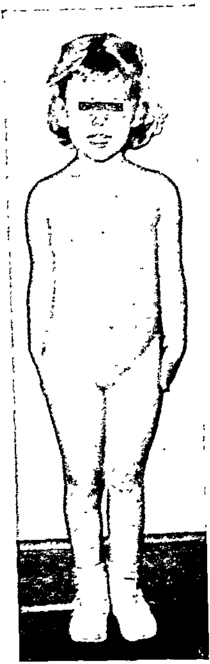

Fig. 370.—Congenital atresia of common bile duct with normal hepatic and cystic ducts and gall bladder Baby K. was brought to the hospital when 4 weeks old in July, 1945. At that time she was deeply jaundiced and the stools were white in color. The child appeared to be acutely ill. After careful study a diagnosis was made of congenital atresia of the common bile duct and operation was performed in July, 1945. At operation the liver was found to be enlarged and was firm. The gall bladder was present and contained a small amount of bile. The bile was aspirated and physiological saline was injected through a small hypodermic needle. However, it remained within the gall bladder. The common bile duct appeared to be a fibrous cord and there was some dilation of the hepatic ducts. A cholecystoduodenostomy was performed using a single layer silk suture technique. The photograph is that of the child as she appears now at 4 years of age. She is in an excellent state of health. (Referred by Dr. Herbert Call.)

hepatic bilirubin is reduced by bacterial action to urobilinogen, which is excreted in the feces in great part. Some is reabsorbed and re-excreted. Normally, traces of urobilinogen and no bilirubin are excreted in the feces.

Tests

1. Van den Bergh reaction is performed by using solution A (sulfanilic acid, concentrated hydrochloric acid, and water) and B (sodium nitrite and water). The direct reaction occurs without the addition of alcohol. Normal bile and the serum in obstructive jaundice give the prompt direct reaction; that is, the reaction of posthepatic bile. The indirect reaction requires alcohol (to separate the prehaptic bilirubin from its protein molecule). Normal serum, the serum in hemolytic jaundice, and the bilirubin formed in blood extravasations give the indirect reaction. All sera which give the direct also give the indirect reaction. A variation of the direct reaction is the delayed and biphasic reaction (color appears promptly but takes more time to change to violet); this occurs in jaundice due to extensive liver damage.

2. Icteric index is the comparison of the serum with that of a standard solution (potassium bichromate); normal, about 5 to 10. An index over 100 means complete continuous obstruction or severe and extensive destruction of liver cells. Less than 100 may indicate calculus obstruction or hepatitis of a mild type. A fluctuation reading means a stone in the common duct as a rule. The test should be repeated often to get the depth of the jaundice. With a lower icteric index (30 to 50) hemolytic or prehepatic jaundice is suspected and is proved by a test of the urine for urobilin.

3. Quantitative serum bilirubin (0.1 to 0.5 mg. per cent is normal). Icteric index of 100 usually means about 12 mg. per 100 c.c. The test is useful to know the degree of jaundice. In hemolytic jaundice it is low, 0.2 mg. to 4 mg. In hepatocellular jaundice it is high, 15.0 mg. per cent or over. In obstructive jaundice it is also high, 10 mg. per cent or over.

4. Test for duodenal damage. Using a Miller Abbott or Kantor type tube, checked for position by the fluoroscope, one can determine whether bile is entering the intestinal canal. Even a Levine tube may be used. This is especially useful in babies with possible atresia of the common bile duct, because the stool will contain some bile which is secreted in the succus entericus. In adults, small amounts indicate incomplete obstruction, blood may mean carcinoma, and no bile means complete obstruction, and, since in hemolytic jaundice stones are frequently present, producing obstruction, this method, with the addition of blood smears and fragility test, may help in the diagnosis of both conditions.

5. Examination of the urine for bilirubin and urobilinogen—normally, traces of urobilinogen and no bilirubin. In hemolytic jaundice there is no bilirubin but increased amounts of urobilinogen. In jaundice with complete obstruction, the urine contains bilirubin but usually only traces of urobilinogen (may be more due to bacteria in the obstructed ducts). Urobilinogen is found in the feces (2 to 4 Gm. per day) normally. In hemolytic jaundice, it is high; it is normal or low in hepatocellular jaundice and absent in obstructive jaundice.

In intrahepatic jaundice the urine contains bilirubin and urobilinogen in the incipient and recovery stage but very little urobilinogen in the advanced stage.

Congenital Anomalies of the Liver and Bile Ducts

These are so common that the so-called normal pattern is found in only 60 per cent of cases.

The liver varies greatly in size and position normally. Sometimes a wide tongue of liver descends from the inferior margin lateral to the gall bladder and may reach as far as the iliac crest. It is known as "Riedel's lobe." A similar process occasionally descends from the left

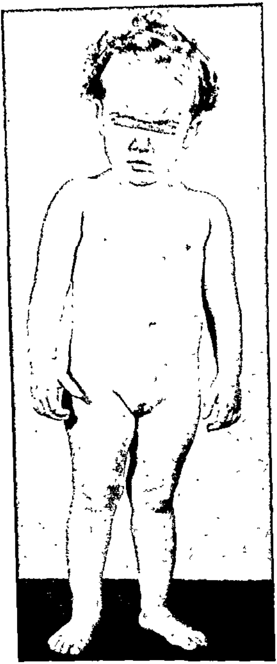

Fig 371.—Congenital absence of common bile duct, cystic duct, and absence of gall bladder. S A. S. was brought to the hospital when 2 weeks of age deeply jaundiced. She was studied for approximately two weeks, and during this time she was given many blood transfusions in an effort to correct a severe anemia. At operation no gall bladder or common duct was present. However, the hepatic ducts ended blindly at their junction. This junction was slightly dilated. An anastomosis was made between the common hepatic duct and duodenum over a piece of No. 6 catheter about 2 cm. long, using a single layer of interrupted silk stitches. The catheter passed per rectum on about the fourth day postoperative. The photograph is that of the child who is now 2 years of age and who has had no symptoms since operation. (Referred by Dr. I. Rosenbaum.)

lobe. Congenital irregularities may produce extra fossae and lobes as are commonly found in the fetus and in higher apes normally, or the liver may be divided up into a large number of distinct and separate lobes.

Arterial anomalies are extremely common. These consist of the following: (1) Accessory cystic arteries; a dozen or more different types of origin of the cystic artery have been described including abnormal position of cystic artery (anterior to common duct, to the left or right of the cystic duct, etc.). (2) Multiple hepatic arteries may be present instead of a right and left branch; there may also be an abnormal position of the right hepatic artery (to the right and anterior to common duct, under the common duct, and to the right running parallel to the cystic duct and to its right or left or posterior to it). Division of the right hepatic is fatal in over 50 per cent of the cases. (3) The gastroduodenal artery may lie anterior to the common duct and frequently a small branch from this vessel or the hepatic artery lies in the anterior wall of the common duct.

Venous anomalies and variations occur in the portal vein which bifurcates before entering the liver in 90 per cent of the cases; in 10 per cent it does not. It may receive many cystic veins and sometimes none are found. The coronary right gastric and splenic usually enter separately. Sometimes the coronary enters the splenic and also the right gastric.

The ducts are also subject to great variations. The common hepatic duct bifurcates inside the liver in 90 per cent of the cases; in 10 per cent it does not. There may be two or three cystic ducts which may all enter the common hepatic, the right hepatic, or at various levels in the common duct. The common duct may be absent, atretic, cystic, or duplicated. Duplication of the gall bladder occurs, and sometimes it is completely atretic. The cystic duct may run parallel to the common duct or enter at various angles, and the common duct may be extremely mobile so that during surgery it may assume a "/\" shape when the gall bladder is seized with forceps.

All of this discussion is extremely important because it emphasizes the care and caution that should be exercised during operations upon the biliary tract if injuries are to be avoided. It is also important because of the curative procedures that are occasionally possible in congenital atresia of the bile ducts and in cysts of the common duct.

Congenital Atresia of the Bile Ducts

We have seen how the bile ducts permeate the liver in the embryo in a solid state. It is easy to understand, therefore, that when there is atresia in the duct system, it is apt to involve all ducts in most of the cases (80 per cent in our series of twenty cases). In about 20 per cent there will be patency of the intrahepatic ducts and in one or more of the extrahepatic ducts; namely, hepatic, hepatic and part of common hepatic, and cystic. In addition, the gall bladder may be atretic or stenosed or

gall bladder formation. Whatever the cause, as the pouch increases, it consumes more and more of the bile, with less entering the duodenum.

The predominant symptoms and signs include the presence of an enlarging, painless mass in the right hypochondrium and epigastrium and increasing jaundice which is extremely slow in its development. The stools vary in color with the degree of obstruction but rarely remain white. Differential diagnosis includes congenital anomalies of the kidney and ureter and pancreas. Since they are retroperitoneal, tympany on percussion may reveal the presence of bowel anteriorly. X-ray of the gastrointestinal tract to help rule out duplication of the stomach or duodenum

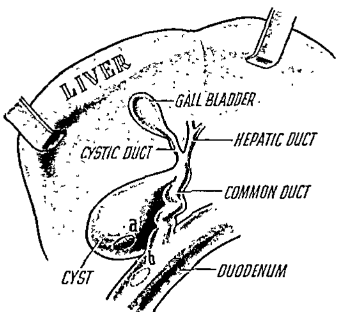

Fig. 372.—Congenital cyst of the common bile duct. The diagram is that of the condition found in a girl 4 years of age who came to the hospital complaining of pain in the abdomen of four weeks' duration, jaundice, loss of weight, and a large tumor mass in the abdomen. Her illness began about four weeks prior to admission with pain in the right upper quadrant. The patient became slightly jaundiced and this gradually deepened. On the third day of illness the referring physician stated that there was a mass about the size of an egg just to the right and below the umbilicus. On admission this tumor was easily felt and extended to three inches below the right costal border. Below the mass, filling the right lower quadrant and extending over beyond the midline, was another swelling approximately 20 cm. in diameter, and this was thought to be a cystic structure. The preoperative diagnosis was congenital cyst of the common bile duct with partial obstruction to the latter together with a greatly enlarged liver due to the obstruction The diagnosis was based upon the following facts: (1) increasing jaundice, (2) a rapidly enlarging mass in the right hypochondrium which was in a great measure cystic and which was practically painless; (3) no chills, fever, or leucocytosis; and (4) the patient was a girl and the lesion is usually encountered in the female sex.

Upon opening the abdomen a large cyst measuring approximately 30 cm. was encountered on the right side; 1400 c.c. of bile were aspirated from the cyst. The common bile duct was identified and found to be somewhat dilated and extremely tortuous and long. The gall bladder was found to be very small and was embedded in the substance of the liver, however, it did contain bile. The large cyst was attached to the common bile duct. The cyst was anastomosed to the duodenum as illustrated in the diagram at *a* and *b*. The child recovered and has remained well. The anastomosis of the cyst to the duodenum is the procedure of choice in such cases Other methods of treatment have not been very satisfactory One case reported where the cyst was extirpated was followed four years later by splenomegaly and splenic anemia for which splenectomy was necessary and this may have been due to an intrahepatic portal obstruction or thrombophlebitis of the splenic or portal vein or portal bed irritation. External drainage alone is practically always fatal and so is marsupialization.

large and filled with mucus or "white bile," being unconnected with patent ducts or distended with bile, indicating connection with a patent duct system. Rarely all the ducts are potentially open but obstructed because of retained thick mucus.

In all cases there will be varying degrees of portal cirrhosis, depending on the duration of the obstruction. The liver is hard, large, and dark green. Sometimes the spleen is also enlarged.

The chief symptom is jaundice which is usually present at birth but may be subclinical for one to two weeks. The stools are white or clay colored and of puttylike consistency. Sometimes there is a little bile pigment in the stool due to the high saturation of bile pigment in all organs. Some of this is excreted in the intestinal tract. The urine is dark in color and contains bilirubin; diagnosis is made by a process of elimination, and, therefore, surgery is not usually done before the third or fourth week of life. The following conditions must be ruled out: icterus neonatorum which usually disappears by the second week; erythroblastosis fetalis which is usually fatal early in life; the history of an Rh-negative mother with previous pregnancy and transfusion or stillbirths—presence of erythroblasts in large numbers help in excluding this; congenital syphilis; icterus from sepsis or hemolytic crises are not accompanied by acholic stools, and in the latter there is increased fragility of the red cells.

The treatment is surgical. After careful preparation with vitamin K and transfusions, a right paramedian muscle-splitting incision is made. The transversalis fascia and the peritoneum are incised transversely. This is important because where there is complete atresia of the duct system, nothing can be done, and as the liver enlarges and some ascites develops, the wound may break open unless carefully made and sutured. A systematic inspection is made starting with the gall bladder. Any duct containing bile, no matter how small, may be used. If there is bile in the gall bladder, it too may be employed. The anastomosis is made to the duodenum, and the duct is preferable to the gall bladder. We have anastomosed a patent hepatic duct to the duodenum using a piece of No. 6 catheter about 1 inch (2½ cm.) long with successful outcome. One of our patients is now 9 years old and in good health. Three notes of warning: Tie all bleeding vessels so that the operative field is clean; be sure the anastomosis is to the duodenum and not to the hepatic flexure of the colon; if all ducts seem atretic, inject saline solution—this may open the channel entirely or sufficiently to allow bile to appear in the hepatic duct which may then be anastomosed.

Congenital Cyst of the Common Duct

Choledochus cyst is rare. We have seen two cases both in female children aged 2 and 4 years. The cysts may occur in adults. The cause is unknown, but various theories have been advanced: anomalous direction of the duct, congenital stenosis, duplication, diverticulum and accessory

Infectious hepatitis is probably a virus disease, although its exact mode of transmission is unknown. It may occur sporadically or in epidemic form. The chief symptom is jaundice, although in the preicteric phase other symptoms are present; namely, chilly feeling, headache, malaise, weakness, anorexia, nausea, and occasionally vomiting. The liver is tender and enlarged with the onset of jaundice. The disease is usually over in about two weeks. However, severe cases accompanied by coma, hemorrhagic manifestations, and even death from acute hepatic necrosis may occur. There may be relapse or recurrence.

Homologous serum jaundice occurs after transfusion with plasma or whole blood. The jaundice varies in depth and persistence. There may be fever, anemia, great hepatic enlargement with or without ascites, abdominal pain, and hemorrhages. Sometimes the disease runs a rapidly *fatal course; usually it is benign. It is to be distinguished from blood* incompatibilities which are also accompanied by jaundice.

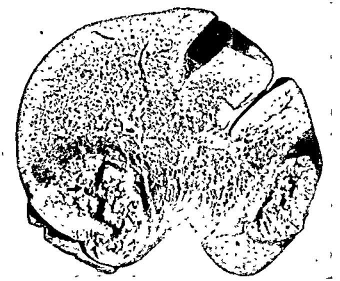

Fig. 373.—Abscessed liver in cross section. Man, aged 49 years, with amebic dysentery. Arrow points to one of the two large amebic abscesses. There was also a subphrenic abscess in this case Patient died from a perforation at the site of an amebic ulcer in the colon, with general peritonitis.

Cholangiolitic cirrhosis may be a late residue of infectious hepatitis. It is chronic with jaundice, large liver, and spleen, and it is apparently incurable.

Weil's disease is caused by a spirochete, the *Leptospira* icterohemorrhagiae. The usual vector is the gray rat. The disease manifests itself by chills and fever, great prostration, jaundice, hepatolineal enlargement, hemorrhagic tendency, and frequently renal failure. The disease can be diagnosed by finding the spirochete in the blood under dark-field illumination or by injecting blood of the patient intraperitoneally in a

or diverticula of these organs and intravenous pyelograms to rule out kidney anomalies help confirm the diagnosis.

Treatment consists of surgical exploration, examination of the cyst, and anastomosis of the cyst wall to the duodenum. Extirpation of the cyst is hazardous and may result in stricture of the duct; external drainage and marsupialization are practically always fatal. Our two cases recovered. One child is in good health eight years after operation (12 years of age now). The other is well two years after surgery.

Injuries and Diseases of the Liver

Injuries of the liver are seen following accidents and from stab and bullet wounds. The most serious is rupture of the liver, which gives rise to shock, due to intra-abdominal hemorrhage. Such injuries are usually associated with other intra-abdominal or thoracic contusion or lacerations (see Chapter 20). The diagnosis is suspected from the history, which usually reveals the site or position of the injuring force, or there may be ecchymosis or suffusion of blood over the region of the liver. There is tenderness and muscle rigidity, but it is usually generalized and is not always accurate in patients who are being revived from shock. Pain in the right shoulder (due to diaphragmatic irritation) is an accompanying symptom. Usually it is not difficult to make a diagnosis of intra-abdominal injury, but it may not be easy to name the exact site. We have observed that when the routine blood count is made in liver injury, there is a prompt leucocytosis of 16 to 20,000, with a preponderance of leucocytes. Fever soon appears, but due to shock it is not as prompt as the leucocytosis. We have not observed this in any other intra-abdominal injury, including splenic rupture. Is it due to the bacteria in the Kupffer cells and the rich blood and lymph drainage which carries the antigen into the blood stream rapidly? The treatment is prompt surgical intervention. The liver may be sutured in many ways. We have usually employed the greater omentum and used mattress sutures through it. If the omentum is ample and readily available, it may be left attached; if not, free grafts may be used. The falciform ligament may be employed in the same way, or fascia may be used. Recently Gelfoam has been used in the same manner. Dependent drainage is imperative because of the danger of bile peritonitis. If the gall bladder or external ducts have been torn, they should be repaired if possible and drainage used. If not, a catheter may be placed in the torn duct so that the bile will flow to the outside.

Infections of the Liver.—The liver stands infections well. The term hepatitis has been used rather loosely to describe an enlarged, pale, swollen liver, with rounded margins instead of the usual sharp edges. It is commonly seen in association with gall bladder or bile duct disease, and it impairs liver function (jaundice). The liver cells show cloudy swelling. This is said to improve after elimination of the gall bladder disease. This type of hepatitis may be said to be secondary.

Infectious hepatitis is probably a virus disease, although its exact mode of transmission is unknown. It may occur sporadically or in epidemic form. The chief symptom is jaundice, although in the preicteric phase other symptoms are present; namely, chilly feeling, headache, malaise, weakness, anorexia, nausea, and occasionally vomiting. The liver is tender and enlarged with the onset of jaundice. The disease is usually over in about two weeks. However, severe cases accompanied by coma, hemorrhagic manifestations, and even death from acute hepatic necrosis may occur. There may be relapse or recurrence.

Homologous serum jaundice occurs after transfusion with plasma or whole blood. The jaundice varies in depth and persistence. There may be fever, anemia, great hepatic enlargement with or without ascites, abdominal pain, and hemorrhages. Sometimes the disease runs a rapidly fatal course; usually it is benign. It is to be distinguished from blood incompatibilities which are also accompanied by jaundice.

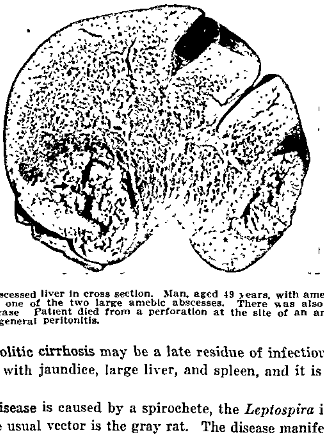

Fig 373 —Abscessed liver in cross section. Man, aged 49 years, with amebic dysentery. Arrow points to one of the two large amebic abscesses. There was also a subphrenic abscess in this case Patient died from a perforation at the site of an amebic ulcer in the colon, with general peritonitis.

Cholangiolitic cirrhosis may be a late residue of infectious hepatitis. It is chronic with jaundice, large liver, and spleen, and it is apparently incurable.

Weil's disease is caused by a spirochete, the *Leptospira* icterohemorrhagiae. The usual vector is the gray rat. The disease manifests itself by chills and fever, great prostration, jaundice, hepatolineal enlargement, hemorrhagic tendency, and frequently renal failure. The disease can be diagnosed by finding the spirochete in the blood under dark-field illumination or by injecting blood of the patient intraperitoneally in a

or diverticula of these organs and intravenous pyelograms to rule out kidney anomalies help confirm the diagnosis.

Treatment consists of surgical exploration, examination of the cyst, and anastomosis of the cyst wall to the duodenum. Extirpation of the cyst is hazardous and may result in stricture of the duct; external drainage and marsupialization are practically always fatal. Our two cases recovered. One child is in good health eight years after operation (12 years of age now). The other is well two years after surgery.

INJURIES AND DISEASES OF THE LIVER

Injuries of the liver are seen following accidents and from stab and bullet wounds. The most serious is rupture of the liver, which gives rise to shock, due to intra-abdominal hemorrhage. Such injuries are usually associated with other intra-abdominal or thoracic contusion or lacerations (see Chapter 20). The diagnosis is suspected from the history, which usually reveals the site or position of the injuring force, or there may be ecchymosis or suffusion of blood over the region of the liver. There is tenderness and muscle rigidity, but it is usually generalized and is not always accurate in patients who are being revived from shock. Pain in the right shoulder (due to diaphragmatic irritation) is an accompanying symptom. Usually it is not difficult to make a diagnosis of intra-abdominal injury, but it may not be easy to name the exact site. We have observed that when the routine blood count is made in liver injury, there is a prompt leucocytosis of 16 to 20,000, with a preponderance of leucocytes. Fever soon appears, but due to shock it is not as prompt as the leucocytosis. We have not observed this in any other intra-abdominal injury, including splenic rupture. Is it due to the bacteria in the Kupffer cells and the rich blood and lymph drainage which carries the antigen into the blood stream rapidly? The treatment is prompt surgical intervention. The liver may be sutured in many ways. We have usually employed the greater omentum and used mattress sutures through it. If the omentum is ample and readily available, it may be left attached; if not, free grafts may be used. The falciform ligament may be employed in the same way, or fascia may be used. Recently Gelfoam has been used in the same manner. Dependent drainage is imperative because of the danger of bile peritonitis. If the gall bladder or external ducts have been torn, they should be repaired if possible and drainage used. If not, a catheter may be placed in the torn duct so that the bile will flow to the outside.

Infections of the Liver.—The liver stands infections well. The term hepatitis has been used rather loosely to describe an enlarged, pale, swollen liver, with rounded margins instead of the usual sharp edges. It is commonly seen in association with gall bladder or bile duct disease, and it impairs liver function (jaundice). The liver cells show cloudy swelling. This is said to improve after elimination of the gall bladder disease. This type of hepatitis may be said to be secondary.

tion). This is seen occasionally after suppurative appendicitis or diverticulitis and rarely after infections about the rectum, some of which occur postoperatively. We have seen one case after ischiorectal abscess. The liver is studded with small abscesses, giving rise to chills, fever, sweats, and mild jaundice. The treatment consists of attention to the cause of the condition; also, the use of penicillin and streptomycin. Surgical treatment is directed to the primary cause. In the liver, surgical intervention is usually unavailing unless a large solitary abscess results. This can be drained.

Subdiaphragmatic or subphrenic abscess may follow multiple or single abscess of the liver. However, it is more often seen following suppurative appendicitis, perforation of a peptic ulcer, or a gangrenous gall bladder. Pus accumulates between the diaphragm and the liver, pushing the former up and the latter down. Sometimes the infection finds its way through the lymphatics or, by perforation, into the pleural cavity, giving rise to empyema. The history, physical findings, and x-ray make the diagnosis certain. The patient shows a septicemia, with chills, fever, and a high leucocyte count. The physician's maxim is: "After appendectomy, if septic fever continues, think of abscess in the pelvis, the right lumbar gutter, or the subphrenic space." Aspiration reveals the exact location of the pus. The treatment consists of incision and drainage, usually done by removing a portion of the tenth rib on the right side, and stitching the parietal pleura in the costophrenic angle, followed by incision and drainage after forty-eight hours. This is done to prevent pleural infection.

Cirrhosis of the liver implies a hardening process which interferes with its circulation and function. In general there are two types: (1) Portal cirrhosis or the atrophic cirrhosis of Laennec. In this group belong the form associated with Banti's syndrome (intrahepatic portal hypertension), portal cirrhosis with progressive lenticular degeneration (Wilson's disease), cirrhosis of hemochromatosis, alcoholic (hobnail or gin drinkers' liver) or nutritional deficiency cirrhosis, cholangiolithic cirrhosis, chrronic hepatitis cirrhosis. (2) Biliary cirrhosis. In this group are two types: Hanot's hypertrophic biliary cirrhosis and Charcot's obstructive biliary cirrhosis. *Portal cirrhosis* is thought to represent a reaction to injury due to infections, toxic agents, avitaminosis, and many other agents and factors as yet unknown. The chief pathological change is a great increase in the fibrous tissue of Glisson's capsule on the surface and throughout its ramifications along the portal radicles. The liver becomes hard and shrunken and presents a "hobnail" appearance. The sequence of events is first a degeneration of liver cells in the periphery of the lobules, then regenerative hyperplasia of the remaining liver cells and bile ducts (compensatory hyperplasia) and repair by proliferation of the interstitial connective tissue and contraction, and, finally, as a result of this contraction, portal obstruction and the formation of col-

guinea pig and finding the spirochetes in the peritoneal fluid in ten to fourteen days. After about two weeks, serum agglutination tests may be used.

The importance of these conditions is in distinguishing them from obstructive jaundice which may be amenable to surgical intervention. A careful history may reveal that the patient came into contact with jaundiced people or recently had a transfusion. If there is bile in the stools with jaundice, the possibility of a nonsurgical jaundice will be suspected. If the patient has no bile and has had previous attacks of pain, a common duct obstruction is considered. A careful physical examination may give clues such as a nodular liver, a palpable mass indicating a nodular liver. Also, the various laboratory tests may give aid as previously discussed. Finally, surgical exploration may be necessary. While waiting for a diagnosis, a diet rich in protein and carbohydrate should be supplied, hepatotoxic substances should be diluted with intravenous medication, neutralized, and eliminated, and the patient should be kept at rest.

Specific infections include *syphilis* (Chapter 9) and *amebiasis* (Chapter 7). The latter produces a solitary large abscess caused by the Entamoeba's entrance into the portal system. The diagnosis rests upon the history, which need not include a visit to the tropics. Symptoms include diarrhea, abdominal pain, especially in the right upper quadrant, chills, fever and sweats, and great prostration. The liver is large and tender. The diagnosis is established by finding the organism in the stools. It will rarely be found in the abscess cavity but is present in the wall of the abscess. The pathological changes in the liver vary from a diffuse hepatitis to multiple small abscesses. More common is the single large one with thick violaceous pus. Treatment of diffuse hepatitis or multiple abscess consists of large doses of penicillin with emetine, alternating with Vioform. Large abscesses require aspiration in addition. This we have done in late cases with large livers without surgery. If in doubt as to the exact location, we have resected a small portion of the tenth rib, then packed with gauze for twenty-four to forty-eight hours, and then aspirated. If subdiaphragmatic abscess or empyema are present, open drainage of these collections is indicated because they are mixed infections. Syphilis may be congenital or acquired (see Chapter 9).

Tuberculosis occurs in three forms in the liver: (a) miliary; (b) conglomerate; (c) tuberculous cholangitis or pericholangitis (see Chapter 8).

Actinomycosis is not rare and may be secondary to intestinal actinomycosis by extension through retroperitoneal tissue, or directly, or by metastasis from more distant foci. The first evidence of the disease may be a subphrenic abscess (see Chapter 7).

Multiple abscess of the liver is a serious condition resulting from pylephlebitis (infection of the mesenteric veins with thrombus forma-

of the portal vein or its tributaries from infections, traumatic, or unknown causes, or combined intra- and extrahepatic causes such as portal cirrhosis plus portal vein thrombosis. The methods employed are as follows: (1) creating new venous channels by forming adventitious veins from adhesions between the liver and diaphragm or between esophageal veins and diaphragm by packing the mediastinum, or between the greater omentum and the abdominal wall—omentopexy (Talma); (2) creating portacaval shunts between the portal vein and vena cava unless a cavernomatous transformation or other complications have occurred making this procedure impossible; (3) splenectomy and end-to-side anastomosis of the splenic to the left renal vein; splenectomy alone is probably useless and may actually increase varices; (4) anastomosis of the superior mesenteric vein (proximal end) and vena cava; (5) anastomosis of other veins such as the inferior mesenteric (proximal end) and left ovarian; (6) resection of lower esophagus and upper end of stomach or entire stomach, thereby obliterating varices; (7) ligation of splenic artery to cut down flow through splenic vein and varices; (8) temporary arrest of bleeding varices by Miller-Abbott tube balloon. Of all these methods, the splenorenal shunt is perhaps most satisfactory. (See Chapter 18 and Chapter 20 under Esophageal Varices.)

The technique is as follows: First the pressure in the splenic and portal veins is ascertained. This is done to determine whether or not, in addition to intrahepatic obstruction, there may be obstruction in the splenic vein as well. If so, then splenorenal shunt is less apt to help divert blood from bleeding eophageal varices, and a mesenteric caval or portacaval anastomosis should be done. If the pressures are the same, then the splenic artery is identified, doubly ligated, and divided. The splenic vein is freed. Then the renal artery and vein are carefully dissected free. Next, the spleen is removed after a gauze-shod bulldog clamp has been placed on the splenic vein. Bulldog clamps are then applied to the renal artery and two to the renal vein. Then an end-to-side anastomosis is done using 00000 silk sutures. After the operation, pressures are again taken in the portal vein—a distinct drop is noted (10 to 12 cm. of water), because there are no valves in the portal system and blood is readily diverted from the higher pressure splenic vein into the lower pressure renal vein.

Hypertrophic biliary cirrhosis occurs in two forms: (a) Primary biliary cirrhosis or Hanot's cirrhosis and (b) secondary or obstructive or Charcot's cirrhosis.

The primary type occurs in youth and early adult life. Its cause is unknown, but many theories have been advanced: its familial tendency as in hemolytic (familial) jaundice which it resembles; its relation to infections such as typhoid; its possible relation to infectious hepatitis. The liver is large and hard, and dense fibrosis can be seen to surround the individual lobules and small bile ducts. The principal symptom is jaundice and itching, but the feces contain bile and so does the urine. There are gastrointestinal upsets. The liver is enlarged. The course of the disease is chronic, and death results in three to six years from acute degeneration of the liver cells as in acute yellow atrophy. The condition must be differentiated from portal cirrhosis (in older people),

lateral circulation. This is evidenced by (1) esophageal varices due to anastomoses between the esophageal veins with the coronary veins; (2) hemorrhoids due to anastomoses between the inferior mesenteric and hemorrhoidal veins; (3) "caput medusae" or prominent veins about the umbilicus due to anastomoses between the epigastric and portal veins by way of the paraumbilical vein of Sappey; also anastomoses form between the portal vein and vena azygos by way of the veins of the diaphragm; (4) the dilated veins of Retzius (retroperitoneal veins), connecting the inferior and superior mesenteric radicles to the inferior vena cava.

Other secondary changes are also due principally to obstruction: "vascular spiders" about the face, arms, and trunk, congestion of the mucous membrane in the gastrointestinal canal, ascites which is due to portal hypertension as well as to increased capillary permeability (from toxemia and local anoxemia) and decreased osmotic pressure (from primary and secondary hypoproteinemia), splenomegaly, interstitial fibrosis of the pancreas.

The symptoms and signs are the direct result of these changes and include those due to portal obstruction: nausea and vomiting due to congestion of the mucosa of the stomach, varices superficially and about the esophagus producing hematemesis and about the rectum producing bleeding hemorrhoids, ascites, peripheral edema, splenomegaly, and *jaundice*, which comes and goes. Two-thirds of the cases have jaundice at some time during the course of the disease and may be mistaken for external obstructive jaundice.

The diagnosis is certain when signs of portal obstruction are present. However, in its early phase the disease may resemble infectious hepatitis or obstructive jaundice if jaundice is present. Later it must be differentiated from primary or secondary carcinoma. A careful history (alcoholism, syphilitic infection, recurrent hepatitis, etc.) and physical examination coupled with laboratory aids as previously discussed will usually lead to at least a consideration of the possibility of cirrhosis. Confirmation may be had by liver biopsy taken with a needle. This method, while very informative, is not without very serious danger. Exploratory operation may be necessary. Usually careful observation soon leads to the unmistakable signs of the disease.

The treatment may be divided into medical and surgical. Both are necessary when portal obstruction is present. The medical regimen includes a diet rich in protein, high in vitamins and carbohydrates, low in fats supplemented by specific lipotropic substances (choline and cystine, methionine), whole liver extract, with vitamin B complex.

Surgical treatment is directed against the portal hypertension and its effects, whether due to intrahepatic causes, such as portal cirrhosis with or without splenomegaly, posthepatitis, cirrhosis, schistosomiasis, Chiari's syndrome (hepatic vein obstruction), or to extrahepatic causes, such as Banti's syndrome with congenital obliteration of the portal vein and cavernomatous transformation, or acquired thrombosis

thorax breast, and other situations. (b) Sarcomas—from melanoblastoma, skin melanosarcoma. Often sarcoma is associated with cirrhosis.

The diagnosis of *benign liver tumors* may be difficult. The chief symptoms are those of fullness or pressure or indigestion with or without jaundice. There is a palpable abdominal mass which is firm, movable, solitary, and rarely tender. The history of long duration will help rule out malignancy, and the absence of fever, chills, and leucocytosis makes infection improbable. The final diagnosis is made by exploration and biopsy. The treatment consists of removal of the tumor, or, if in the left lobe, a lobectomy is preferable and feasible because of the lobe's thinness, less vascularity, and more connective tissue at the insertion of the falciform ligament which renders the tissue more capable of holding sutures. More important, lobectomy permits complete removal. The various methods of resection represent different ways of dealing with hemorrhage and avoiding complications. The control of bleeding is difficult because the tumor increases vascularity and hyperemia in adjacent liver tissue, the vessels are thin walled, less contractile, and more easily torn, and the liver tissue adjacent to the tumor may be friable. Sudden hemorrhage may be controlled by pressure on the aorta above the celiac axis or by squeezing the hepatic artery in the hepatoduodenal ligament. If bulldog clamps are used on the hepatic artery, they should be removed within thirty minutes, at least temporarily. Sometimes a profound fall in blood pressure occurs after ten minutes of compression. Less severe bleeding may be arrested by gel foam, digital pressure, tourniquet of the liver proximal to bleeding edge, application of Alis clamps covered with gauze.

Methods of resection include cautery excision after suturing for hemostasis and the introduction of parallel rows of sutures, dividing between them with the scalpel. The former produces much necrosis and prevents primary closure or cover of liver edge. The latter is preferable and permits individual ligation of remaining bleeders; then the raw surface may be covered with omentum or the falciform ligament may be sutured with the free ends of the mattress hemostatic stitches.

Complications which may occur are (1) secondary hemorrhage, (2) infection in the liver edge or peritonitis; (3) metabolic disturbances such as liver shock or liver deaths, hepatorenal syndrome, hepatic insufficiency; (4) postoperative ileus and shock from bile peritonitis or from engorgement of the gastrointestinal tract if a clamp was used on the hepatoduodenal ligament, causing temporary portal obstruction; (5) persistent sinuses or bile fistulae from liver sloughs.

Primary malignant tumors are accompanied by pain over the liver area, loss of weight, anemia, weakness, and loss of appetite. There may be bleeding from esophageal varices. The tumors are multiple and hard so that the liver is a large, irregular, fixed organ. Jaundice is usually present. Secondary malignant neoplasms give rise to the same symptoms

obstructive jaundice due to stone (clay-colored stools, pain, fever, and chills), and hemolytic jaundice (increased fragility of red cells and acholuric urine). There is no specific treatment except when associated with splenic disease where splenectomy may be indicated.

The secondary type is caused by a proliferative fibrosis around the intrahepatic ducts which results from the chronic obstruction of the extrahepatic duct system. There is an associated cholangitis which also stimulates periductal fibrosis around the intrahepatic bile ducts. The causes include congenital atresia, wedged in stone in the common duct, postoperative or inflammatory stricture, and carcinoma of the ampulla, the duct, or the head of the pancreas. The symptoms and signs are those of the causative condition. The treatment consists of early removal of the obstruction or short circuiting around it. If too long a time has elapsed, the liver may be damaged beyond redemption, even after the obstruction has been relieved. The medical management as described under portal cirrhosis is followed in addition to surgical intervention.

Obstruction of the hepatic veins (Chiari's disease) is due to thrombosis of the hepatic veins where they empty into the vena cava. The obstruction may be partial or complete or complete with recavalization. As a result of the obstruction, there is central necrosis of the liver lobules, congestion of blood in this locality, fibrosis of the liver, and splenomegaly. The liver is greatly enlarged and there are ascites, pleural effusion, and leg edema. The disease may be acute or chronic, and it occurs usually between 20 and 40 years of age. The cause is unknown. The diagnosis is rarely made ante mortem or before surgery, because the clinical picture is that of portal cirrhosis. Formerly the prognosis was always fatal; now some lives have been prolonged by splenorenal shunt.

Tumors and Cysts of the Liver

Primary neoplasms of the liver are rare. They may be classified as follows:

(A) Benign: (1) hamartoma (congenital, teratoid tumors which have a relative quantitative disproportion of tissue elements normally comprising the liver but have not attained the complete pattern of the organ); hamartomas also occur in thyroid, lung, spleen, heart, mediastinum; (2) hepatoma or liver-cell adenoma; (3) cholangiomas—adenomas of the intrahepatic bile ducts, solid or cystic; (4) cholangiohepatomas of both liver-cell and duct elements; (5) neoplasms in the liver but not of specific hepatic elements—(a) cavernous hemangioma (the commonest tumor in the liver); (b) fibrous; (c) lipoma; (d) neurofibroma; (e) adrenal inclusions; (f) mesenchymoma.

(B) Malignant: (1) Liver cell carcinoma with or without cirrhosis; (2) cholangiocarcinoma; (3) sarcoma—(a) spindle-cell; (b) round-cell; (c) hemangioendothelioma.

Secondary neoplasms: (a) carcinomas secondary to carcinoma of the stomach, intestines, colon, pancreas, the organs of the pelvic cavity,

diaphragm is fixed probably due to reflex inhibition (splanchnics and vagi) caused by pain. Distention of the gall bladder will produce disturbances in blast rate rhythm and the T waves, but electrocardiogram changes in patients without clinical coronary artery disease are insignificant. There is apparently no definite electrocardiographic pattern in gall bladder disease.

The sphincter of Oddi or sphincter choledochus has a definite group of circular fibers which invest the ampulla and common duct distal and proximal to their junction. Its function seems to be that it contracts so that the gall bladder can fill. A spastic sphincter causes pain and may be the true cause of biliary colic. Intestinal distention causes a decrease in the secretion of bile and in sphincteric tone. Normally rhythmic contractions occur every two to six seconds and pressures vary between 90 to 150 mm. of water. Hydrochloric acid on the duodenal mucous membrane causes a decrease in tone; so do inhalations of amyl nitrite and Pituitrin, which at the same time increase the amplitude of contraction. Calcium chloride increases tone, as does vomiting (thus preventing a reflux of duodenal content into the duct). Morphine sulfate causes an increase in the number and amplitudes of contraction. Hypertonic solutions of glucose increase tone, whereas magnesium sulfate in the duodenum decreases tone.

Complete obstruction of the cystic duct does not produce inflammation of the gall bladder in the experimental animal if the bile is replaced by physiological saline. If bile is left within the gall bladder, inflammation results. The "white bile" usually encountered is mucus secreted by the inflamed mucosa to protect itself. Interference with the blood supply results in infarction and even gangrene. Bacterial invasion is secondary.

Complete occlusion to the common bile duct leads to dilatation of the entire ductal system with the deevlopment of fairly large interlobar communications.

Diseases of Gall Bladder and Bile Ducts

Functional disorders of the gall bladder and bile ducts occur frequently and have been listed as *dyskinesias*. Gall bladder stasis may be a forerunner of gall stones and is therefore of interest. It may be due to hypotonicity of the gall bladder or hypertonicity of the sphincter of Oddi or of the duodenum. Hypertonicity of the sphincter does occur, but its exact causes are difficult to find. Constipation of the spastic type is often associated with dyskinesia. Some observers have even advocated opening the duct and dilating or even dividing the sphincter. There is no proof that such measures are indicated unless the dyskinesia is associated with organic disease. Dyskinesia in the aged or debilitated patient may lead to hydrops of the gall bladder.

Organic diseases of biliary tract include: (1) Congenital anomalies which have been reviewed earlier in the chapter. (2) Injuries which have also been discussed and which occur usually in conjunction with injuries to the liver or other abdominal organs. In this connection we should remember that diseased gall bladders may perforate from minor injuries; normal gall bladders rarely do so. The danger in the latter instance is bile peritonitis (see Chapter 20) which may cause death by its toxic action on the capillaries and other organs, causing shock. Bacteria apparently play a minor and secondary role. Drainage is always indicated. (3) Gall stones. (4) Inflammations. (5) Obstructions. (6) Tumors and cysts. (7) Jaundice.

and signs and in addition the symptoms and signs of the primary site of the carcinoma. The treatment of primary malignancy is excisoin if possible. Even secondary carcinomas may be removed if single or if limited to one area (left lobe) and if the primary site may also be removed.

Cysts of the liver may be single or multiple, nonparasitic or parasitic, retention or due to new growth. Nonparasitic cysts are said to occur from intrahepatic obstruction of bile ducts due to congenital atresias or cicatricial obstruction. These are usually multiple but may be single or may coalesce to form one large cyst. Another type is known as cystic disease of the liver, cystic liver, cystic degeneration of the liver, polycystic liver disease, or congenital cysts of the liver. These cysts are usually more superficial and may be a part of polycystic disease in the kidneys, pancreas, or even the lungs. A third variety includes the lymphatic cysts.

Parasitic disease may also cause single or multiple cysts. Usually they are due to the echinococcus. Rarely, cystadenomas or dermoid or teratomatous cysts are encountered.

Treatment of nonparasitic cysts is by enucleation or resection; even the left lobe may be excised. A solitary cyst of the right lobe in close vicinity of the bile ducts may be marsupialized.

Echinococcus cysts of the liver may be excised if possible, or 10 per cent solution of formaldehyde may be injected and the hooklets, daughter cysts, and germinal layer removed. If this is not possible, the cyst is incised and wiped with gauze soaked in 10 per cent formaldehyde, washed with saline, and closed or drained if secondarily infected. When calcification occurs it is necessary only to remove the chitinous or germinal layer of the cyst, leaving behind the calcified wall.

The Gall Bladder and Bile Ducts

The liver cells secrete bile continuously and at a fairly constant rate. This substance, with its cholesterol, bile salts, and bile pigments, finds its way down the hepatic ducts into the common bile duct. Some of it is then poured through the ampulla of Vater into the duodenum, where it aids in the digestion of fats after a meal. Most of it, due to the contraction of the sphincter of Oddi, will course back through the cystic duct into the gall bladder for storage until fats and acids ingested call forth cholecystokinin, which causes contraction and emptying of the gall bladder. (The bile in the gall bladder is concentrated from seven to ten times by the removal of water.)

The gall bladder also acts as a pressure-regulating mechanism to take care of the continuous flow of bile, which would otherwise back into the bile ducts when the sphincter of Oddi is closed. The secretory pressure of the liver is about 30 cm. of bile pressure. The maximum expulsive power of the gall bladder is 20 to 30 cm. The sphincter of Oddi offers a resistance of 9 to 25 cm., but when in spasm the pressure may reach 75 cm. or more. After cholecystectomy, the sphincter is left more or less incompetent, with a resistance of about 15 cm.; in spite of this, however, the bile ducts dilate. The gall bladder then absorbs water, secretes mucin, and contracts to empty itself. Sudden elevation of pressure in the gall bladder or ducts will cause pain, nausea, and vomiting in dog and man. These symptoms may be abolished when the splanchnics are cut (pain) and the vagi are cut (nausea and vomiting). The right half of the

The anatomical facts collected by Sweet are as follows: (1) The presence of small pouches known as parietal sacculi (Beale) which may act as miniature gall bladders when this organ has been removed. These little sacs are lined with cuboidal epithelium. (2) The gall bladder cells are of the high columnar type, which may readily absorb sterols. (3) The gall bladder, unlike other organs, has two veins for every artery and is liberally supplied with lymphatics. (4) The mechanism by which the valves of Heister act as a baffle system, permitting stones to form within them as a mould.

Fig. 375.—*A.* Cholesterosis of the gall bladder (strawberry gall bladder). The cholesterol-containing cells are under the mucosa. *B.* High power, showing the histiocytes, which are full of lipoid material. This is seen grossly as small yellow areas which show through the mucosa.

The ideas presented by Sweet which differ from those usually accepted are: (1) Nothing leaves the gall bladder, once it has entered its lumen, except by way of the veins (crystalloids) and the lymphatics (colloids). (2) Stones form in the valves of Heister and are forced into the gall bladder by pressure within the common duct due to the contraction of the sphincter of Oddi, or they form within the lumen of the gall bladder itself, but stones in the gall bladder never leave it except by erosion through its wall into the gut, or unless removed by surgery. Stones in the common duct form because of precipitation and stasis and are usually soft (mud stones). Therefore, stones in the common duct are usually separate and distinct entities and differ from stones in the gall bladder. However, they may form in the dilated common duct when stasis is present and may resemble gall bladder stones. Therefore, the old dictum of surgeons,

Gallstones.—A stagnated pool of bile may give rise to crystallization which ultimately leads to the formation of *concretions* or *stones.* Whether this is entirely a crystallization process or the result of infection, constitutional predilection, or some chemical change is unknown. Some believe such factors as *disturbed cholesterol metabolism, bile stasis,* and *change in reaction play a role.* (Gall bladder bile is acid; liver bile is alkaline.) Should the gall bladder fail to change the reaction of the liver bile from alkaline to acid, calcium carbonate will be thrown down as a precipitate, for it stays in solution only so long as the bile is acid. Infants have been born with stones, and people ostensibly without infection may have them. Although there seems to be a hereditary tendency to obesity in patients with gallstones, this is by no means constant.

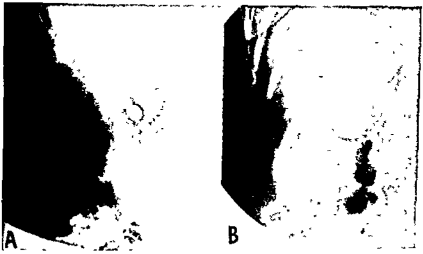

Fig. 374.—*A.* Flat plate of the abdomen, showing opaque gallstones. *B.* Gall bladder and gallstones visualized after the ingestion of tetraiodophenolphthalein.

Sweet has collected *old facts concerning the anatomy and histology of the liver* and bile ducts and has introduced new concepts of the function of these structures and the formation of gallstones.

In general, the body is equipped with balancing devices for pressures and fluids. An illustration of the former is the cerebrospinal fluid system. An illustration of the latter is the mechanism for the secretion of water and electrolytes into the upper bowel and their absorption by the lower bowel. However, glands usually secrete a substance and then have no power to alter it. The kidney is an example of the resorption mechanism if we consider the glomerulus as the beginning of the system and the tubules as the absorptive device. Sweet believes that the liver cell corresponds to the glomerulus. The bile ducts, down to and *including the gall bladder and cystic duct,* are comparable to the kidney tubule. In this system the common duct, like the ureter, is the purely excretory duct.

Another important mechanism in the body is the one *which prevents the formation of precipitates.* This may depend upon the maintenance of balance between positive and negative ions, upon the mutually protective action of colloids, and upon the lining wall of the cavities in which the fluids exist. For example, we have seen that should the limiting membrane of blood vessels (the intima) be *injured, thrombosis* occurs; should a bursa become injured, calcium may be deposited. This same mechanism may be active in the common duct, where stones form due to obstruction at the ampulla, with perhaps a *reflux of the pancreatic juice,* producing chemical irritation.

3. Hypertrophy and thickening due to edema and cholesterolosis, chronic hypertrophic cholecystitis

4. Atrophy with degeneration of mucous membrane—thin empty gall bladder—will store bile and empty feebly

5. Atrophy with fibrosis with loss of all function (storage, concentration, and expulsion of bile), chronic atrophic cholecystitis

6. Obstruction of cystic duct
   a. Intermittent with hypertrophy of gall bladder
   b. Gradually progressive with hydrops due to absorption of bile and excessive secretion of mucin
   c. Sudden and complete with
      (1) Atrophy
      (2) Acute cholecystitis
      (3) Venous obstruction causing edema and passive congestion, then interference with arterial flow when venous pressure equals arterial pressure; results in infarction and gangrene
      (4) Secondary infection as a result of (2) or (3), causing empyema of the gall bladder
      (5) Perforation with bile and bacterial peritonitis as a result of (3) or (4), or local abscess, subphrenic abscess, empyema thoracis
      (6) Infarction with erosion and formation of cholecystogastric, cholecystoduodenal, cholecystocolic or combination types of fistulae
      (7) As a result of (6) may be intestinal obstruction due to gallstone (see Chapter 20).

7. Associated diseases which may result from gallstones or which may occur in their presence
   a. Carcinoma of gall bladder may precede or follow, present in about 2 per cent
   b. Acute pancreatitis, present in about 4 per cent
   c. Pericholecystic adhesions which may cause partial obstruction or interfere with motility of duodenum or colon
   d. Interference through nervous reflex with secretory function of stomach

8. Stones may pass into the common duct in about 12 per cent and may produce:
   a. Chills, fever, and jaundice—ball valve stone; Charcot's intermittent hepatic fever (Charcot's tread)
   b. Progressive jaundice if stone is wedged
   c. Cholangitis
   d. Biliary cirrhosis of the liver (Charcot)

Symptoms and Signs of Gall Stones.—

(1) Gall stones may be present for years and remain entirely symptomless. (2) They may produce reflex symptoms of the gastrointestinal tract, both motor and secretory. (3) Gallstone colic may occur periodically. (4) The first symptoms may be those of complications such as cholecystitis, empyema, gangrene. The diagnosis is made from the symptoms and signs and the use of x-ray (cholecystogram).

Stones may remain in the gall bladder and give rise to no symptoms (silent stones). They may be single (round) or multiple (faceted) or more in the nature of small particles of sand. Usually the mucous membrane of the gall bladder is thickened, and often its columnar epithelium is studded with small cholesterol granules (strawberry gall bladder), although concretions are also found in a normal-appearing gall bladder. The stones may be made of bile pigment, cholesterol, calcium, or com-

that stones found in the common duct after a previous gall bladder operation were overlooked, is not necessarily true. (3) After removal of the gall bladder the common duct system dilates, including the parietal sacculi, and this dilatation includes the sphincter of Oddi, thereby establishing open drainage and preventing the re-formation of stones. (4) After the gall bladder dye test, the apparent emptying of this organ following a fatty meal is simply a shifting of the shadow due to absorption of the dye through the lymphatics: the dye does not leave by way of the cystic duct.

According to Sweet, the formation of stones within the gall bladder is not due to precipitation, with deposition of crystals around a nucleus. It is due to the occurrence in the bile of calcium and cholesterol in colloidal suspension. Because of the mutual protective action of colloids, certain definite patterns (such as the Maltese cross) will be laid down centripetally, within the stone, as the colloidal substance turns to a solid state. The reasons for the change in the substance after secretion may be, first, a disturbance of the absorbing function of the gall bladder, causing a damming back of the sterol; second, a reflux into the common duct of intestinal content and pancreatic juice, causing the precipitation of all the contents of bile, with the formation of biliary "mud"; third, a change in the solubility relationships of the constituents of the bile, brought about by infectious or chemical processes which injure the mucous membrane of the biliary passages and thereby permit the entry of abnormal constituents into the bile. The symptoms of biliary disease are due largely to an involvement of the motor and sensory functions of the common duct; the gall bladder takes very little part in the symptom complex. When a gall bladder is filled with dozens of faceted stones of equal size, these have formed within the valves of Heister from masses of gel like those which occur in the gall bladder and have then been pushed back into the gall bladder after they became solid.

We speak of gases of which the molecules are in a completely free state, of solutions in which the molecules are less free, of colloids in which they are still less movable, and of solids in which they move very little, retaining their positions. Sweet believes, like Liesegang, that the precipitation of a material contained in a colloidal mass by another substance which diffuses through the colloid mass does not cause a uniform precipitation but a series of rings, precipitated in rhythmic order. Such is the case in the formation of a gel of cholesterol and some calcium compound in the colloidal state.

Women are more likely to have gallstones than men. Pregnancy seems to account for this preponderance, but this is difficult to prove. No one theory as to the formation of stones is conclusive. Stasis of bile, changes in constituents of bile, infection, associated diseases and constitutional susceptibility, neurogenic disturbances, alterations in the absorptive and secretory functions due to hormonal imbalance during the active sex life have been invoked as possible causes. The association of gallstones and hemolytic jaundice has been attributed to an increased amount of bile pigment carried to the liver, causing the bile to become thick and therefore sluggish in its movement as well.

Pathology.—Gallstones are not innocuous. They may cause little change in the gall bladder but more often they lead to one or more complications. Some of these effects may be listed as follows:

1. Very little or no demonstrable change in the gall bladder, bile ducts, or liver
2. Acute inflammatory changes (acute cholecystitis usually associated with obstruction to the cystic duct but not always) which may occur without stones. Theories as to how the injury is sustained: vascular (obstruction to cystic vein and artery), chemical (pancreatic juice by reflux through spasm of sphincter of Oddi, bile), bacterial (chiefly of the streptococcus group as a secondary invader but may be primary) which may go on to gangrene and perforation

and if there has been no history of jaundice, the duct is not opened. Instead, it is our practice to open the gall bladder routinely, remove the stones, probe the common duct through the cystic duct, and then remove the gall bladder, subserously covering over the gall bladder bed with its serosa. If there is any doubt, particularly where there has been a history of jaundice, the gall bladder is opened and probed with filiform bougies and small rubber catheters. The more important complications and sequelae of cholecystectomy are (1) inflammatory stricture of the common bile duct, (2) traumatic stricture of the common bile duct, (3) "hepatorenal syndrome," and (4) "postcholecystectomy syndrome," which implies a persistence of symptoms after cholecystectomy.

While it is true that sometimes an inflammatory process (cellulitis) occurs after cholecystectomy due to secondary bacterial invasion which may cause partial destruction and cicatrization of the common duct, yet most strictures follow surgical trauma to this structure. The complication is recognized by a persistence of bile drainage or jaundice. The treatment is surgical and requires either a short circuiting around the obstruction (choledochoduodenostomy) or resection and anastomosis between the duct and the duodenum.

"*Hepatorenal syndrome*" consists of a hepatic, and later kidney, insufficiency with little or no secretion of bile, slight jaundice, slight fever, oliguria, and azotemia followed by paralytic ileus. The condition is serious and may be fatal. Many theories have been advanced to explain its cause. Among them are (1) severe trauma to the liver with hepatitis, toxemia, dehydration, hemoconcentration, anuria, (2) trauma to the liver and bile peritonitis, and (3) bacterial peritonitis, (4) serum hepatitis following transfusions, (5) infectious hepatitis. The condition as seen clinically probably has many causes. Perhaps most commonly the sequence is severe liver trauma, or operation in the presence of hepatitis, progression of the hepatitis with local peritonitis at the site of the gall bladder bed, incomplete bowel obstruction and paralytic ileus, dehydration, hypoproteinemia, and then oliguria and its effects. The condition is not seen commonly. The treatment is the same as for hepatitis and in addition decompression of the gastrointestinal tract with the Miller-Abbott tube, attention to water balance and blood volume chemotherapy.

"*Postcholecystectomy syndrome*" implies a persistence of symptoms after cholecystectomy. Causes include (a) benign stricture of common duct, (b) parenchymatous pancreatitis, (c) hepatitis, (d) residual stones in the common duct or gall bladder neck if not removed, (e) biliary dyskinesia and spastic sphincter of Oddi, (f) adhesions between pylorus or duodenum and gall bladder bed, (g) duodenal diverticulum, irritable or spastic bowel. In addition to these more or less demonstrable causes, the fact that the syndrome rarely occurs after cholecystectomy for stones but is more apt to follow cholecystectomy for cholesterolosis has led to the supposition that there is less adjustment (dilation of intrahepatic ducts) in the latter case than in the former. Finally, it is an observed

binations of these substances. (Cholesterol stones are most common.) The patient usually presents a *history of discomfort in the upper right quadrant, with attacks of indigestion* (belching, intolerance to certain foods, etc.). If a small stone begins its course down the cystic duct, there result attacks of excruciating pain, known as a *gallstone colic*. This pain is said to be due to a spasm of the sphincter of Oddi and a sudden elevation of pressure in the gall bladder or bile ducts. Therefore, sodium nitrite and magnesium sulfate are more efficient than morphine for relief. The attacks are characteristic, the *pain radiating to the back and right shoulder*. *If the stone finds its way into the common duct*, the attacks of pain are followed by jaundice and clay-colored stools (due to an absence of bile), and since a cholangitis (q.v.) is often associated with stones, there is a *clinical picture of pain, chill, fever, and jaundice* (*Charcot's intermittent hepatic fever*). Many pathological states affect the color of the stool. The stool may be black (due to partially digested blood from a bleeding ulcer or esophageal varices), red (due to bright blood from the rectum), watery with blood and mucus (ulcerative colitis), white or acholic (obstructive jaundice), etc. The urine also varies in color: in obstructive jaundice (choluria) it is deep orange; in other types of jaundice (acholuria), it is normal in color. The *treatment for gallstones is surgical removal of the stones and the gall bladder—cholecystectomy*. Cholecystostomy (removal of stones and drainage of gall bladder) is rarely done. It is indicated in those patients who are in poor condition or in those cases with superimposed acute inflammation where because of technical difficulties cholecystectomy would be too hazardous. Cholecystectomy may then be done at a more favorable time. Stones in the common duct are removed through an incision (choledochostomy), followed by drainage. If a bile fistula persists after this operation, an overlooked stone is probably obstructing the common duct. This may be visualized by injecting Lipiodol and making an x-ray. Ether in oil has been injected to dissolve soft common duct stones with partial success; also, Albright's solution G (similar to magnesium citrate) may facilitate their passage.

It is very important that the surgeon *identify* the ducts and blood vessels. Since congenital anomalies are very common, and since acquired distortions are to be expected in the presence of disease due to inflammation, edema, dense adhesions, serious injuries may follow careless surgery. *In order to avoid injuries to the common bile duct*, some surgeons have advocated a "*high cholecystectomy*," leaving a part of the lower portion of the gall bladder. This is apt to be followed by reformation of a tiny gall bladder in which stones may reform.

The question of routine exploration of the common bile duct has been thoroughly discussed in current literature. Those who advocate it aver that otherwise stones may be overlooked. All are agreed that choledochostomy is not entirely innocuous. It is our custom to expose the cystic and common ducts routinely. The latter is carefully palpated,

gall bladder, removing all stones, and, then, by subserous dissection, removing it after carefully identifying the cystic duct and artery.

In the presence of perforation, cholecystostomy followed by drainage of the gall bladder area is the treatment of choice, because manipulations spread infection and the simplest procedure possible is done.

It is unwise to explore or even uncover the common bile duct in the presence of acute cholecystitis because the swelling and edema and adhesions make such exploration difficult and also because such maneuvers spread infection. The treatment of some of the *complications* and sequelae of acute and chronic cholecystitis should be mentioned.

Perforations causing local abscess or subphrenic abscess or empyema will require cholecystostomy and drainage of the localized accumulation of pus. Biliary branchial fistulae are best attacked transpleurally as well as through the abdomen.

Perforations causing *fistulae* into the gastrointestinal tract can be diagnosed by the history of gall stone disease and x-ray studies which may *show air in the biliary tract.* Surgery consists of separation of the gall bladder from the organ involved, cholecystectomy, and closure of the opening in the hollow viscus. If the stone has caused an intestinal obstruction, this will obviously take precedence and will be treated first (see Chapter 20).

Adhesions about the gall bladder are dissected free by sharp dissection as close to the gall bladder as possible.

Stones in the common duct should be removed. Sometimes they reform; more often some are overlooked. Their removal is done by choledochostomy. This should be done carefully and under full exposure. The incision is made longitudinally and should be large enough to permit the removal of the stone without tearing the duct. The duct should be drained with a small catheter or T tube (we prefer the former because removing the T tube is always attended by more than minimal trauma and sometimes actual tearing). Closure is made with interrupted silk sutures and may be done so as to close the opening transversely if small. Some surgeons inject Lipiodol or other opaque media through the tube and make an x-ray film before closing the abdomen to prevent overlooking a stone. The gastrohepatic ligament is sutured around the closure, and soft Penrose tubes are placed around the opening in the duct to take care of leakage.

Acute cholangitis is seen associated with "ball valve" stone in the common bile duct (Charcot's intermittent hepatic fever). Formerly a mild form was described as ascending catarrhal jaundice. It was thought that infection from the duodenum spread up a patulous duct, infecting the bile duct. This type is now thought to be due to infectious hepatitis. The most common variety of acute cholangitis follows common duct surgery, either simple exploration (choledochostomy) or, more commonly, following repair of benign strictures by excision and anastomosis, or cholecystoduodenostomy. Here again the explanation has been on the

fact that the vague pain which persists in the region of the gall bladder occurs more commonly in those cases where considerable trauma was necessary to remove the organ. This has been explained on the basis of nerve irritation which may correspond to amputation neuroma and "phantom limb" (see Chapter 6).

Inflammations of the Gall Bladder.—Usually when there are stones there are signs of chronic inflammation of the gall bladder, and occasionally there is inflammation in the absence of stones (typhoid cholecystitis, biliary ascariosis). Experimentally acute cholecystitis may be produced by injecting concentrated bile into the gall bladder or into the peritoneal cavity. Also, concentration of bile salts may produce a chemical irritation of the gall bladder. Its wall is not full of bacteria and polymorphonuclear leucocytes as in an acute infection. However, the edema and softening of the gall bladder wall as a result of chemical inflammation may permit bile to seep through the gall bladder wall, giving rise to biliary peritonitis without demonstrable perforation. However, the gall bladder is well able to cope with this situation, and it is extremely uncommon to find this organ acting as a focus of infection. This makes it possible to open the gall bladder and remove the stones without postoperative wound or peritoneal infection. Chronic inflammations of the gall bladder are common and are probably due to *chemical* causes, or if stones are present, to *mechanical* ones. Those due to *infections* are rare and are practically always associated with obstruction of the cystic duct, which interferes with the blood supply (gangrene) or impairs it sufficiently to cause infarction. Following this interference with function and blood supply due to stone impaction, the gall bladder may become inflamed (acute cholecystitis), or gangrenous, or (occasionally) filled with what appears to be pus (empyema of the gall bladder). We have made repeated cultures of this pus and found it sterile; there were some lymphocytes and a few polymorphonuclear leucocytes and mucus. Even sections of the gall bladder wall show relatively few pus cells. The entire process resembles a chemical rather than a bacterial one. Pancreatic juice is found in the gall bladder frequently and is due to the pancreatic and common bile ducts being converted into a continuous tube by spasm of the sphincter of Oddi. When the two ducts enter through the same opening, should pancreatic juice enter the gall bladder under pressure, cholecystitis may result. The reverse of this is true in pancreatitis, *q.v.* Rarely, a gall bladder, like an appendix, will rupture; incidence is about 1/4 of 1 per cent. Therefore, when a patient has pain, rigidity, and tenderness over the gall bladder area, and, in addition, has chills, fever, and leucocytosis, his course should be carefully observed by the surgeon from hour to hour. If all symptoms and signs subside, surgery is deferred to a more favorable time. If not, surgery is done, and usually it is as conservative as possible; that is, drainage of the gall bladder (cholecystostomy) after removal of the stones, although cholecystectomy may be done in selected cases, preferably by the "open method" (that is, opening the

bottom. It has been our observation that such reflux does occur as shown by ingestion of barium or Lipiodol and seeing the mixture in the biliary tract and also that it does not occur when special measures are used as described above to prevent it. Far more important, however, is the patency of the anastomosis. In the presence of a wide open junction, reflux apparently causes no trouble, whereas in those anastomoses with strictures, repeated attacks of cholangitis occur no matter what variety of anastomosis is employed. This same principle is true with ureterocolic anastomosis also.

Chronic cholangitis is seen in association with stones in the ducts and requires drainage of the common duct after choledochostomy, although drainage *down to* the duct is practiced by many surgeons (as in pyelostomy).

Obstructions of the Common Bile Duct.—These obstructions are usually due to stones within the lumen or to carcinoma of the pancreas, which causes pressure from without. Occasionally acute cholangitis may produce so much edema and swelling as to obstruct the duct. This is not a chonic state, however, and soon clears as the inflammation subsides. The common duct may be injured during an operation. If it is not properly repaired, stricture may result. In any of these cases, jaundice occurs, the stools are clay colored, and the urine assumes a deep orange color. The differential diagnosis is mentioned in the paragraphs dealing with the above causes.

The entire list of the more common causes of obstruction may be outlined as follows:

1. Congenital malformations
   a. Atresia
   b. Stenosis with thick mucus or bile
2. Gallstones
3. Trauma
   a. Injury due to severe external force
   b. Operative injury (95 per cent of all postoperative obstructions)
   c. With acute cholecystitis or its complications
   d. Pancreatitis
5. Cysts
   a. Within duct
   b. Outside duct (hydrops of gall bladder, mesenteric cyst, pancreatic cyst)
6. Neoplasms
   a. Benign
      (1) Within the duct—adenomyoma, fibroma, papilloma, polypi
      (2) Outside—hepatic, pancreatic, and mesenteric
   b Malignant
      (1) Within—carcinoma of ducts primary or by extension from gall bladder or liver; carcinoma of ampulla
      (2) Outside—carcinoma of pancreas

Stricture of the duct is difficult to cure. Usually the gall bladder has been removed and cannot be used for anastomosis. (Therefore, some advocate cholecystostomy when choledochostomy is necessary.) The duct

basis of reflux; that is, duodenal content is carried into the biliary ducts, causing repeated acute inflammations. To offset this possibility, various operative maneuvers have been suggested; namely, suturing the duct to the jejunum and anastomosing the ascending and descending loops (hepaticojejunostomy and jejunojejunostomy); the Y loop or Roux principle with and without artificially constructed valves, forming a baffle against ascending infection (valves are made by infolding all the coats of the jejunum or simply the serosa over a catheter; using special Vitallium or plastic or rubber tubes wide at the top and narrow at the

Fig. 376.—Cicatricial obstruction to the common bile duct. The x-ray photograph is that of a woman age 54 years who was operated upon elsewhere for gallstones in the gall bladder and common bile duct. Following her operation she became deeply jaundiced and developed what she termed an abscess at the site of the incision. This was opened and a prodigious amount of bile was drained. Following this procedure the jaundice disappeared but the bile continued to drain.

On entering the hospital the patient was greatly emaciated and extremely weak. She complained that she had lost her appetite, that the stools were light in color, and that the bile flowed continuously from the incision.

At operation the common hepatic duct was identified but the common duct was not present. The duodenum was mobilized and was brought up to the common hepatic duct over a Vitallium tube as shown in the x-ray photograph. The patient was greatly improved and was released from the hospital two weeks after surgery.

Eight months later she returned complaining of jaundice, chills, and fever. The patient was operated upon again and the Vitallium tube was found to be completely occluded by muddy bile and was removed. At this time the jejunum was brought up to the common hepatic duct in the manner of a Roux Y anastomosis.

She re-entered the hospital one year later stating that she had had some episodes of chills and fever. However, after a period of approximately ten days' observation she was released from the hospital and was well when last seen. This illustrates the great problem of cicatricial obstructions to the common bile duct. The use of a foreign body to maintain a patent lumen is questionable. The new plastics which are supposed to be entirely innocuous are still foreign bodies. The present method of treatment is to anastomose the ends of the common duct if this is possible and, if not, to bring up a loop of bowel to the proximal end of the duct so that there will result a mucosa-to-mucosa union. This should be done even if it is necessary to resect a part of the left lobe of the liver to get a normal duct. Then, and only then, can stricture be prevented from reforming.

appearance of being old, rather than the soft mushy variety; in cases of bile stasis as a result of carcinoma of the common duct or head of the pancreas, the incidence of stones is no greater than in the age group affected. Pathologically three types are seen. All are adenocarcinoma: the villous papillomatous or fungating type, the gelatinous type, the diffuse flat infiltrating type. The symptoms and signs are those of chronic cholecystic disease with stones. The diagnosis is difficult to make in the early stage, although occasionally the cholecystogram may arouse suspicions. In late cases with a large, hard mass in the right upper quadrant, painless jaundice, loss of weight, and anemia, it may be suspected. Usually the diagnosis is made at operation or after the gall bladder has been removed. Treatment consists of resection of the gall bladder and the adjacent liver bed, and if there is involvement of the common duct, this, too, may be removed, followed by anastomosis of the common hepatic duct with the duodenum or jejunum.

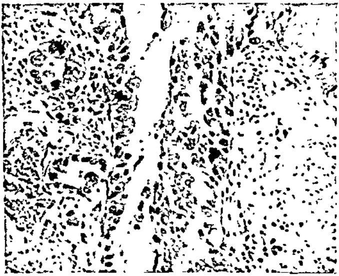

Fig. 377.—Carcinoma of the gall bladder. Note the large undifferentiated cells and their invasion of the submucosa. The gall bladder was enormously distended with a clear mucoid fluid.

Carcinoma of Extrahepatic Ducts and the Ampulla of Vater.—Carcinoma of the extrahepatic ducts is rare and of two pathological types, nodular and papillary. Both grow inward, causing early obstruction to the duct. The common duct is the most frequent site if the ampulla and papilla of Vater are included, next, the junction of the cystic, hepatic, and common, and, last, the hepatic ducts. Symptoms and signs are jaundice with complete biliary obstruction in over 90 per cent. The onset is usually sudden and may be accompanied by chills and fever, vomiting, and pain in over half the cases. Therefore, the usual diagnosis is stone in the common duct, and the true nature of the lesion is discovered at surgery. The treatment consists of resection of the duct, and if the

itself may be so fibrosed that it cannot readily be sutured. This may be facilitated by introducing into it a catheter which is allowed to protrude into the duodenum and then suturing the duct around the catheter. Another ingenious method is to transplant the fistulous tract (which is usually present) into the duodenum.

Some of the methods employed in treating strictures have been described. The principles involved are:

1. Suture of the proximal to the distal end of the duct if possible. This may be accomplished sometimes by splitting the pancreas and uncovering the distal end of the duct. This method has the advantage of preserving the sphincter.

2. Anastomosis to the duodenum or jejunum with as wide a stoma as possible in an isoperistaltic manner.

3. Mucosa sutured to mucosa to avoid stricture.

4. Foreign bodies (Vitallium, plastic tubes, rubber tubes) useful as *temporary splints*. Like all foreign bodies, they soon become obstructed or induce such reaction as to engender fibrosis unless they are passed spontaneously.

5. Division of liver substance between mattress sutures until the proximal end of a large duct is encountered or removal of a portion of left lobe of the liver using the large duct of this lobe.

6. In intrahepatic anastomoses a cuff of mucous membrane may be fashioned by removing the outer coats of the bowel. This cuff is sutured to the proximal end of the duct. The outer coats are then sutured to the liver.

Tumors and Cysts.—Common duct cysts are best *treated* by anastomosis of the cyst wall to the duodenum. We have had two cases. Wide anastomoses were made, and no cholangitis has followed. If in the gall bladder, they may be removed or treated as above.

Benign neoplasms of the common duct or ampulla are removed through choledochostomy or transduodenal resection. Usually they are diagnosed as impacted stones. When removed, they are submitted for biopsy, and if found to be malignant, more radical surgery is done. Benign neoplasms of the gall bladder are usually discovered after cholecystectomy. By careful x-ray studies they may be diagnosed preoperatively. Treatment consists of cholecystectomy.

Malignant neoplasms of the gall bladder comprise about 5 per cent of all cancers seen at post-mortem. In various reported series of surgically removed gall bladders, the incidence of the disease has ranged from 0.2 to 5 per cent. Gallstones apparently constitute an exciting factor and may, in addition to the irritative and digestive action of bile, combine to produce a susceptibility to the disease. Stones have been found in 60 to 80 per cent of all carcinomas of the gall bladder. Although they may be the result of carcinoma, this seems unlikely because there is usually a history of gallstone colic and the stones are hard and faceted, giving the

The patient complains of itching. There are bradycardia, sometimes delirium, and a marked bleeding tendency. The bleeding tendency in jaundice is thought to be due to loss of capillary tone and deficiency in prothrombin. Vitamin K (derived from liver, putrefied fish meal, and alfalfa and the action of coliform bacteria in the large bowel—intrinsic source) seems to increase the prothrombin when given with bile by

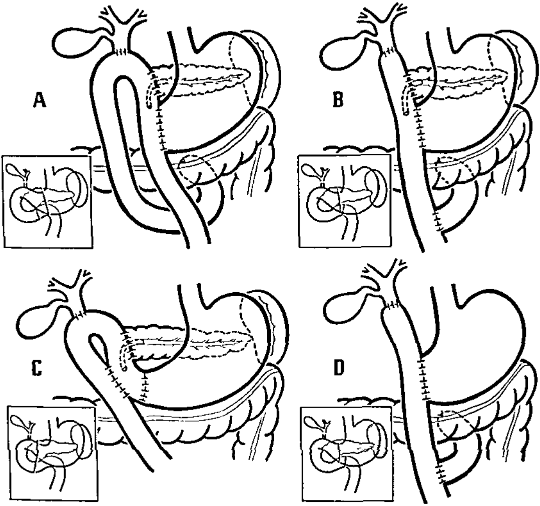

Fig. 378.—Diagrams illustrating methods of resection of the head of the pancreas and of all the pancreas Partial pancreatectomy and total pancreatectomy (Whipple). *A.* An antecolic, isoperistaltic anastomosis with a loop of jejunum. *B.* Antecolic (or postcolic) anastomosis with the Roux Y jejunojejunostomy. *C.* Resection of the head of the pancreas with a Billroth 1 type of stomach-duodenal anastomosis and, in addition, a duodenojejunal anastomosis. *D.* Total pancreatectomy, partial (or total) duodenectomy and splenectomy with Roux Y anastomosis.

mouth. The endothelioblastic or P factor in this hemorrhagic tendency is controlled by giving large doses of vitamin C (cevitamic or ascorbic acid), whereas the calcium balance may be influenced by vitamin D. Therefore, in preparing a jaundiced patient for surgery, a diet rich in protein and carbohydrate and low in fat is given to prepare the liver

gall bladder is uninvolved, it may be used to form an artificial duct by attaching the proximal end to one side of the gall bladder, then doing a cholecystoduodenostomy. If the gall bladder and cystic duct must be sacrificed, a tube may be fashioned from the jejunum much like the Janeway gastrostomy.

Ampullary carcinoma (including the ampulla of Vater and duodenal papilla) constitutes about 1½% of all carcinomas found at autopsy. Grossly there are two types, the papillary type and the ulcerating type, whereas microscopic studies will show adenocarcinoma of all varieties. The neoplasms spread by direct extension into the duodenal wall, pancreas, and common bile duct. They metastasize to nodes of the first echelon, the liver, and the lungs by lymphatic routes and also by the portal vein.

Symptoms and signs include pain which is vague and constant, jaundice which may be painless and progressive or intermittent, or painful intermittent jaundice; occasionally there are chills and fever from an associated cholangitis. Later there are loss of weight, anorexia, and anemia. The gall bladder is distended if there is no associated cholecystitis with stones. A distended gall bladder in the presence of painless jaundice suggests obstruction due to malignancy—Courvoisier's law. Laboratory studies which may help in the diagnosis include tests for occult blood in the stoools, duodenal drainage and study of the duodenal content for blood and neoplastic cells; x-ray examination may show a filling defect at the papilla or flattening or displacement or reversed **3** sign of the preampullary portion of the duodenum. The diagnosis is usually established at operation because the symptoms and signs resemble stone in the common duct, carcinoma of the head of the pancreas, carcinoma of the duodenum or extrahepatic bile ducts. The treatment consists of removal of the distal portion of the duct together with the involved part of the duodenum and pancreas followed by implantation of the common duct into the jejunum. The extent and variety of this procedure will vary with the size and position of the growth and the preference of the surgeon. Our usual desire is to do a one-stage "Whipple type" operation, consisting of resection of the common duct, first portion of the duodenum, and head of the pancreas, part or all, and then closure of distal end of the duodenum, anastomosis of the jejunum to the pyloric end of the stomach (anticolic, Polya type), and implantation of common bile duct into the jejunum (ascending loop). The pancreas is closed with interrupted silk sutures and the pancreatic duct is ligated or, if feasible, anastomosed over a small tube to the jejunum. (See Fig. 378.)

Jaundice.—The clinical state known as jaundice consists of a yellow pigmentation of the skin and is due to the deposition of bile pigment (or pigment from the disintegration of blood corpuscles) in the skin. The sclera are tinted yellow and, in jaundice of the obstructive type the urine is deeply colored due to the presence of bile. The serous cavities and parenchymatous organs may also be bile-tinged due to cholemia.

b. Causes in the wall of the ducts
  (1) Inflammation (cholangitis)
  (2) Strictures
  (3) Congenital anomalies (atresias and stenosis)
  (4) Benign and malignant neoplasms in the ducts or ampulla
c. Causes outside the ducts
  (1) Carcinoma at the head of pancreas
  (2) Carcinoma of the duodenal papilla
  (3) Tumors and cysts pressing on ducts
  (4) Lymphadenopathy at the hilus
  (5) Chronic pancreatitis
  (6) Cysts of the pancreas

The cause of the jaundice is an increase in the intrabiliary pressure with a rhexis of the ampullary portions of the small bile capillaries, permitting posthepatic bile to be absorbed by the liver lymphatics. There is also leakage without actual rupture of the bile capillaries which become more permeable as they dilate. The bile capillaries also become more permeable as a result of toxic agents and anoxemia, permitting bile leakage.

Intrahepatic jaundice or jaundice due to hepatocellular damage (toxic or infective) is due to a destruction of liver cells by some disease such as *acute yellow* atrophy of the liver or by poisons which affect the liver cells, such as chloroform, or toxins from bacteria, or virus infections. In this case some bile may be present in the stools, the urine will contain large quantities of bile, the liver will be markedly enlarged, and no symptoms of obstruction as previously described will be present, although when hepatocellular damage is extensive, the stools may be acholic and the urine may contain very little urobilinogen. Since there is some hepatocellular damage in all types of jaundice, particularly the obstructive variety, it is possible to classify the intrahepatic type of jaundice with precision. The causes, therefore, must include those mentioned under obstructive jaundice and, in addition, epidemic hepatitis, homologous serum jaundice, poisons (carbon tetrachloride, chloroform, phosphorus, phenylhydrazine, arsenic, cinchophen, the sulfonamides), epidemic jaundice, Weil's disease (Chapter 7), hyperthyroidism, eclampsia, severe or prolonged hematogenous jaundice, yellow fever, the cirrhosis, carcinoma, lymphosarcoma, the leucemias.

Hemolytic or acholuric jaundice has nothing to do with the liver per se but is due to a dissolution of red blood cells in large numbers with disintegration of the hemoglobin and deposition of the pigments in the skin. This condition is diagnosed by the fragility test of red blood cells, the presence of abnormal cells such as the spherical microcyte of congenital hemolytic arteries, the sickle cell in sickle-cell anemia, the variation in types and numbers of white cells in the leucemias. The urine contains no bile as a rule. Since about half or the cases of congenital hemolytic jaundice have stones, there may be an obstructive jaundice as well. It is associated with splenomegaly and is treated sometimes by splenectomy.

for the ordeal (since the crippled liver may not be able to store glycogen). Blood transfusion, vitamin K with bile, and vitamins C and D should also be a part of the preoperative prepartion. (Vitamin K is now produced synthetically and may be given parenterally without bile.) Other symptoms and signs depend upon the causative factors. We have discussed previously the physiology of bile formation, excretion, and absorption; also, the difference between pre- and posthepatic bile. Function tests and methods which help in evaluating liver reserve and the probable cause or causes of jaundice have also been mentioned. It remains now to classify the types of jaundice as to their cause, to evaluate symptoms and signs in an effort to make the proper diagnosis, and to institute the correct treatment.

In general, there are three causes for jaundice: excessive hemolysis, destruction of liver cells, and obstruction of the duct system, although any two or all three causes may be present at the same time; that is, jaundice may be due to (1) the production by the reticulo-endothelial system of more bile pigment than the liver can excrete (as in hemolytic jaundice and malaria), (2) inability to excrete a normal amount of bile because of liver damage (as in cardiac decompensation and Hanot's cirrhosis), or (3) failure to eliminate the bile which is secreted because of obstruction.

The first two conditions produce *retention* jaundice; bilirubin is held back, which may be suspected by the fact that the serum gives an *indirect* van den Bergh reaction. The third condition produces *obstructive* jaundice (or regurgitation jaundice) and may be due to calculi, inflammation, neoplasms, stenosis, or necrosis of liver cells. Bilirubin is secreted by the liver cells but because of the obstruction cannot be excreted. In this condition the blood serum gives a *direct* van den Bergh reaction (just as bile itself does) and the urine contains bilirubin.

Obstructive jaundice is due to a blockage of the common bile duct. This may be due to obstruction within the duct, as in the case of a stone, or to obstruction caused by extraneous pressure, as in carcinoma of the head of the pancreas (as will be pointed out in the following section). The stools will be white in color. The causes of obstructive jaundice may be classified as follows:

1. Obstruction of bile ducts in the liver
   a. Partial
      (1) Inflammatory lesions such as amebic, pyelephlebitic, and pyemic abscesses; cholangitis
      (2) Early biliary cirrhosis
      (3) Tumors and cysts, such as carcinoma, primary or metastatic, echinococcus cysts
   b. Total or almost total
      (1) Late biliary cirrhosis
2. Obstruction of bile ducts outside the liver
   a. Causes within the ducts
      (1) Stone
      (2) Papilloma
      (3) Carcinoma

The alveoli of the gland develop as dark-staining buds in 45-day embryos, and the islands do not appear until about 60 to 70 days.

The main arterial supply is from the gastroduodenal artery, a branch of the hepatic from the celiac artery. The gastroduodenal descends between the duodenum and pancreas and divides into the right gastroepiploic and the superior pancreaticoduodenal. The pancreas also receives blood from the inferior pancreaticoduodenal artery, a branch of the superior mesenteric artery, or one of the jejunal branches, and the pancreatic rami from the splenic. The veins are the pancreatic duodenal and small branches which empty into the splenic. The lymph vesels empty into the celiac nodes as well as the superior mesenteric chain. The nerves are now medullated and come from the celiac, hepatic, and splenic plexuses.

From this discussion, it may be understood how some of the pancreatic variations and anomalies may occur. Among these are the following: (1) Duplication. The uncinate process may be entirely separate, forming a lesser pancreas. (2) Overdevelopment of the uncinate process, converting the letter J, which lies thus ⊂ normally, to the letter U, lying thus C. This is important in pancreatic resections. (3) Annular pancreas which completely surrounds the duodenum and which may cause an obstruction. (4) The pancreatic duct may open into the duodenum separate from the common bile duct in 20 per cent of people; in 20 per cent they form a common channel of some length; in 60 per cent they empty together in the ampulla. (5) Accessory pancreas may be found in the wall of the stomach or duodenum, or heterotopias may be found in Meckel's diverticulum or parts of the gastrointestinal tract. (6) Duodenal diverticula may, in fact, be remnants of the outpouchings which give rise to the liver and pancreas.

The pancreas is located in the upper posterior portion of the abdomen in what is roughly described as the epigastric region. The organ lies against the spinal column and is covered by a layer of visceral peritoneum (on its inferior surface) and by the bursa omentalis (on its anterior surface). Anterior to the pancreas is the lesser peritoneal cavity, which, as we have learned, is bounded anteriorly by the stomach, on the right by the gastrohepatic ligament, and on the left by the gastrosplenic ligament. There is one opening between the lesser and the greater peritoneal cavity known as the foramen of Winslow, or the gastroepiploic foramen. It may be readily understood, then that the pancreas (even when diseased) is not readily palpable because of the deep situation of the organ and the fact that the stomach lies anterior to it.

The pancreas elaborates an external secretion (pancreatic juice) and, in addition, an internal secretion (insulin), which has to do with sugar metabolism. The external secretion flows through the pancreatic duct (duct of Wirsung, and the accessory pancreatic duct (duct of Santorini) and enters the duodenum. (Usually the pancreatic duct empties at the ampulla of Vater with the common bile duct, but often the ducts empty separately.) The pancreatic juice contains amylase (or amylopsin or diastase), which digests carbohydrates, lipase (or steapsin), which digests fats, trypsin, which digests protein, rennin, which has an action similar to that of gastric rennin, and maltose in small amounts (see Chapter 20).

The internal secretion, insulin, is elaborated by the islands of Langerhans and metabolizes sugar. This secretion is hormonal, for it is carried by the blood stream, and when it is absent or decreased, *diabetes mellitus* results. *Diabetes mellitus* is also intimately related to the pituitary secretion (diabetogenic factor). Houssay has shown that diabetic symptoms following pancreatectomy almost disappear after hypophysectomy. Dogs die after pancreatectomy unless treated with insulin. If, however, the hypophysis is removed, symptoms disappear.

Total pancreatectomy in man requires only small amounts of insulin. In fact, the depancreatized man requires less insulin and is more sensitive to insulin than many diabetic patients, a fact which makes one think that diabetes mellitus

The causes of *hematogenous* jaundice include severe infections with septicemia or bacteriemia (see Chapter 5), malaria, pernicious anemia, icterus neonatorum, high gastrointestinal or internal hemorrhage, erythroblastosis fetalis, familial hemolytic icterus, sickle-cell anemia, hemolytic transfusion reaction, hemolytic poisons or allergens. As we review the respective causes, we see that they are interrelated and more than one factor may be acting simultaneously. Thus a patient with obstructive jaundice and liver damage may have extensive internal hemorrhage (all three types) or severe anemia, hepatic anoxia, and thick bile, causing an obstruction (again all three types). Such combinations occur commonly in yellow fever, spirochetal disease, erythroblastosis fetalis, hemolytic icterus, and after administration of the hemolytic-hepatotoxic drugs such as arsphenamine, phenylhydrazine, etc.

The diagnosis of the type of jaundice depends on an accurate history, careful study of all symptoms and signs, and laboratory aids.

The treatment depends upon the cause. The greatest problem is not the medical management of the jaundiced patient, but the decision as to whether or not surgery is indicated. It is indicated in the obstruction types—gallstones, bile fistulae, complete and permanent obstruction from carcinoma. It is not indicated in primary hepatocellular types. Thus, a history of blood or plasma transfusions within recent months, or the taking of certain drugs as mentioned, the presence of collateral circulation or vascular spiders or edema lead one to think in terms of nonsurgical jaundice. Severe jaundice with bile in the stools usually means diffuse hepatocellular (intrahepatic) jaundice, and if, in addition, the prothrombin time is not shortened by the administration of vitamin K, the damage is probably widespread.

The Pancreas

The pancreas develops from two anlages which appear in 3 to 4 mm. embryos about the same time. The *dorsal pancreas* arises as a pouch from the posterior wall of the duodenum just above the diverticulum. It grows in the greater omentum between the duodenum and stomach, where its distal portion is constricted to form the accessory pancreatic duct, and its main portion takes part in forming the head and uncinate process and makes up the whole of the body and tail. The *ventral* pancreas develops in the angle between the hepatic diverticulum and the duodenum, and with the development of the bile duct it becomes separated from the duodenum, although it may arise directly from the wall of the duodenum. The ventral pancreas is much smaller, and it gives rise to the main pancreatic duct which enters into the common bile duct and forms part of the head and uncinate process. Ultimately the two ducts unite and the duct of the dorsal pancreas becomes the accessory duct (Santorini), whereas the duct of the ventral becomes the functional pancreatic duct (Wirsung).

In 35-day embryos the portal vein separates the two pancreatic anlages, and later they partially surround the vein. The superior mesenteric vein thus passes through the pancreas and is joined by the splenic vein which runs along the posterior surface of the pancreas, receiving small veins from the organ. As the stomach and duodenum rotate to the right, the pancreas takes a transverse position with its tail to the left, and the transverse mesocolon comes to be anterior to it. The gland has no true capsule.

The alveoli of the gland develop as dark-staining buds in 45-day embryos, and the islands do not appear until about 60 to 70 days.

The main arterial supply is from the gastroduodenal artery, a branch of the hepatic from the celiac artery. The gastroduodenal descends between the duodenum and pancreas and divides into the right gastroepiploic and the superior pancreaticoduodenal. The pancreas also receives blood from the inferior pancreaticoduodenal artery, a branch of the superior mesenteric artery, or one of the jejunal branches, and the pancreatic rami from the splenic. The veins are the pancreatic duodenal and small branches which empty into the splenic. The lymph vessels empty into the celiac nodes as well as the superior mesenteric chain. The nerves are now medullated and come from the celiac, hepatic, and splenic plexuses.

From this discussion, it may be understood how some of the pancreatic variations and anomalies may occur. Among these are the following: (1) Duplication. The uncinate process may be entirely separate, forming a lesser pancreas. (2) Overdevelopment of the uncinate process, converting the letter **J**, which lies thus ⊂ normally, to the letter **U**, lying thus **C**. This is important in pancreatic resections. (3) Annular pancreas which completely surrounds the duodenum and which may cause an obstruction. (4) The pancreatic duct may open into the duodenum separate from the common bile duct in 20 per cent of people; in 20 per cent they form a common channel of some length; in 60 per cent they empty together in the ampulla. (5) Accessory pancreas may be found in the wall of the stomach or duodenum, or heterotopias may be found in Meckel's diverticulum or parts of the gastrointestinal tract. (6) Duodenal diverticula may, in fact, be remnants of the outpouchings which give rise to the liver and pancreas.

The pancreas is located in the upper posterior portion of the abdomen in what is roughly described as the epigastric region. The organ lies against the spinal column and is covered by a layer of visceral peritoneum (on its inferior surface) and by the bursa omentalis (on its anterior surface). Anterior to the pancreas is the lesser peritoneal cavity, which, as we have learned, is bounded anteriorly by the stomach, on the right by the gastrohepatic ligament, and on the left by the gastrosplenic ligament. There is one opening between the lesser and the greater peritoneal cavity known as the foramen of Winslow, or the gastroepiploic foramen. It may be readily understood, then that the pancreas (even when diseased) is not readily palpable because of the deep situation of the organ and the fact that the stomach lies anterior to it.

The pancreas elaborates an external secretion (pancreatic juice) and, in addition, an internal secretion (insulin), which has to do with sugar metabolism. The external secretion flows through the pancreatic duct (duct of Wirsung, *and the accessory* pancreatic duct (duct of Santorini) and enters the duodenum. (Usually the pancreatic duct empties at the ampulla of Vater with the common bile duct, but often the ducts empty separately.) The pancreatic juice contains amylase (or amylopsin or diastase), which digests carbohydrates, lipase (or steapsin), which digests fats, trypsin, which digests protein, rennin, which has an action similar to that of gastric rennin, and maltose in small amounts (see Chapter 20).

The internal secretion, insulin, is elaborated by the islands of Langerhans and metabolizes sugar. This secretion is hormonal, for it is carried by the blood stream, and when it is absent or decreased, *diabetes mellitus* results. *Diabetes mellitus* is also intimately related to the pituitary secretion (diabetogenic factor). Houssay has shown that diabetic symptoms following pancreatectomy almost disappear after hypophysectomy. Dogs die after pancreatectomy unless treated with insulin. If, however, the hypophysis is removed, symptoms disappear.

Total pancreatectomy in man requires only small amounts of insulin. In fact, the depancreatized man requires less insulin and is more sensitive to insulin than many diabetic patients, a fact which makes one think that diabetes mellitus

is due not only to too little insulin, but to an insulin-inhibiting mechanism as well, although there is no proof for the latter. The depancreatized human being requires about 40 to 70 units of insulin daily during the first week, and can be maintained on 25 to 40 units daily thereafter.

Depancreatized dogs receiving insulin and a diet of meat and carbohydrates develop fatty livers unless raw pancreas is added to the diet. Lecithin, choline (a base in the lecithin molecule), the amino acid methionine, which gives its methyl group to aid in the formation of choline, and *lipocaic* (Dragstedt), a pancreatic hormone, also prevent the formation of fatty livers in depancreatized dogs. In addition, dogs without a pancreas lose about 50 per cent of the fat and about 20 per cent of the carbohydrate in their stools.

This work is now of great practical importance because it provides a scientific basis for maintaining the depancreatized patient. To prevent a fatty liver and hypolipemia, readily available lipotropic substances are given such as choline (one egg yolk contains 0.5 Gm. of choline; it is also found in liver and may be given as choline chloride). Lipocaic and choline may be given by adding raw pancreas to the diet; also pancreatin, which will also reduce the loss of nitrogen and fat.

It remains to be seen whether the degenerative complications of diabetes such as diabetic arteriosclerosis, retinopathy, neuropathy, and intercapillary glomerulosclerosis) will occur after pancreatectomy in man.

Hypoglycemia.—We have just considered the cause or causes of hyperglycemia due to insufficient insulin. This is diabetes which, if untreated, does not provide for proper sugar metabolism, and the parenchymal cells of the liver as well as the cells of other tissues receive an insufficient supply of sugar, and glycogen will not be stored in them or in the liver. Hypoglycemia due to too much insulin as well as other causes provides for sugar metabolism at such a fast rate that again the liver cells cannot store glycogen nor can the tissue cells utilize it. The causes of hypoglycemia may be (1) hepatogenic, (2) organic hyperinsulinism, (3) functional hyperinsulinism. A more detailed outline has been arranged by Conn:

Etiologic Classification of Spontaneous Hypoglycemia

I. Organic—recognizable anatomic lesion
  A. Hyperinsulinism
    1. Pancreatic island cell adenoma
      (a) Single
      (b) Multiple
      (c) Aberrant
    2. Pancreatic island cell carcinoma
      (a) Localized
      (b) With metastases
    3. Generalized hypertrophy and hyperplasia of the islands of Langerhans
  B. Hepatic disease
    1. Ascending infectious cholangiolitis
    2. Toxic hepatitis
    3. Diffuse carcinomatosis
    4. Fatty degeneration or "fatty metamorphosis"
    5. Glycogenosis (von Gierke's disease)
  C. Pituitary hypofunction (anterior lobe)
    1. Destructive lesions (chromophobe tumors, cysts)
    2. Atrophy and degeneration (Simmonds' Disease)
    3. Thyroid hypofunction (? secondary to pituitary hypofunction)

D. Adrenal hypofunction (cortex)
    1. Idiopathic cortical atrophy
    2. Destructive infectious granulomas
    3. Destructive neoplasms
E. Central nervous system lesions (hypothalamus or brain stem; interference with nervous control of blood sugar)

II. Functional—no recognized anatomic lesion but explainable on basis of unusual somatic function
A. Hyperinsulinism (imbalance of the autonomic nervous system): hypoglycemic fatigue, nervous hypoglycemia, functional hypoglycemia, reactive hypoglycemia
B. Alimentary hyperinsulinism (rapid intestinal absorption)
    1. After gastroenterostomy
    2. After gastric resection (partial or total)
C. Renal glycosuria (severe degrees of low renal threshold for dextrose)
D. Lactation
E. Severe continuous muscular work

III. Miscellaneous
A. Factitious (surreptitious insulin administration)
B. Postoperative hypoglycemia
C. Severe inanition
D. Unknown

The various causes for hypoglycemia are important to remember because upon proper diagnosis depends the treatment. Although glycogen is found in many tissues of the body, the fact that fatal hypoglycemia always follows hepatectomy is sufficient evidence that the liver is the main source. Glucose or those substances which may be converted to glucose without the aid of the liver are the only remedies which will prevent death from hypoglycemia in the liverless animal. The cause of death from hypoglycemia may be due to functional alterations in the central nervous system. Glucose is the main, if not the only, source of energy for the brain. It would appear that the cause of death in hypoglycemia, no matter what its cause may be, is the same; namely, an interference with oxidative metabolism of the brain. The cerebral hemispheres are affected first and then the vital centers in the medulla. Thus glucose is as necessary for life as is oxygen, and when the blood sugar gets below a certain critical level, symptoms will occur which are characteristic, and death will follow if the condition is not alleviated.

The usual symptoms of hyperinsulinism as defined by Whipple (Whipple's triad) and which usually indicate organic disease are (1) disorders of the central nervous system such as confusion, coma, convulsions, collapse coming on in a fasting state, (2) a drop in the blood sugar level to 50 mg. per 100 c.c. or less, (3) relief of symptoms brought about by the administration of glucose.

The possibility of a spontaneous hypoglycemia must be kept in mind so that erroneous diagnosis will not be made (epilepsy, intracranial tumor, narcolepsy psychosis, psychoneurosis, peptic ulcer, etc.). Moreover, in a given case of hypoglycemia, the differential diagnosis may be difficult. Certain tests are helpful: (1) a fasting blood sugar below 50 mg. per 100 c.c. usually means organic hypoglycemia; (2) dextrose tolerance test (low curve); (3) liver function tests; (4) progression of symptoms clinically and lowering of blood sugar as the disease progresses means either hyperinsulinism or liver disease. (5) A diet low in carbohydrate (50 Gm. or less) and high in protein may relieve the attacks (due to the fact that while 50 per cent of the protein may yield dextrose, the slow even rate of conversion as well as the slower absorption of protein will prevent quick and great elevations in blood sugar and thereby prevent stimulation of the pancreas).

In the absence of extrapancreatic causes for hypoglycemia with low blood sugar during symptoms which are relieved by administration of dextrose, with repeated fasting blood sugars of 50 mg. per 100 c.c. when the patient has been on an adequate diet, and with depression of the fasting blood sugar below 40 mg. per 100 c.c. by carbohydrate restriction, a diagnosis of organic hyperinsulinism may be made and exploration done. The more severe and rapidly progressive the symptoms, the more apt the possibility of malignancy rather than an adenoma as a cause. Apparently the size of the carcinoma or adenoma is not necessarily commensurate with the degree of hyperinsulinism. In severe cases of hyperinsulinism where no tumor has been found, partial pancreatectomy is indicated. Apparently alloxan does not control the symptoms in human beings.

Severe postoperative hypoglycemia may occur from (1) the utilization of glucose faster than it is being supplied, (2) an insufficient amount given, (3) failure of the intrinsic hepatic mechanisms for storage, synthesis, or secretion of glucose, (4) primary hepatic insufficiency. In this discussion we are interested in (1). Any one of the conditions mentioned in the outline may be the cause or any combination may occur. In postoperative stupor, coma, or other central nervous system dysfunction hypoglycemia must be considered as a cause for the symptoms.

Tests of Pancreatic Function.—Experimental obstruction of the pancreatic duct causes a rise in blood amylase and lipase. Morphine is said to increase resistance in the sphincter of Oddi from the normal (about 150 mm. of water) to higher levels (about 250 to 300 mm. of water) causing pancreatic reflux. Normally a small amount of lipase and amylase are present in the blood stream, but not trypsin. This may mean that the former are, in part, an "internal secretion," but whether they enter the blood stream directly from the acinar cells or indirectly from the gastrointestinal tract is not known. It is thought that in inflammations the former is true because the rise in serum amylase is prompt. However, the enzymes may enter the blood stream as a result of rupture of small pancreatic canaliculi, permitting the lymphatics to carry the pancreatic juice directly into blood vessels. It is possible that inflammations of acinar cells cause a hypersecretion, whereas destruction decreases the secretion. Serum amylase may be quickly determined and varies between 80 to 180 mg. per 100 c.c. (Somogyi method), or when iodine is used to measure the rate of disappearance of starch, 300 to 350 units are considered normal. Urine amylase is also quickly measured. Serum lipase determination requires about twenty-four hours. The normal value is 1.5 c.c. of twentieth normal sodium hydroxide per cubic centimeter of serum using the method of Cherry and Crandall (olive oil is used as the substrate, and lipolytic activity is expressed in terms of c.c. n/20 Na OH liberated in 1 c.c. of serum). Elevated amylase values occur within a few hours after the onset of inflammation and reach a maximum in twenty-four to forty-eight hours. Elevated values of lipase also occur early and persist for a much longer period and are more apt to be associated with malignant disease.

Analysis of duodenal content and stools for pancreatic enzymes may give valuable information. Also, analysis of stools for undigested and unabsorbed foods in the cases where no pancreatic juice is present will show a decided increase in the quantity of fat, nitrogen, starch, and the total carbohydrate eliminated in the feces.

Tests for disturbed secretion of insulin include the examination of urine for glycosuria which may be present in acute pancreatitis and examination of the blood for hyperglycemia which may also occur in acute pancreatitis as well as in diabetes mellitus.

The pancreatic hormone concerned with fat metabolism is thought to be lipocaic. It is also believed that the alpha cells of the islands of Langerhans secrete the substance which, when excluded, leads to hypolipemia and fatty metamorphosis with impaired liver function diminished excretion of dextrose, and great sensitivity to insulin. In such cases the disturbed fat metabolism may be discovered by blood cholesterol studies and the disturbed liver function by liver tests as previously described in this chapter.

Functional Diseases of the Pancreas

Pancreatic insufficiency may occur in infancy. Fibrocystic disease or pancreatic fibrosis of the pancreas may be congenital and even familial. Either the infant dies of malnutrition or he develops pulmonary infection with fibrosis, bronchiectasis, and patchy atelectasis and may succumb before he reaches the age of adolescence. The pancreas shows the acinar tissue to be replaced by fibrous tissue or fat.

Obstructive conditions in the pancreas in the fetus are associated with meconium ileus after birth and later with nutritional disturbances in which celiac syndrome and respiratory disease predominate. The obstruction is thought to be tenacious mucus or inspissated secretion in the acini and dilated ducts, resulting in parenchymal atrophy. In children who survive more than a few months after birth both lungs nearly always show effects of obstruction in the trachea, the bronchi, and bronchioles by thick tenacious mucoid and mucopurulent material (Farber). The mucous glands of the trachea, bronchi, esophagus, duodenum, gall bladder and jejunum are distended with mucoid material. The liver resembles the pancreas in these cases.

Achylia pancreatitis may be purely functional or it may have as its background partial fibrotic changes. The exclusion of pancreatic juice from the intestine results in impairment of digestion and absorption of protein, fat, and carbohydrate. Patients lose weight and strength and have frequent bulky stools which show an excess of fat and nitrogen. Substitution therapy (pancreatin) helps in relieving symptoms and restoring health. Indeed it may be a therapeutic test as to the accuracy of diagnosis.

Pancreatic pain is due to (1) visceral impulses by way of the celiac ganglion, causing girdle pain around the mid-abdominal region and radiating in a diffuse way to the lower abdomen and (2) somatic impulses which occur when the peritoneum is stimulated. Since the peritoneum covers the body and tail of the pancreas, lesions involving this part of the organ are notorious for their severe pain carried by sensory fibers in the lower intercostal and upper lumbar nerves and extending down into the groins (ilioinguinal and iliohypogastric nerves).

The cause of pain may be inflammatory (acute and chronic pancreatitis, acute pancreatic edema, calcareus pancreatitis) or neoplastic (carcinoma, especially of the tail of the pancreas).

The treatment consists in a direct attack on the primary cause of the pain. If this is not feasible or if pain persists after pancreatic resection, unilateral (or bilateral) splanchnic nerve section and lower dorsal sympathectomy may be indicated.

Congenital Anomalies of the Pancreas

Congenital abnormalities have been enumerated under the discussion on embryology of the pancreas. Cystic fibrosis of the pancreas has been described. Although its etiology is not definitely known, it seems that

one component of the syndrome (atresia of the pancreatic ducts) is due to a congenital malformation; the other theories as to its cause (inflammation of the pancreas during fetal life and vitamin A deficiency during life) are not.

Pancreatic heterotopia, pancreatic dystopia, or **heterotopic pancreatic tissue** is not, strictly speaking, an anomaly of the pancreas itself or its blood supply but rather the presence of pancreatic tissue outside its normal location. The heerotopias are usually single and may include all components of the normal pancreas or pancreas without the islands of Langerhans. The presence of these heterotopias may mimic benign growths (adenomyoma, fibroma, leiomyoma) or carcinoma of the viscus involved. A few cases of hypoglycemia have been traced to such aberrant pancreases either because of islet-cell adenoma or carcinoma or merely hyperplasia. Furthermore, such tissue may undergo pathological changes similar to the pancreas itself (inflammation, new growths, cysts, hemorrhage, and necrosis).

Heterotopias are usually found in the stomach or duodenum but may occur in the jejunum or transverse colon or in the gastrocolic omentum or transverse mesocolon and ileum in a Meckel's diverticulum. When symptoms occur which resemble organic disease of the gastrointestinal tract, the possibility of heterotopia of the pancreas should be considered. X-ray studies may reveal the defect. If the symptoms are acute, resembling appendicitis, or if intussusception is present as a result of heterotopia, the diagnosis will be made at operation. Surgery consists of removing the tissue together with the involved segment of intestine or stomach.

Annular pancreas has been mentioned previously. The ring of pancreatic tissue may cause obstruction in the duodenum. This condition cannot be diagnosed as such prior to operation. However, the site of the obstruction may be ascertained by x-ray studies and clinical symptoms and signs (see Chapter 20). The condition is best treated by short circuiting around the obstruction by gastrojejunostomy or duodenojejunostomy.

We have recently encountered two cases of annular pancreas. One was associated with malrotation of the mid gut. Both were successfully treated by duodeno-jejunostomy, and in one the duodenum was released by dividing adhesions to the lateral abdominal wall.

Injuries of the Pancreas

Injuries to the pancreas are usually suspected in penetrating or perforating wound of the upper abdomen. However, the pancreas may be injured by direct trauma to the abdomen without external wound, and this type of injury may account for the pancreatitis which is apt to follow. The treatment of penetrating and perforating wounds is surgical. Usually the stomach or transverse colon or other organs will be injured in the line of the bullet or sharp object. All wounds are closed. If the pancreas has been penetrated, drainage is indicated because the

apparently small wound may slough and leakage may occur. Contusions to the abdomen with injury to the pancreas may give rise to symptoms and signs resembling pancreatitis. Surgery is not indicated if there has been no ruptured hollow viscus or solid organ.

Diseases and Inflammations of the Pancreas

Pancreatic calculi are rare, occurring about once in 2,000 cases seen at autopsy. Yet minor degrees of calcification within the gland are probably common. The cause of the disease is unknown. However, many theories have been advanced. (1) Calcification may be caused by the reflux of bile into the pancreas. (2) Since the stones are made almost entirely of calcium carbonate and calcium phosphate and since these salts are not normal constituents of pancreatic juice, the calculi are due to an alteration of the pancreatic secretion caused by infection (by way of the blood, lymph, or ducts). (3) Pancreatitis may give rise to calcification in the areas of necrosis which, like any infection, may heal by fibrosis or calcification—these are not calculi but may enter the ducts like the broncholiths which also occur as a result of calcifications in the lung.

Pathology.—Pancreatic calculi are like salivary calculi, being white in color and hard and rough and vary greatly in size. Rarely are they found as a solitary stone. Often there are several hundred which may be in the head (usually) or tail or all of the gland. Fibrosis is frequently present as is cystic degeneration or dilatation of the obstructed ducts. In this regard the organ resembles fibrocystic disease in infants which is due to blockage by inspissated secretion or mucus instead of calculi. Associated pathology includes large cysts, abscesses, carcinoma, or hemorrhage due to erosion of a stone into a large vessel. Sometimes the stone becomes lodged in the ampulla, giving rise to jaundice and changes in the liver if long continued (Charcot's biliary cirrhosis). In advanced stages fatty changes occur in the liver due to interference with lipocaic production. Over 35 per cent of patients with pancreatic calculi have diabetes. Pain in the upper abdomen in patients with diabetes may mean calculi in the pancreas.

The association of pulmonary tuberculosis in many of these cases may be due to the loss of weight and strength caused by achylia pancreatica due to stones in the duct. It is true that digestion is impaired and that there may be diarrhea or pale, frothy, bulky stools with undigested fat and meat, yet tuberculosis is often found without this syndrome.

Pancreatic abscess may precede the formation of stones. We have seen two cases of this kind in children: One, a girl 11 years old, later developed extensive calcification after the abscess had been drained and also pulmonary tuberculosis, from which she ultimately succumbed. The other, a boy 10 years of age, has not been heard from recently but was well five years after drainage. Rarely, other calculi are present in the bile ducts or kidneys. Hyperparathyroidism may also be present.

Symptoms.—Pain is the most common symptom but may vary from an occasional twinge to severe colic, requiring morphine. Some patients are asymptomatic. The pain is in the midline and radiates to the left upper quadrant, left back, and scapular region. There is nausea and vomiting and weight loss. Many of these patients are alcoholics or barbiturate addicts because of pain. The pain resembles that of gallstone colic or renal colic. The frequent association of diabetes and jaundice makes the diagnosis difficult. The age varies, but usualy pancreatic calculi are seen in the third or fourth decade. There are few signs. A mass may be felt if there is a cyst or extensive swelling. Laboratory studies may show elevated lipase, hyperglycemia, or glucose tolerance curves characteristic of diabetes. X-ray studies constitute the best diagnostic aid. Films should be taken in the anteroposterior, lateral, and oblique views, and since the stones are composed of calcium, they throw a dense shadow. They may be confused with renal calculi, gallstones, calcified lymph nodes, and phlebolites.

Treatment consists of dietary management and pancreatin if no pain is present or if no associated disease is noted. Otherwise surgery is indicated. The procedure most likely to give permanent relief is partial or total pancreatectomy, and this should be done where feasible. If not, the pancreatic duct may be ligated so that atrophy of the gland will take place in the acini but probably not in the island of Langerhans. An indirect method of attacking the problem is the amelioration of pain by dividing the autonomic fibers as described under Functional Diseases of the Pancreas in this chapter. Transthoracic resection of the thoracic sympathetic ganglia (third to twelfth) and of the great splanchnic nerve on one side will give relief. If the pain is in the midline, the right side is treated; if on the left, the left side is treated. Bilateral subdiaphragmatic splanchnicectomy has also been advocated. It may be done transabdominally so that exploration of the pancreas may be carried out.

Pancreatitis may be acute or chronic. The *acute* varieties may be subdivided into (1) fat necrosis, (2) hemorrhage or "pancreatic apoplexy," (3) acute hemorrhagic pancreatitis or acute hemorrhagic necrosis, (4) acute interstitial or acute parenchymatous pancreatitis, or acute pancreatic edema, (5) acute secondary pancreatitis due to perforated peptic ulcer, purulent peritonitis of lesser peritoneal cavity, acute pancreatitis as a result of pyemia, (6) virus pancreatitis associated with mumps or epidemic parotitis.

Fat necrosis is a fat tissue necrosis in the pancreas, omentum, mesentery, abdominal wall, and, rarely, the liver and subcutaneous fat. It is seen in hemorrhage of the pancreas, obstruction of the ducts by stones, trauma, acute hemorrhagic pancreatitis, and any condition which liberates lipase, splitting the fat, and, trypsin, digesting cellular tissue.

Hemorrhage is seen in passive congestion with general passive hyperemia in which there are small areas of bleeding and in pancreatic necrosis

from any cause in which a large vessel is eroded, causing extensive bleeding. Sudden death, "pancreatic death," may occur in the latter instance.

Of the inflammations of the pancreas, *acute hemorrhagic pancreatitis* is perhaps the most alarming. It has been called acute hemorrhagic pancreatitis because the activated ferment, *trypsin*, digests the pancreas, causing hemorrhage and leakage of other ferments into the general peritoneal cavity. The cause of this is thought to be the reflux of bile into the pancreas under pressure, due to closure of the sphincter of Oddi by stones or spasm (as seen in those who overeat). Mallet-Guy and co-workers have produced the disease experimentally by electrical stimulation of the greater splanchnic nerve. *Steapsin* needs no activation and readily digests peritoneal and omental fat, causing "fatty necrosis," although some observers believe that intestinal juices or tissue kinases are needed. Bile in the peritoneal cavity may produce fat necrosis by affecting tissue permeability, allowing the escape of pancreatic juice. Pathologically, this condition is characterized by little soap deposits (calcium plus fatty acids) in the fatty tissues of the abdomen.

Clinically, it is characterized by very great pain, vomiting, and often shock, with tenderness and rigidity of the upper abdomen. There is perhaps no disease except mesenteric thrombosis with as much pain. The cause has been attributed to gall bladder disease, but this is not certain.

Most patients are obese and middle-aged, although no age group is excluded. Either sex is affected and the disease is usually seen in those who have within an hour or two indulged in a heavy meal with liberal amounts of alcohol.

Acute parenchymatous pancreatitis (acute pancreatic edema, acute interstitial pancreatitis) is the most common form of acute pancreatic disease. It is a much milder condition pathologically and clinically and resembles gallstone colic or acute cholecystitis. The pathological reaction of the pancreas in acute inflammations of any kind is due to the activation of *trypsinogen to trypsin, producing edema, necrosis, and hemorrhage.* Once the process begins, it may be self-perpetuating, even though the original cause has been removed. The amount of damage depends on the amount and concentration of the enzymes in the juice which escapes. As a result of this, the damage may vary from a transient edema to necrosis of all tissue, including blood vessels with resultant hemorrhage. Secondary infection may supervene, producing *pancreatic abscess.* The presence of shock depends also on the amount of destruction and the rapidity with which it occurs. Shock may be due to hemorrhage, the presence of autolyzed tissue in the retroperitoneal and peritoneal spaces, chemical peritonitis, and reflex neurogenic factors.

The necrotic tissue may liquify, giving rise to *pseudocysts*, or it may be absorbed with resultant fibrosis or calcification or both. There will be some regeneration of glandular tissue. Extreme fibrosis, with some pseudo-

cysts, hemorrhagic cysts, necrotic suppurations, and retention cysts due to distortion or occlusion of pancreatic ducts may remain, giving rise to chronic pancreatitis.

We may summarize the two principal types of acute pancreatitis as follows:

ACUTE HEMORRHAGIC PANCREATITIS	ACUTE PARENCHYMATOUS PANCREATITIS; ACUTE INTERSTITIAL PANCREATITIS; ACUTE PANCREATIC EDEMA
	Etiology
Chemical (*activated trypsin*); cause of activation thought to be the passage of *bile* under great pressure *into the pancreas* due to increased duct pressure; this is caused by obstruction at the sphincter of Oddi by stone or by spasm	*Bacterial. The infection may be systemic* (like mumps), or local, ascending from the duodenum; rarely, it is caused by emboli
	Pathology
Necrosis of pancreatic tissue due to digestion by activated trypsin, and chemical peritonitis and fat necrosis caused by release of steapsin	*Cloudy swelling of pancreatic cells, inflammation of connective tissue, and, in some cases, suppuration with abscess; if due to the streptococcus, may be necrosis and a resemblance to the hemorrhagic type; peritonitis rarely occurs; when it does, is bacterial in type*
	Symptoms and Signs
Sudden onset, intense pain, shock, little *fever, high leucocyte count, rigidity,* vomiting, high blood diastase, and, frequently, glycosuria: *usually occurs after a heavy meal, at which time bile is poured forth*	Slow onset, less pain, more fever, higher *leucocyte count, less rigidity, palpable* mass, vomiting, normal blood diastase, and, rarely, glycosuria
	Prognosis
Serious	Less serious
	Treatment
Fat free diet, fluids, relief of pain, and "peritonitis regimen" if diagnosis can be made; if in doubt, surgical exploration; recently partial pancreatectomy has been tried	Fat-free diet, fluids, and, if an abscess forms, drainage

In both types an increase in intraluminal pressure occurs. Rich believes that in some instances a metaplasia of the epithelium of the ducts causes obstruction. In the hemorrhagic type, atheroma of the pancreatic vessels is said to be a factor.

Associated pathological states include (1) liver edema and cloudy swelling of the cells around the central vein and portal areas with necrosis; this may account for the severe toxemia occurring in acute pancreatitis; (2) suppuration in the pancreas and rarely liver abscess as well; (3) gallstones or other biliary tract disease as a predecessor or common duct ob-

struction as a result of edema or fibrosis or both; (4) chemical peritonitis with fat necrosis with subsequent infection resulting in bacterial peritonitis; also "bile" peritonitis.

Variations in symptoms and signs are many. The predominating symptoms are pain, nausea, and vomiting. Since these symptoms are common to so many intra-abdominal and even thoracic and cardiac diseases, they mean very little alone. Shock is usually present but not always. If there is shock and rigidity in the upper abdomen and some cyanosis, the diagnosis is more apparent and tends to rule out perforated peptic ulcer where there is rarely shock and the rigidity is more general. Although the above picture does simulate acute coronary occlusion, mesenteric thrombosis must be thought of because in both conditions the pain, adynamic ileus, high leucocyte count, and all other symptoms and signs may be very similar.

In mesenteric thrombosis, blood is usually found in the stool; in pancreatitis, none is present as a rule. Rarely this does occur. Coronary occlusion may mimic pancreatitis. In both conditions there may be low blood pressure and pain in the epigastrium (in the case of pancreatitis, local tenderness and rigidity). If a friction rub is present over the precordium, the differential diagnosis is easily made.

The picture may resemble mechanical bowel obstruction, acute alcoholism, acute perforating appendicitis, renal colic, and twisted ovarian cyst.

The laboratory aids in the differential diagnosis are as follows: (1) Elevated blood amylase during the first forty-eight to seventy-two hours, The *urinary diastase* becomes elevated after twelve to twenty-four hours and remains elevated longer. Therefore, both tests should be done. If there is extreme destruction of the pancreas, the blood amylase may actually fall. (2) Depressed blood calcium due to utilization of ionizable calcium. Pancreatic lipase acts on fats, splitting them into glycerol and fatty acids. Calcium unites with free fatty acids, forming soap. Enough calcium may be used up to cause tetany. (3) X-ray which shows gaseous distention of overlying viscera (stomach and transverse colon). (4) Glycosuria and hyperglycemia which may occur due to destruction or inhibition of islands of Langerhans.

Treatment.—

If the diagnosis is established, then surgery should be withheld. The patient is treated conservatively. Water balance and blood volume are maintained by adequate parenteral fluids, plasma, and blood transfusions. Distention is controlled by the Levine tube with suction. Demerol is given in adequate amounts to control pain, nitroglycerine to relax the sphincter of Oddi, atropine to reduce gastric and pancreatic secretions. X-ray treatment may be of value according to some observers.

If the surgeon is not sure of the diagnosis, exploration is indicated. Should pancreatitis be found, closure is accomplished without drainage,

using silk sutures or other nonabsorbable material. Interference with the biliary tree is not desirable unless gallstones are present; if gallstones are present, their removal with cholecystostomy or choledochostomy may be indicated. If drainage is necessary for collections of fluid or pus in the lesser peritoneal cavity, drainage is accomplished through stab wounds in the right and left hypochondrium but not through the incision because of the dangers of digestion and wound dehiscence even though catgut closure is avoided. Psuedocysts may be drained or marsupialized. A few cases of resection of the necrotic portion of the pancreas have been reported with results that are fairly promising.

Should conservative management fail, surgery may be necessary to drain the lesser peritoneal sac or an abscess. These are cases of true pancreatic necrosis which are rare. In such cases right splanchnicectomy has been advocated.

Recurrent attacks of pancreatitis are usually of the parenchymatous type. They are best treated by a dietary regimen restricting the quantity of food at any one time, alcohol, and fatty foods. Surgical drainage of the common duct by T tube, cholecystectomy, and dilation and even cutting of the sphincter of Oddi have been suggested, but the results have been disappointing. Results have been more gratifying with conservative treatment. Complications such as pseudocysts, fibrosis, and calcifications are best treated by partial pancreatectomy. Left splanchnicectomy is said to be helpful even after complications occur.

Chronic interstitial or *parenchymatous pancreatitis, chronic relapsing pancreatitis,* is far more common than is generally believed. It may be produced by repeated attacks of acute parenchymatous or hemorrhagic pancreatitis or by a progressive lesion. Gallstone formation is a frequent complication but is not known to be causative. The changes in the pancreas vary, and indeed the acute phase of a recent attack with edema, inflammation, hemorrhagic necrosis, and abscess may be superimposed on the chronic changes of atrophy, fibrosis, cyst formation, calcification, and stone formation. In a recent case pancreatectomy was done, and the duct epithelium showed a piling up of the columnar lining cells with papillary infolding in addition to the changes mentioned.

The syndrome of chronic pancreatic insufficiency is characterized by steatorrhea, malnutrition, weakness, hypotension, hypoproteinemia, vitamins K and D deficiency. In the recurrent types of acute pancreatitis, diabetes ultimately occurs. Symptoms include chills, slight fever, diarrhea, nausea, vomiting, and some jaundice. Sometimes an epigastric mass with enlarged liver and spleen may be felt. Laboratory examinations may reveal anemia, hypoproteinemia, albuminuria elevated serum lipase and amylase at times, hyperglycemia, elevated serum bilirubin, and abnormal glucose tolerance curve. The disease may mimic the acute type and all of the lesions with which this type may be confused. In addition, carcinoma of the pancreas or of the ampulla of Vater may cause pancreatitis which at

first resembles primary chronic pancreatitis, but, of course, carcinoma is progressive. Nontropical sprue also resembles chronic pancreatitis.

Treatment may be medical, with careful dietary management as previously described. Surgery may be necessary for gall bladder disease, stones in the pancreas, cysts, or chronic painful pancreatitis. The cysts may be drained, or pancreaticolithotomy done, or partial pancreatectomy may be required especially to relieve persistent and disabling pain. Other surgical measures which have been advocated are subtotal gastrectomy (to reduce gastric acidity and therefore secretin formation); vagotomy (also reduces gastric acidity); splanchnicectomy (to increase blood supply and to inhibit reflex vasospasm to other organs, namely, lungs and gastrointestinal tract; also decrease pain).

Neoplasms and Cysts of the Pancreas

Benign neoplasms of the pancreas are not common. They include fibroma, chondroma, lipoma, myxoma, and adenoma.

Adenomas may be solid or cystic, and the latter may be of the proliferating papillary type. *Islet-cell adenomas* are of importance because they may be secretory, producing an excess amount of insulin, with resulting hypoglycemia. There may be only one tumor or many or a diffuse adenomatosis. They are usually located in the tail but may be anywhere on the gland, deeply within the gland, or extrapancreatic. They may be benign, histologically malignant but not metastasizing, malignant with metastasis. Lastly, they may be functionally active in the young or inactive in the older groups, and it is not possible to tell by examining the beta cells which are secretory and which are not. The tumors resemble normal pancreatic tissue, are round, and usually are well defined by compression (false capsule) or true capsule. Their microscopic appearance resembles an enlarged islet. The tumor is probably derived from the ductules but may be derived from pre-existing islets. The symptoms and signs may be extremely sparse or nonexistent except for the palpation of a mass. Usually, *however, the symptoms are those of hyperinsulinism and* hypoglycemia and exhibit Whipple's essential triad: attacks of central nervous system disorder—motor, vasomotor, psychic; coming on during the fasting state; fasting blood sugar levels of 50 mg. per cent or less and immediate recovery from attacks upon administration of glucose by mouth or vein. A tumor may or may not be felt before operation or during surgery. If the latter is true, a wide search should be made for extrapancreatic tissue and failing in this search, the lesion may be considered a hyperplasia or diffuse adenosis of the pancreatic islets. If the symptoms persist after subtotal resection, pancreatic islet adenomas may have been overlooked outside the pancreas. Differential diagnosis includes liver disease, affecting glycogen storage, and diseases of the adrenal cortex, anterior lobe of the pituitary, and the thyroid gland, producing hypofunction. A test which may aid in the diagnosis is the glucose tolerance, which

is normal except for the initial value (low) for about three hours and then drops sharply, and, unlike the normal, returns to average value due to the compensatory secretion of adrenaline; it stays down due to oversecretion of insulin. Epinephrine and pituitary extract do not raise the blood sugar as much as in the normal, and insulin lowers it more than normal.

The treatment is surgery with removal of the tumor or tumors or subtotal pancreatectomy and rarely total pancreatectomy.

Malignant neoplasms include primary carcinomas of the islet-cell type or acinus duct type, sarcomas of the spindle-cell variety; or lymphosarcoma, and, rarely, secondary carcinomas or sarcomas, especially the melanoblastomas.

Primary carcinomas are more frequently scirrhus than medullary; microscopically they may be of the adenocarcinoma, simplex, or mucinous types. The growth may extend into the duodenum or surrounding tissues or organs and may metastasize to the neighboring nodes or the liver. It may occur in the head or tail of the pancreas or may involve the entire gland. *Symptoms* and *signs* include rapid weight loss, boring upper abdominal pain with penetration to the back, jaundice, palpable nontender gall bladder (Courvoisier's law), gastric and intestinal disturbances including nausea, vomiting, partial obstruction. Laboratory findings which are helpful are alcholic stools, no urobilinogen in the urine, high serum lipase, normal serum amylase, excess of fat and nitrogen in stools. X-ray studies show deformities in adjoining hollow viscera. Carcinoma of the *tail* of the pancreas may give rise to severe persistent boring pain in the left upper quadrant and epigastrium which is referred to the back. This may be the *only symptom* or sign. There may be diabetes and sugar tolerance disturbances, ascites, widespread metastases, phlebothrombosis, and edema in the portal and systemic venous circulations especially in the mucinous carcinomas, splenomegaly, some deformities in the stomach or duodenum as seen by x-ray examination. The *association* of *weight loss* and *abdominal pain* in the epigastrium with negative physical and gastrointestinal x-ray findings should suggest the possibility of carcinoma of the pancreas. The differential diagnosis includes silent common duct stone, hepatic disease with jaundice, chronic pancreatitis with edema and obstruction of the common bile duct, pancreatic calculi, and carcinoma of the ampulla.

The treatment is surgical, requiring subtotal or total pancreatectomy if feasible. Contraindications to surgery include distant metastases, extensive local spread (although the spleen, a portion of the liver, the stomach, the duodenum, and transverse colon have been removed when involved), and involvement of the portal or the superior mesenteric vein. The steps of the operation (Whipple): (1) right paramedian or transverse incision; (2) search for metastases to liver and adjacent organs; (3) incision of peritoneum to the right of the duodenum and mobilization of duodenum to determine mobility of pancreas; (4) examination of pancreas to determine site of emergence of superior mesenteric vessels, the presence of an uncinate process, and the degree of encirclement of this process; (5)

separation of the common duct from the portal vein in the gastrohepatic omentum or hepatoduodenal ligament well below the cystic duct and behind the duodenum where it is divided between clamps; (6) the pyloric end of the stomach is freed and divided between clamps; (7) ligation of the gastroduodenal artery after it is identified so that the hepatic artery will not be accidently tied and cut; (8) division of the duodenum or jejunum, depending on the extent of the carcinoma and presence of an uncinate process; if the latter is present, it must be separated from the superior mesenteric vessels which lie anterior to it as well as posterior to the neck of the pancreas; (9) the inferior pancreatico-duodenal artery is tied and divided; (10) division of the pancreas anteriorly at the junction of the head and body, and dissection of the splenic vessels and portal vein and superior mesenteric vessels away from the head of the pancreas; the head of the pancreas, pyloric end of stomach, duodenum, and end of common duct are removed as a unit; the duodenum (or jejunum) is closed; (11) end-to-side gastrojejunostomy of a loop of jejunum or a vertical limb in which a Roux type of jejunojejunostomy has been done; (12) anastomosis of the pancreatic duct to the jejunum over a small rubber catheter proximal to the gastrojejunostomy; (13) end-to-side or end-to-end anastomosis of the common bile duct to the jejunum, depending on whether a loop or vertical limb of jejunum was employed. Sometimes a total pancreatectomy may be necessary; in such cases impairment of gastrointestinal function will result unless pancreatin is administered and the diet is high in calories, protein, and carbohydrate and low in fat. Should resection not be feasible, palliation may be obtained by (1) cholecystoduodenostomy or choledochoduodenostomy or chelecystostomy in desperate cases to relieve obstruction of the biliary tract; (2) gastrojejunostomy to relieve obstruction; (3) reduction in size of tumor by ligation of the major blood supply. Since biopsy of pancreatic lesions is often unreliable, a cholecystoduodenostomy may be done in doubtful cases. Later, a second operation may be done. If the pancreas has decreased in size, the lesion may be considered benign; if not, pancreatectomy is indicated.

Pancreatic cysts may be classified as follows:

1. Developmental cysts
   a. Congenital
   b. Fibrocystic disease of pancreas
   c. Inclusion cysts
2. Distention cysts
   a. Retention (lined by epithelium and due to obstruction)
   b. Exudation (due to degenerative changes, hemorrhagic cysts, pseudocysts)
   c. Extravasation (traumatic, pseudocysts)
3. Cysts of new formation
   a. Dermoid cysts
   b. Teratoma
   c. Cystadenoma
   d. Cystadenocarcinoma
   e. Parasitic cysts (hydatid)

is normal except for the initial value (low) for about three hours and then drops sharply, and, unlike the normal, returns to average value due to the compensatory secretion of adrenaline; it stays down due to oversecretion of insulin. Epinephrine and pituitary extract do not raise the blood sugar as much as in the normal, and insulin lowers it more than normal.

The treatment is surgery with removal of the tumor or tumors or subtotal pancreatectomy and rarely total pancreatectomy.

Malignant neoplasms include primary carcinomas of the islet-cell type or acinus duct type, sarcomas of the spindle-cell variety; or lymphosarcoma, and, rarely, secondary carcinomas or sarcomas, especially the melanoblastomas.

Primary carcinomas are more frequently scirrhus than medullary; microscopically they may be of the adenocarcinoma, simplex, or mucinous types. The growth may extend into the duodenum or surrounding tissues or organs and may metastasize to the neighboring nodes or the liver. Since biopsy of pancreatic lesions is often unreliable, a cholecystoduodenostomy may be done in doubtful cases. Later, a second operation may be done. If the pancreas has decreased in size, the lesion may be considered benign; if not, pancreatectomy is indicated.

Pancreatic cysts may be classified as follows:

1. Developmental cysts
   a. Congenital
   b. Fibrocystic disease of pancreas
   c. Inclusion cysts
2. Distention cysts
   a. Retention (lined by epithelium and due to obstruction)
   b. Exudation (due to degenerative changes, hemorrhagic cysts, pseudocysts)
   c. Extravasation (traumatic, pseudocysts)
3. Cysts of new formation
   a. Dermoid cysts
   b. Teratoma
   c. Cystadenoma
   d. Cystadenocarcinoma
   e. Parasitic cysts (hydatid)

The cysts may be present in the gastrohepatic omentum, the transverse mesocolon, or the gastrocolic ligament. The symptoms and signs vary with the size and location of the cyst. There are usually pain in the epigastrium referred to the back, pressure symptoms on neighboring organs which may produce nausea, postprandial discomfort, vomiting, and distention. Often the swelling may be felt as a smooth fixed mass. X-ray helps materially, revealing distortions or obstructions in hollow viscera. Since the cyst may fill a great portion of the abdomen, it may have to be distinguished from hydrops of the gall bladder, mesenteric cyst, hydronephrosis, cysts of the liver or the ovary.

Treatment consists of removal of the cyst or subtotal pancreatic resection if at all possible. If this cannot be done, the cyst may be drained externally by marsupialization or internally by anastomosis to the stomach, duodenum, or jejunum.

Fibrocystic disease of the pancreas is frequently associated with respiratory disease (bronchiectasis) and a great nutritional disturbance. Recently right total splanchnicectomy has been advocated for its treatment.

The Spleen

The spleen normally weighs about 160 grams and measures 12 by 7 by 4 cm. It is of mesodermal origin and originates as a thickening of the dorsomesogastrium due to division of cells of the peritoneal mesogastrium and also of the mesenchymal cells. The spleen develops in the cranial portion of the greater omentum, and that portion of the greater omentum which extends between the stomach and the spleen is known as the gastrolienic ligament. The dorsal wall of the omentum between the spleen and the kidney is known as the lienorenal ligament. The first vascularization is by a capillary network which forms into the intrasplenic arteries and veins. The undifferentiated capillaries between them form the capillary tufts or spherules. These become transformed into pulp. The spleen is supplied with blood by the splenic artery which is a branch of the celiac axis and which lies behind the stomach, giving off small (vasa brevia) branches to the fundus of the stomach. The artery, as has been said, breaks up into many branches as it enters the hilus in the lienorenal ligament. The splenic vein runs along with the artery and pours its blood into the portal system. The spleen is held in place by the lienorenal ligament which carries the blood supply, the gastrosplenic ligament, which is continued as the gastrocolic ligament, and the phrenocolic ligament which forms somewhat of a sling for the spleen to rest upon. The spleen lies in close contact with the stomach, the diaphragm (which many times has numerous small arterial twigs in its adhesions to the spleen), the pancreas, the anterior surface of the left kidney, the splenic flexure of the colon.

The spleen is covered by thin elastic capsule which adheres to the underlying tissue. It is thickened at the hilus where the arteries and veins enter and leave the viscus. The trabeculae are continuations of the capsule which penetrate the organ and form its framework. Splenic tissue resembles lymphatic tissue, and this fills the space between the trabeculae and consists of red pulp and white pulp. The white pulp is often called malpighian bodies. They consist of diffuse and nodular lymphatic tissue which surround the terminal subdivisions of the splenic artery. The red pulp is dark red in color and can be scraped from the cut surface. The veins seem to be connected with the red pulp, whereas the arteries seem to be connected with the white. The connections between the veins and the arteries have given rise to much speculation and the three main theories are as follows:

1. That the arterial capillaries open directly into the pulp spaces between the reticular cells of the splenic cords and the blood gradually filters into the venous sinuses

(the open circulation theory), irregular, inconstant channels, lined by fixed and wandering cells and reticulum. They are a plexiform three dimensional system of channels which intercommunicate. They are 6 microns wide and may enlarge in Banti's disease to 16 microns.

2. That the arterial capillaries communicate directly with the lumen of the venous sinuses (the closed circulation theory).

3. That both types of circulation are present. The collagenous fibers of the trabeculae are continuous with the reticular fibers in the white pulp. In the center of the lymphatic nodules, just as in the nodules of lymph nodes, the framework consists of thin scattered threads, and lymphocytopoietic centers are present in these areas. In the red pulp venous blood vessels are called venous sinuses and appear as cords. These have been known as the splenic or Billroth cords. They run in all directions from a spongy framework throughout the venous sinuses. The venous sinuses do not contain vascular endothelium but are lined by long narrow cells arranged parallel to the axis of the vessels. These lining cells are macrophages, identical in origin and properties with those of the adjacent splenic cords and their cells. The spleen may be looked upon as a vast reticulo endothelial sponge with a supporting framework of trabeculae and reticulum and a certain amount of lymphoid tissue. There are no lymphatics in the splenic pulp. There are some in its capsule.

When the spleen is removed in man, (1) anemia develops to about 3,000,000 red blood cells, but this returns to normal in about two months; (2) a leucocytosis occurs, mostly polymorphonuclears—20,000 to 30,000, also thrombocytosis; (3) the spleen makes erythrocytes thicker and more fragile to hypotonic solutions; the fragility of red blood cells is decreased; Howell Jolly bodies in the erythrocytes and target cells (abnormally thin erythrocytes) are found; these are less fragile; (4) hemolytic substances produce jaundice less readily; (5) in pernicious anemia the urobilin in the urine is decreased, showing less red blood cell destruction; there is also a lowered urobilinogen output in the feces after splenectomy.

In experimental animals such as rats there is a definite decrease in the resistance to infection and a hypertrophy of the reticulo endothelial cells of the body.

Hyperactivity of the spleen seems to sensitize the red blood cells for easy destruction by the liver. It is thought that splenectomy is beneficial in many diseases accompanied by splenomegaly, not because of removal of injurious substances produced by the spleen, or normal inhibitory mechanisms such as normal serum lysin, but chiefly because it relieves the liver of a vast amount of work since 25 per cent of the portal blood going through the liver is from the spleen normally. Perhaps this explains the amelioration of symptoms such as jaundice, toxic symptoms, and leg ulcers. The leg ulcers are relieved due to collateral circulation around the portal system, less venous stagnation in the local extremities, and less stagnant anoxia.

The physiology of the spleen seems to be as follows:

1. The destruction of red blood cells—not normal ones but those which are worn out, damaged, or abnormal.

2. Storage of blood and the emptying of this storage during hemorrhage due to the contraction of muscle fibers in the capsule and trabeculae. The contraction results from stimulation of the sympathetic nervous system. Normally one-fourth of the total erythrocytes and one-sixth of the total blood volume are stored in the spleen.

3. Manufacture of lymphocytes.

4. Reticulo-endothelial function which plays a role in immunity and removal of disintegrated red blood and other cells. In connection with this function, the role played in lipoid metabolism is extremely important.

5. A blood forming organ in the embryo.

6. Iron metabolism. There is a storage of pigment in the reticular cells and this is again utilized in the formation of hemoglobin. Splenic regeneration occurs from accessory spleens in a few cases.

7. The production of a hormone or hormones that seem to inhibit or control the output of cells by the bone marrow. In hypersplenism these hormones may be excessive,

greatly inhibiting blood cell production, or the spleen may destroy more cells than it should, *or both. In other words, the spleen* has a direct effect on the erythrocytes, leucocytes, and thrombocytes which traverse its sinusoids and indirect effects on the hemopoietic cells of the bone marrow.

The normal pressure in the portal vein is 8 to 12 mm. Hg or 108 to 162 mm. H_2O and slightly less in the coronary *vein and splenic vein. In the inferior vena cava it is* about 4 to 5 mm. Hg or 40 to 110 mm. H_2O, depending on the position of the arm. In portal hypertension the portal pressures become very high.

Congenital Anomalies of the Spleen

The spleen may be entirely absent or may be on the right side in cases of *situs inversus. There may be a double spleen with an independent* vascular pedicle derived from the splenic artery and vein. Fissures and lobulation occur infrequently. *Accessory spleens* are common in children and decrease with advancing age, although we have recently operated upon a woman 32 years of age with Banti's disease with a double spleen and twelve accessory spleens. Accessory spleens probably disappear as age advances unless the individual has some intrinsic pathology such as congenital hemolytic icterus. The position of the accessory spleens is variable but generally they are in the hilar region or the splenic pedicle, less often surrounding the tail of the pancreas, the greater omentum close to the greater curvature of the stomach, the splenocolic ligament, the mesentery of the small and large bowel, the left broad ligament, the ovary, the tunica vaginalis, and retroperitoneal space. *Splenosis* is probably *an acquired lesion* in which multiple splenules may be found throughout the abdomen and may run into the hundreds. These spleens *are thought to be autotransplants resulting from* traumatic rupture, spontaneous rupture, and even accidental rupture during splenectomy. *Accessory spleens are unimportant except in diseases* where splenectomy is indicated. If in such cases accessory spleens are overlooked, the symptoms *may not be ameliorated. Occasionally the spleen* has a long pedicle and moves freely through a wide area. It may become twisted on its *pedicle.*

Injuries of the Spleen

The spleen is commonly ruptured by a fall or blow on the abdomen without any external wound. Penetrating wounds may also cause a tear in the spleen. Sometimes there is a splenic tear without apparent cause or following a coughing spell or sneezing or straining, due probably to adhesions pulling on a movable spleen or pressure by adjacent viscera when the abdominal muscles contract when the spleen is fixed. "Spontaneous" rupture also occurs without any apparent cause, and the spleen may be normal. More often, the spleen is the seat of some pathological process, primarily or secondarily, such as malaria, infectious mononucleosis, leucemia, typhoid, Banti's syndrome, tropical splenomegaly, etc. In malaria there is reticular and endothelial hyperplasia which obstructs the venules and sinuses, causing interstitial and subcapsular

hemorrhages that may lead to rupture. Indeed traumatic rupture may be produced in such a way that the capsule is not torn; blood accumulates under the capsule, causing a tear with massive hemorrhage days or even weeks after the injury. This is called "delayed rupture" of the spleen.

The symptoms and signs will be mild in the absence of hemorrhage—Left upper quadrant pain which radiates to the left shoulder, especially when a deep breath is taken, left-sided muscle spasm, and tenderness on palpation. Sometimes a mass may be felt. With great blood loss there is shock. Laboratory aids include a leucocytosis, which in our experience appears early and before there is a decrease in the red blood count; and x-ray studies, which show some distortion of adjacent viscera, especially the stomach, which contains gas, soft tissue mass, and elevation of the diaphragm, with evidence of free fluid between intestinal loops.

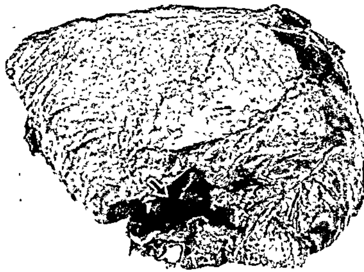

Fig. 379.—Traumatic rupture of the spleen. The patient, a man aged 60 years, was in an automobile accident. Arrow points to the tear.

Treatment consists of adequate preparation by blood replacement and immediate splenectomy to prevent fatal hemorrhage.

"Wandering spleen" is the term used to describe a spleen with an abnormally loose attachment and pedicle which moves to various positions in the abdomen, usually without symptoms or danger and commonly seen in multiparous women. Treatment will usually consist of exploration because of the difficulty in making the diagnosis of the palpable movable mass and its variable symptoms. Should the spleen become twisted on its pedicle, it would become swollen due to the trapping of venous blood until the pressure in the veins and their tributaries equalled the arterial pressures, causing anoxia and infarction. The

patient would complain of severe pain, and the mass would be palpable and tender. Splenectomy should be done in case of torsion and is probably indicated when torsion is not present because anchorage of the spleen is not satisfactory. The abnormality is rare. We have seen two cases.

Diseases and Infections of the Spleen

Splenomegaly or **splenomegalia** refers to enlargement of the spleen which may be due to many causes, some of which are but vaguely understood.

Group I Infections

- A. Nonspecific
  - 1. Primary abscess following trauma or infarction or hematoma or thrombosis of splenic vein
  - 2. Secondary abscess from pyemia, typhoid fever, puerperal sepsis, embolism, extension of adjacent suppurative processes
- B. Specific
  - 1. Primary
    - a. Tuberculosis
  - 2. Secondary involvement or enlargement due to the spleen's action as a filter or phagocytic organ
    - a. Tuberculosis
    - b. Malaria
    - c. Syphilis
    - d. Kala azar
    - e. Chronic sepsis
    - f. Schistosomiasis
    - g. Histoplasmosis (may also cause hepatomegaly)
- C. Amyloidosis of spleen secondary to chronic infections anywhere in the body (tuberculosis, chronic empyema, etc.)
  - 1. Primary amyloidasis in which the cause is unknown

Group II. Lipoid dyscrasias

- A. Generalized forms
  - 1. Lipoidosis or xanthomatosis
  - 2. Primary or essential xanthoses
    - a. Gaucher's disease
    - b. Niemann Pick's disease
    - c. Hand-Schüller-Christian's disease
    - d. Primary nonsymptomatic external and internal xanthomatoses
  - 3. Lipoid neoplasms
    - a. Lipoma
    - b. Xanthomatous carcinoma
    - c. Xanthomatous sarcoma

Group III. Lymphatic dyscrasias, lymphoblastic diseases

- A. Lymphatic leucemia
- B. Splenomyelogenous leucemia
- C. Hodgkin's disease
- D. Agnogenic myeloid metaplasia
- E. Lymphosarcoma of the spleen

Group IV. Anemias with primary or secondary disease of the liver or hepatomegaly

- A. Banti's syndrome (Banti's disease, congestive splenomegaly, splenic anemia)
- B. Cirrhosis of the liver
- C. Erythroblastic anemia (Cooley, von Jaksch)
  1. Thalassemia major and minor
- D. Hemochromatosis
- E. Diseases in this group associated with arthritis
  1. Still's disease (rheumatoid arthritis of children)
  2. Felty's syndrome (in adults)

Group V. Erythremia

- A. Polycythemia vera, splenomegalic polycythemia, Vaquez's disease, Osler's disease
- B. Symptomatic or secondary polycythemia may be accompanied by splenomegaly
  1. Tetralogy of Fallot
  2. Pulmonary stenosis
  3. Pulmonary arteriosclerosis (Ayerza's disease)
  4. Congenital polycythemia
  5. Polycythemia with hypertension in elderly patients

Group VI. Hemolytic, leucocytolytic, and thrombocytolytic diseases

- A. Hemolytic
  1. Hemolytic (spherocytic, acholuric) jaundice
  2. Acute hemolytic anemia (Lederer)
  3. Sickle-cell anemia
- B. Leucocytolytic
  1. Splenic neutropenia
- C. Thrombocytolytic
  1. Thrombocytopenic purpure (Werlhof's disease, idiopathic thrombopenic, purpura hemorrhagica)
- D. Combined form
  1. Splenic panhematocytopenia

Group VII. Neoplasms and cysts

- A. Neoplasms
  1. Primary
     - a. Benign—Fiboma, lymphoma, hemangioma, lymphangioma, chondroma, osteoma, leiomyoma
     - b. Malignant—Fibrosarcoma, leiomyosarcoma, endothelioma, hemangioendothelioma, angiosarcoma, lymphosarcoma, reticulum-cell sarcoma
  2. Secondary malignant neoplasms (by blood stream, which is very rare, by contiguity, or by generalized abdominal seeding); metastases from any organ but stomach carcinoma most common
- B. Cysts
  1. Distention cysts
     - a. Retention—dilatation cysts, polycystic disease due to ectasia of splenic sinuses
     - b. Infoliation cysts due to peritoneal inclusions

2. Cysts of new formation
   a. Traumatic arising from hematoma
   b. Degenerative cysts *following infections or infarctions*
   c. Neoplastic
      (1) *Dermoid*
      (2) Epidermoid
      (3) *Hemangiomatous*
      (4) Lymphangiomatous
      (5) Cystic degeneration in neoplasms
   d. Parasitic
      (1) Hydatid disease

Group VIII. Vascular splenic enlargements

A. Aneurysm of splenic artery
B. Arteriovenous fistula due to wounds
C. Embolism in subacute bacterial endocarditis and auricular fibrillation
D. Thrombosis of the splenic vein from inflammation, trauma, pressure from without by inflammatory disease or neoplasms, polycythemia vera

Group I. Infections.—*Nonspecific* infections with abscess formation due to primary or secondary causes are more common than is ordinarily supposed. The abscess, as in the liver, is apt to form large necrotic masses. The symptoms and signs are those of an acute septic focus with chills, fever, high leucocyte counts. After the splenic capsule becomes involved, there is pain, rigidity, and tenderness over the spleen. The pain radiates to the left shoulder and is intensified on deep breathing. A left subphrenic abscess gives almost the same symptoms and may occur as a complication. Also, the left pleura may be involved, giving rise to effusion or empyema. *Splenectomy is indicated* because of the extensive tissue destruction, the possibility of multiple necrotic areas, and the possibility of sloughs with hemorrhage after simple drainage which some surgeons regard as the treatment of choice.

Of the *specific infections*, only "*primary*" *tuberculosis* of the spleen warrants splenectomy. Even here it is doubtful whether the disease is primary in the spleen.

Group II. Lipoid Dyscrasias.—The spleen acts as a filter in disturbances of lipoid metabolism. There are three generalized forms:

1. Xanthomatosis or lipoidosis. It may be symptomatic, as in diabetes or in jaundice. These dyscrasias are due to a cholesterolemia and selective absorption of the cholesterol fatty acids by the xanthomatous cells. There are deposits in the skin and lymph vessels over the body. These vary in size from a pea or bean and are yellow or brownish and appear as nodules in the skin. The spleen may be enlarged, and the large phagocytes appear as foam cells. They are entirely from the reticulum cells of the pulp. The endothelial cells are not affected.

2. Primary or essential xanthoses. In this group may be placed Gaucher's disease, Niemann-Pick's disease (greatly enlarged spleen and

liver and discolored skin), Hand-Schüller-Christian's disease, and primary nonsymptomatic external and internal xanthomatoses.

3. True neoplasms which may be accompanied by enlarged spleen, such as xanthomatous carcinoma or sarcoma and xanthoma en tumeurs of the skin occurring around the knee, elbow, and heel.

Weber-Christian's disease is a febrile relapsing nonsuppurative panniculitis and is thought to be a lipoid histiocytosis. Bazin's erythema induratum and Darier's sarcoid are said to be related to fat necrosis and lipophage granulomas.

Of this group, splenectomy is indicated in Gaucher's disease, where it may be used as a palliative measure, and in the true lipoid neoplasms of the spleen which cannot be diagnosed preoperatively. Gaucher's disease is a chronic lipoid disturbance producing a splenomegaly. There is a familial tendency, and sometimes it is congenital. The reticuloendothelial cells contain an excessive storage of kerasin (a cerebrosid) giving rise to the Gaucher's cells which appear in the spleen, liver, lymph nodes, and bone marrow. Clinically, Gaucher's disease occurs mostly in girls under the age of 5 years but may occur also between the ages of 25 and 35 years. It is a chronic and progressive disease with brownish-yellow discoloration of the skin of the face, neck, and hands and pingueculae of the conjunctiva. The splenomegaly is progressive but without ascites. There is apt to be generalized lymphadenopathy and hepatomegaly. Hemorrhages occur, and there may be convulsions Laboratory tests will show a hypochromic anemia, leucopenia, and thrombocytopenia. Biopsy of the spleen, lymph nodes, and bone marrow shows the Gaucher's cells which appear in no other disease. They are large with small eccentric and sometimes multiple nuclei and do not stain with fat stains and are not doubly refractile. X-ray examination of bones shows a nodular appearance with osteoporosis but no cortical infiltration. Death is usually due to an intercurrent infection. Tuberculosis is common. Splenectomy is indicated because of the great destruction of blood cells and platelets, the hemorrhagic tendency, and the increasing size of the spleen, but it must be regarded as palliative.

Group III. Lymphatic Dyscrasias.—These have been discussed in Chapter 17. *Splenectomy is not indicated* in such diseases and may actually be harmful. This is especially true in agnogenic myeloid metaplasia of the spleen, a disease of unknown etiology associated with fibrous unproductive bone marrow in which the spleen takes on its embryonic function of producing red blood cells. The syndrome is observed from infancy to old age and is characterized by splenomegaly and the presence of immature red and white cells in the blood. It may be confused with chronic myelogenous leucemia, splenic anemia, erythroblastosis, or Hodgkin's disease. Careful studies of the blood and bone marrow cells and fragility tests will help to identify the condition. This is important because splenectomy or radiation therapy of the spleen takes away the only source of hematopoiesis.

Group IV. Anemias With Primary or Secondary Disease of the Liver or With Hepatomegaly.—

Banti's syndrome (Banti's disease, congestive splenomegaly, splenic anemia) was originally described by Banti as a disease in which there were three stages: anemic, with gastrointestinal hemorrhage and

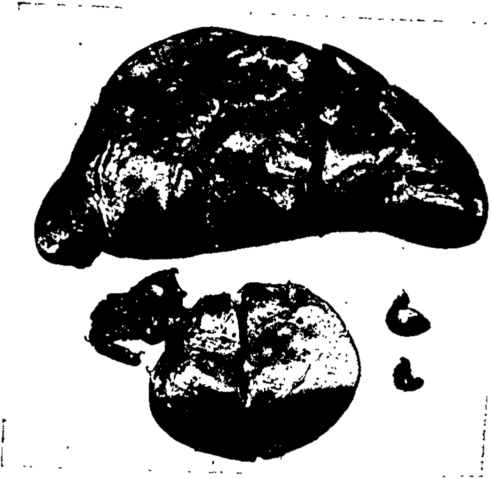

Fig. 380.—Banti's syndrome with multiple spleens. M. H. was a white woman 34 years of age who came to the hospital complaining of soreness in the right upper quadrant of the abdomen for a period of five years. The past history showed that there was a swelling in the right upper quadrant for the past two years and that it was increasing in size. On examination it was found that there was a tumor mass extending down from the costal margin for a distance of about 8 cm., and it extended across the midline into the left upper quadrant. The patient was diagnosed as having an enlarged liver and spleen. There was no jaundice, no hematemesis, and no ascites.

She was operated upon in March, 1948. At this time there was no ascites and the liver was not greatly enlarged, but it was nodular and hard. The venous pressure in the antecubital vein was 100 mm of water; in the portal vein, 290 mm. of water; and in the splenic vein, 260 mm. of water. The normal pressure in the antecubital vein is anywhere from 40 to 110 mm. of water; in the portal vein it is about 8 to 12 mm. of mercury or 108 to 162 mm. of water. Therefore, the pressure within the portal vein in this case was almost double that of the normal. Because of the absence of ascites and esophageal varices and due to the numerous branches of the splenic vein, a splenorenal shunt was not attempted. Instead, the many spleens were removed. There was a very large spleen and a moderately large accessory spleen, the first measuring 21 by 9 by 6 cm. and weighing 750 grams. The large accessory spleen measured 10 by 7 by 4 cm. and weighed 750 grams. There were also sixteen other accessory spleens. These were proved to be so by histological examination. The pathological diagnosis was portal cirrhosis and congestive splenomegaly consistent with Banti's syndrome. The patient was last seen on June 1, 1949. At this time there was still no ascites. Patient has remained in good health. She has been on a high caloric diet with choline dihydrogen citrate, 1.5 Gm. four times a day. The photograph is that of the large spleen and the second largest accessory spleen together with three smaller spleens. Many of the smaller spleens were lost in the pathology laboratory so that they could not be photographed.

anemia; transitional, with oliguria, hepatomegaly, and brown disco tion; and ascitic, with atrophy of the liver, slight jaundice, ascites, hemorrhages. The syndrome included a "fibroadenic" thicke around the central arteries of the Malpighian corpuscles. Ba *syndrome has now come to imply* splenomegaly with anemia, leucop and thrombocytopenia, associated *with increased collateral cir* tion between the portal and systemic venous systems, and character *splenic changes (large* rough surface, perisplenitis, thick capsule, s sparse follicles, sclerotic portal and splenic *vessels, and dilated sinuso* Congestive splenomegaly may be caused by cavernomatous transfo*tion of the portal vein*, sclerosis, thrombosis, stenosis of the port splenic vein, or both. It is a mechanical *obstruction to the* p return and is frequently associated with atrophic cirrhosis of liver *which we have discussed* previously in this chapter. Rarely, plastic disease invades the portal vein.

The causes of obstruction, portal hypertension, and splenomegaly be *grouped as follows*:

A. Intrahepatic due to various *types of cirrhosis* of the liver (atro biliary) and chronic infections which ultimately result in cirr (*schistosomiasis*, infectious hepatitis)
B. Extrahepatic due *to various varieties* of portal occlusion
   1. Within the vein—thrombosis (inflammatory or traumatic)
   2. In the wall of the vein—stenosis (congenital or acquir phlebosclerosis)
   3. Compression on the outside by
      a. *Inflammatory* scar (following pancreatitis, cholangitis,
      b. Pancreatic cyst
      c. Pancreatic tumor
      d. *Aneurysm* of splenic artery
   4. Cavernomatous transformation of the *portal vein*

The *symptoms and signs* vary but usually the first evidenc splen*omegaly and* anemia. Hemorrhages are usually late, but somet the physician is first consulted because of *hematemesis* or bleeding the bowel. Later the enlarged liver shrinks, and there is ascites. Lab tory findings include, first, a normocytic and, later, with hemorrhag microcytic hypochromic anemia. There is practically always a leucop and thombocytopenia. The latter, together with hypoprothrombinemia dilation and thinning of the portal branches due to the hypertension, is cause of the bleeding tendency. In addition, the liver tests as previousl scribed *under* cirrhosis are helpful. The treatment depends entirely on the cause. If due to thrombosis *of the splenic* vein, splenect should be helpful by cutting down the volume of blood returning to liver. If in *the portal or if the* coronary vein joins the splenic an lously, then splenectomy would not help *greatly in reducing* the pr bility of esophageal varix bleeding. In fact, it may increase it due to

formation of more collaterals. In all types of portal obstruction, ligation and division of the splenic artery may materially reduce the volume of blood returning from the spleen but is not entirely without danger of necrosis, although we have not encountered this complication. Sometimes the spleen is not greatly enlarged because of splenic infarction, destruction or adequate collateral circulation, or the short duration of the disease. Also, in elderly people with arteriosclerosis the splenic artery may become narrowed, cutting down the size of the spleen. In all of these instances splenectomy may be helpful but will probably do little more than give temporary symptomatic improvement. Therefore, the surgeon must be prepared to do a splenorenal shunt. Many methods have been devised to increase collateral circulation. These have been described previously under the heading of Portal Hypertension. They include omentopexy, portacaval shunt, splenorenal shunt and anastomosis between the superior mesenteric vein and the vena cava or other vessels of the two systems. Esophageal varices may be treated directly by resection of the lower esophagus and cardiac end of the stomach because ligations and injections of sclerosing agents have proved to be ineffective. At best the treatment of Banti's syndrome is to be regarded as symptomatic unless the cause is a mechanical block outside the liver.

Cirrhosis of the liver has been previously described in this chapter. The problem as related to the spleen is as in Banti's syndrome. Summary of treatment: Splenectomy is usually indicated because: (1) The spleen probably exercises an inhibitory effect on blood formation. (2) After splenectomy there is a rise in leucocytes and thrombocytes, although the erythrocyte rise is slower. (3) The enlarged spleen holds much blood and probably carries 30 to 40 per cent of the total portal flow. Its removal minimizes the enormous increase of blood volume which the esophageal varices may be forced to carry when the spleen contracts. To offset this hazard there is usually a prodigious amount of collateral blood flow into the systemic circulation through adventitious blood vessels in the adhesions between the spleen and surrounding tissues, especially the diaphragm.

If the block is in the splenic vein, splenectomy is curative. When the block is at any point closer to the liver than the entry of the inferior mesenteric vein, splenectomy alone will not suffice to cure bleeding from varices. A shunt must be done and this is best accomplished at the time of splenectomy.

There are two main types of shunts: (1) Splenorenal with preservation of the kidney used in most cases of extrahepatic block because most of the lesions are in the portal vein, precluding its use, and if not in the portal vein, extrahepatic splenectomy alone is curative. (2) Portacaval shunts are useful in intrahepatic types of block and are sometimes employed in cases that have had splenectomy at some previous time, leaving a scarred splenic vein not suitable for anastomosis. In the latter instances other veins may be used, particularly if there is cavernomatous

transformation of the portal vein; namely, superior mesenteric to vena cava, proximal end to side; inferior mesenteric to renal, proximal end to side; inferior mesenteric to vena cava, proximal end to side; inferior mesenteric to ovarian. (See Cirrhosis of Liver, this chapter.)

Erythroblastic anemia (Cooley, von Jaksch; thalassemia major if both parents have it and minor if one parent has it) is a disease of children which is hereditary and seen chiefly in Mediterranean races. The disease is one of abnormal blood formation and is apt to be fatal. The clinical features include splenomegaly and hepatomegaly which cause the abdomen to enlarge and generalized lymphadenopathy enlargement of the molar and cranial bones with skeletal bone changes (osteoporosis,

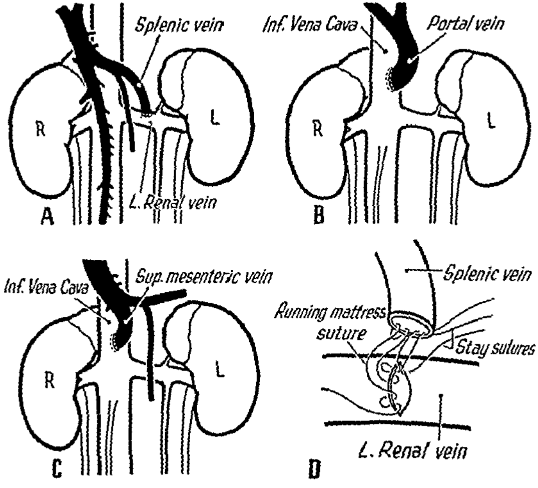

Fig. 331.—Diagram illustrating methods of shunting blood from the portal to the systemic venous system in portal hypertension. *A*, Splenorenal. Proximal end of the splenic vein to the side of the left renal vein. *B*, Portacaval. Anastomosis between the portal vein and the vena cava inferior. Exposure is obtained by a combined thoracoabdominal approach on the left, and for the portacaval anastomosis a thoracoabdominal incision is made on the right extending up into the eighth innerspace. *C*, Superior mesenteric-caval. Anastomosis here is between the proximal end of the superior mesenteric vein and the vena cava. *D*. The method of suture in splenorenal shunts. Other methods of diverting the portal blood into the systemic circulation have been used. These are described in Chapter 20 under the subject of ascites and in this chapter under the subject of portal hypertension.

formation of more collaterals. In all types of portal obstruction, ligation and division of the splenic artery may materially reduce the volume of blood returning from the spleen but is not entirely without danger of necrosis, although we have not encountered this complication. Sometimes the spleen is not greatly enlarged because of splenic infarction, destruction or adequate collateral circulation, or the short duration of the disease. Also, in elderly people with arteriosclerosis the splenic artery may become narrowed, cutting down the size of the spleen. In all of these instances splenectomy may be helpful but will probably do little more than give temporary symptomatic improvement. Therefore, the surgeon must be prepared to do a splenorenal shunt. Many methods have been devised to increase collateral circulation. These have been described previously under the heading of Portal Hypertension. They include omentopexy, portacaval shunt, splenorenal shunt and anastomosis between the superior mesenteric vein and the vena cava or other vessels of the two systems. Esophageal varices may be treated directly by resection of the lower esophagus and cardiac end of the stomach because ligations and injections of sclerosing agents have proved to be ineffective. At best the treatment of Banti's syndrome is to be regarded as symptomatic unless the cause is a mechanical block outside the liver.

Cirrhosis of the liver has been previously described in this chapter. The problem as related to the spleen is as in Banti's syndrome. Summary of treatment: Splenectomy is usually indicated because: (1) The spleen probably exercises an inhibitory effect on blood formation. (2) After splenectomy there is a rise in leucocytes and thrombocytes, although the erythrocyte rise is slower. (3) The enlarged spleen holds much blood and probably carries 30 to 40 per cent of the total portal flow. Its removal minimizes the enormous increase of blood volume which the esophageal varices may be forced to carry when the spleen contracts. To offset this hazard there is usually a prodigious amount of collateral blood flow into the systemic circulation through adventitious blood vessels in the adhesions between the spleen and surrounding tissues, especially the diaphragm.

If the block is in the splenic vein, splenectomy is curative. When the block is at any point closer to the liver than the entry of the inferior mesenteric vein, splenectomy alone will not suffice to cure bleeding from varices. A shunt must be done and this is best accomplished at the time of splenectomy.

There are two main types of shunts: (1) Splenorenal with preservation of the kidney used in most cases of extrahepatic block because most of the lesions are in the portal vein, precluding its use, and if not in the portal vein, extrahepatic splenectomy alone is curative. (2) Portacaval shunts are useful in intrahepatic types of block and are sometimes employed in cases that have had splenectomy at some previous time, leaving a scarred splenic vein not suitable for anastomosis. In the latter instances other veins may be used, particularly if there is cavernomatous

or hormones which greatly inhibit the production of blood cells by the bone marrow, or both mechanisms may be overacting at the same time. In any event there is splenomegaly and deficiency in the number of circulating erythrocytes, leucocytes, thrombocytes, or all of the elements. In addition to the many symptoms and signs that are common to the group as a result of the decrease in circulating blood cells, leg ulcers are present. These are difficult to explain and have been variously ascribed to decreased local resistance from peripheral vasoconstriction, stagnant anoxemia due to pressure on the venous system by the enlarged spleen, lymphedema, anemic anoxemia due to red cell destruction. The remarkable observation is that these ulcers promptly disappear after splenectomy.

HEMOLYTIC.—

1. Hemolytic (spherocytic, acholuric) jaundice is also known as hemolytic splenomegaly and congenital or familial hemolytic jaundice. Some observers distinguish between a congenital and an idiopathic acquired type. The latter is probably a subclinical congenital type manifesting itself in adult life. The cause is unknown. There is a diminution in size and number of the lymphoid follicles in the spleen, an engorgement of the pulp, and dilatation of the sinuses. Symptoms, signs, and laboratory findings include nonobstructive jaundice with a greatly enlarged spleen which is smooth, usually nonadherent, and greatly enlarged, weighing up to 1,500 grams or more. Both sexes are affected and complain of weakness, abdominal pain, vomiting, shortness of breath, and palpitation. Laboratory studies show an anemia, the presence of spherocytes (ballooned erythrocytes), increased fragility of red cells to hypotonic saline (normal erythrocytes begin to hemolyze in saline solution of about 0.45 per cent and are completely laked at 0.35 to 0.3 per cent; in hemolytic jaundice hemolysis begins at 0.7 per cent and is complete at 0.5 to 0.45 per cent), and reticulation of red blood cells. There is a positive indirect van den Bergh and urobilinogen in the urine. The disease goes through remissions and exacerbations (crises), and the latter may be severe enough to cause death. Two complications are seen: (1) Gallstones which are usually bile pigment soft stones due to the excessive amount of pigment in the bile and (2) leg ulcers. The treatment consists of small transfusions of plasma and blood followed by splenectomy which is curative, although the spherocytes remain. Much debate has arisen concerning surgery during a crisis. Most surgeons do not remove the spleen at this time and also do not advise transfusion at this time because the addition of blood with the great numbers of abnormal or devitalized cells usually introduced simply adds to the work of the already overactive spleen and may actually intensify the crisis. In addition, the presence of agglutinin-agglutinogen reactions is common, and theoretically at least the blood serum may contain destructive agents as is demonstrated by increased fragility which is simply the first step in red cell destruction. In other words, there may be an overproduction of hemolysins (auto- and iso-) and an underproduction of antihemolysins.

cortical atrophy, and thickening of medullary trabeculae). The bone marrow is hyperplastic. The laboratory studies show significant blood changes: erythroblastosis, anemia, achromia, anisocytosis and poikilocytosis, and leucocytosis. There is abnormal hemolysis which causes an increase in urobilinogen. The liver and spleen take on their primitive function of hematopoiesis to some extent. After splenectomy, normoblasts are greatly increased in the blood but soon disappear. Splenectomy is indicated and may retard the progress of the disease in addition to giving symptomatic relief because the spleen reaches an enormous size. However, it is not curative.

Hemochromatosis (bronze diabetes) is a metabolic disorder of unknown origin characterized by deposition of pigments, especially hemosiderin, in many organs of the body, cirrhosis of the liver and pancreas, diabetes, and splenomegaly. The spleen is fibrotic. The treatment is that of diabetes mellitus. Splenectomy is not indicated.

Splenomegaly with *arthritis* is seen in Felty's syndrome in adults and in Still's disease (rheumatoid arthritis) in children. *Felty's* syndrome consists of atrophic arthritis, splenomegaly, leucopenia, and normochromic anemia and hepatomegaly. It is attended by fever, loss of weight and strength, and brown pigmentation of the skin. A similar picture, seen in children with atrophic arthritis, is known as Still's disease. Whether the diseases are distinct entities or simply exaggerated manifestations of the arthritides of the rheumatoid type is open to question. Splenectomy is not curative but may give symptomatic relief, especially in Felty's syndrome.

Group V. Erythremia.—

1. *Primary erythremia* or *polycythemia vera* (splenomegalic polycythemia, Vaquez's disease, Osler's disease) is a disease of unknown origin occurring chiefly in male adults. The red blood count reaches from 9 to 10 million, and due to the enormous amount of circulating reduced hemoglobin, there is cyanosis. Splenectomy is not indicated unless there is splenic vein thrombosis with infarction which is extensive.

2. Secondary erythremia or polycythemia is seen as a compensatory mechanism so that oxygenation can take place in the presence of anoxic conditions due to the tetralogy of Fallot, pulmonary stenosis, pulmonary arteriosclerosis (Ayerza's disease), congenital polycythemia, and polycythemia with hypertension in elderly patients. Splenectomy is not indicated. Instead, measures are directed toward improved oxygenation of the blood.

Group VI. Hemolytic, Leucolytic, and Thrombocytolytic Diseases.— These constitute an ill-defined group of maladies which have in common an excessive destruction of blood constituents. This may be due to the overactivity of the spleen as a scavenger of abnormal cells, since in most instances there is a production by the bone marrow of immature or abnormal cells, or the spleen may be guilty of overproduction of a hormone

row or megakaryocytes or destroys the circulating thrombocytes. The latter concepts have not been proved clinically or experimentally, and the spleen is not enlarged because platelets are easily destroyed, nor does it show striking changes except enlarged germinal centers and the presence of megakaryocytes in the splenic pulp. Other theories seeking to explain the disease are faulty maturation of megakaryocytes so that they are easily destroyed and damaged or abnormal capillary endothelium. Symptoms and signs in the chronic variety are remissions and exacerbations which end in death from hemorrhage, or intercurrent infection, or spontaneous recovery, purpuric spots under the skin, fever, hemorrhages from any or all mucous membranes or from wounds or slight bruises. The acute form is more severe and is more apt to be fatal. Tests and laboratory studies help identify the disease. Evidence of increased capillary weakness and permeability is seen in the tourniquet test. If the venous return is occluded, petechial spots appear *promptly distal* to the tourniquet. Blood studies show a thrombocytopenia (100,000 or less), prolonged bleeding time, and normal clotting time but poor clot retraction. Some anemia due to blood loss and some leucocytosis are present. The disease need not be confused with hemophilia, which occurs only in males, with normal bleeding time, prolonged clotting time, good clot retraction, a firm clot, a normal tourniquet test, platelet count which is normal, and a history indicating the hereditary nature of the disease. Other diseases with which it may be confused are aplastic anemia, leucemia, and secondary purpura or symptomatic purpura.

Pseudohemophilia and chronic thrombasthenia are probably not the same entities. All blood studies may be normal, including clotting and bleeding time, yet bleeding continues. The diagnosis is made by exclusion. The spleen may be enlarged, usually much more than is seen in thrombocytopenic purpura, but splenectomy is definitely contraindicated because it will not help the disease and will be followed by continued bleeding. Splenectomy is usually curative. When it fails, an accessory spleen which has been overlooked should be thought of. This is not invariable, and in the acute variety bleeding may continue in spite of splenectomy. Just as thrombocytopenia is not always synonymous with the clinical features of the disease prior to splenectomy, so after the operation, although the platelets do not return to normal, the clinical symptoms, especially bleeding, subside. During a crises, surgery is best postponed. (We have had one patient in whom bleeding continued after splenectomy. No accessory spleens were found; there was generalized lymphadenopathy—perhaps an overactive reticulo-endothelial system.)

Thrombasthenia is a functional defect of platelets which predisposes the patient to repeated hemorrhage. It is probably related to thrombocytopenic purpura and may be suspected if the addition of normal platelets to the patient's deplateletized plasma corrects the coagulation defect (Alexander and Landwehr).

D. Combined Form.—Primary splenic panhematocytopenia is a disease due to hypersplenism in which most of the cellular elements of the bone marrow are destroyed, resulting in neutropenia, anemia, and throm-

Despite these facts, in prolonged crises, we have on several occasions given repeated small transfusions carefully cross matched, including the Rh factor, and at surgery large amounts of plasma followed by whole blood immediately after the splenic pedicle has been ligated, and our results have justified the cautious pursuance of this practice in selected cases. Gallstones should not be removed at the time of splenectomy.

2. Acute hemolytic anemia (Lederer) belongs to the group of intrinsic or idiopathic anemias characterized by fever, anemia, and splenomegaly. Splenectomy is of no value in the treatment of this disease.

3. Sickle-cell anemia is a familial disease occurring almost exclusively in Negroes. There is an anemia, the appearance of sickle-shaped red cells, and splenomegaly. The symptoms and signs are weakness, shortness of breath, abdominal crises with pain, splenomegaly for a while, joint pain and swelling resembling rheumatoid arthritis, leg ulcers, jaundice, and attacks of fever. Rarely there is vascular thrombosis which may occur in the cerebral vessels or elsewhere. Laboratory studies show sicklemia (which does not necessarily mean that the patient has the anemia) and anemia (normocytic type), some nucleated red cells, and leucocytosis with an increase in polymorphonuclears of all types, but also an absolute increase in eosinophiles, thrombocytosis. The sickle cells are best seen in moist preparations which have stood a while or are placed under a decreased oxygen tension. X-ray may show skull changes and osteoporosis of long bone. Splenectomy is indicated but is not curative. It is probably unwise to do this during a crisis.

Leucocytolytic.—Primary splenic neutropenia or idiopathic neutropenia is a disease of unknown origin in which the spleen destroys abnormally large numbers of neutrophiles to the exclusion of other cells. The reticuloendothelial cells of the spleen are engorged with polymorphonuclear neutrophiles as disclosed by supravital staining. The spleen becomes enlarged but is not adherent and is otherwise not characteristically affected. The patient complains of weakness, nervousness, and susceptibility to intercurrent infections. Leg ulcers are common; in fact, in our experience this symptom leads the patient to seek medical aid. The disease must not be confused with symptomatic agranulocytosis due to drugs, chemicals, or infections or aleucemic leucemia. Bone marrow studies are indispensable and will show no abnormalities or hyperplasia of granulocytic cells and no others. Splenectomy is definitely indicated and is curative.

Thrombocytolytic.—Thrombocytopenic purpura (Werlhof's disease, idiopathic thrombopenic purpura, purpura hemorrhagica) is an acute or chronic disease with a great reduction in blood platelets and bleeding from the mucous membranes with or without splenomegaly. It is a primary disease and not the secondary type of purpura which is seen in various types of infections, leucemias, chemical poisons, and nephritis. Girls and young women are affected much more frequently than boys or men. The disease has been ascribed to an increased avidity of the spleen for thrombocytes and/or a splenic extract which acts upon the bone mar-

in (1) Gaucher's disease, (2) erythroblastic anemia, (3) sickle-cell anemia. Splenectomy is not helpful in the infections except perhaps in some cases of abscess, the lipoid dyscrasias, cirrhosis of the liver, hemochromatosis, Still's disease and usually in Felty's syndrome, acute hemolytic anemia, the symptomatic erythremias. The operation should not be done in the lymphatic or lymphoblastic dyscrasias, primary erythremias, and most primary anemias. The operation of splenectomy has in the past carried a high mortality which has been variously estimated as 13 per cent in all cases and up to 34 per cent in those patients who are acutely ill. The chif dangers of the operation are hemorrhage, especially in Banti's syndrome, thrombosis of the portal vein with hepatic infarction, wound dehiscence, unrecognized pancreatic injury with subsequent leakage and fat necrosis, and injury to the diaphragm.

A few practical points concerning technique may be mentioned:

(1) The patient should be placed in the reverse Trendelenburg position on the table. (2) A cannula should be inserted in an ankle vein so that if large quantities of blood or plasma are necessary they may be given rapidly. (3) Incisions should be adaquate—they may be transverse, which is the best in smaller spleens; longitudinal, with left lateral extension; Bevan's Z incision, left paramedian; transthoracic through the bed of the eighth rib, which is useful in large spleens or in those adherent to the diaphragm. (4) The pedicle may be clamped first and this is preferable. In trauma with splenic tear, this should be done as quickly as possible, and the three-clamp method is best. The spleen is delivered by dividing avascular attachments; both vessels are clamped at once and cut between the two distal clamps. In very large spleens, malignant spleens, and those densely adherent to the diaphragm, the splenic artery should be tied close to its origin through the gastrohepatic omentum. After splenic massage or the injection of Adrenalin into the spleen to make it shrink, the vein is tied. Usually the splenic artery is tied through the gastrocolic ligament, then it is freed, and then the vein is ligated. (5) If the spleen is densely adherent to the diaphragm, the peritoneal covering of the undersurface of the diaphragm may be peeled with the adherent spleen instead of trying to separate it. (6) The pancreas should be carefully protected. Despite statements to the contrary, injury to the pancreas, if not recognized, may not only lead to fat necrosis, but also to wound dehiscence and deep abscess. (7) The spleen should be handled carefully so that splenic implantations do not occur through its rupture. (8) Accessory spleens should be sought and removed if found. (9) In certain desperate cases the splenic artery may be tied and divided.

THE ENDOCRINE GLANDS

The endocrine system (comprising the ductless glands or the glands of internal secretion) is only partially understood. However, rapid strides have been made within recent years. This group includes the pituitary (hypophysis); the pineal, the suprarenals or adrenals (which are compound organs and are the principal representatives of the two systems of glandular tissue called chromaphil and cortical systems, respectively); the carotid glands or intercarotid bodies (Chapter 14) (which are outlying parts of the chromaphil system); the thyroid, the parathyroids, and the thymus (which are developed from the entodermal lining of the embryonic pharynx); the spleen and the glomus coccygeum (which are associated with the circulatory system).

In addition, the liver, pancreas, gastric and intestinal mucous membrane, the kidney, testes, ovaries, and corpus luteum have internal as well as other secretions.

bocytopenia. The etiology is unknown, and the disease appears in an acute and chronic form, the latter with remissions and exacerbations. The diagnosis is difficult to establish, but in a case of splenomegaly with the foregoing blood findings, bone marrow studies should be made. These will usually disclose hyperplasia of the elements involved. Splenectomy is curative and should be done as soon as the patient can be prepared for surgery by repeated transfusion.

Group VII. Neoplasms and Cysts.—Neoplasms and cysts as outlined in this chapter are difficult to diagnose as such. In the presence of a large spleen, the diagnosis is made by exclusion and, in addition, bits of evidence which may be gleaned from a careful history and complete physical examination. Primary tumors cannot be recognized preoperatively except perhaps hemangioma, which gives rise to a bruit over the left hypochondrium. Huge cysts cause great distortions of x-ray patterns, and echinococcus disease may be suspected by complement fixation tests or skin tests. Secondary growths are more frequently correctly suspected because of the primary malignancy. Splenectomy is indicated, and because of this group a large spleen without definite contraindications should be removed.

Group VIII. Vascular Splenic Enlargements.—*Aneurysm* of the splenic artery is thought of in syphilis, after trauma, in arteriosclerosis, and in embolism. Pain and splenomegaly are the chief symptoms and signs. A bruit may be heard. Splenectomy should be done.

Arteriovenous fistula must be very rare but has been reported after wounds. The symptoms and signs are as in aneurysm, but, in addition, cardiac hypertrophy may occur together with other phenomena as outlined in Chapter 17. Splenectomy is indicated.

Embolism with infarction is not rare in the spleen. In subacute bacterial endocarditis the infarcts are infected, giving rise to splenic abscess which may undergo resolution or may receive splenectomy.

Thrombosis of the splenic vein has been discussed under Banti's disease. The acute varieties due to trauma or inflammation usually subside. Those due to pressure from neoplasms will not subside and wil require splenectomy when the primary lesion (pancreas, colon) is removed. Sometimes thrombosis occurs in polycythemia vera. We have seen several cases but decided not to do splenectomy. Resolution occurred.

Indications and Contraindications for Splenectomy

While no hard and fast rule can be laid down for the operation, the greatest benefits are derived in the following diseases: (1) traumatic lesions, whether by external force or tension, (2) abscess, (3) early splenic congestive splenomegaly due to portal obstruction and in all cases due to splenic vein obstruction, (4) hemolytic jaundice, (5) splenic neutropenia, (6) thrombocytopenic purpura, (7) splenic panhematocytopenia, (8) neoplasms and cysts, (9) aneurysm of splenic artery or arteriovenous fistula. Less striking results may be expected from splenectomy

capped by the small pars tuberalis), a pars intermedia, and a posterior pars nervosa. The anterior part and the pars intermedia come from an evagination of the ectoderm of the primitive buccal cavity, whereas the posterior pars nervosa and a portion of the intermedia come from the diencephalon. Some *fifteen* different functions have been attributed to it. Its anterior and posterior lobes have entirely different functions. The former controls growth and maturity; the latter, the *contraction of unstriped muscle.*

The anterior lobe secretes six hormones: (1) growth-stimulating, (2) thyrotropic, (3) adrenotropic, (4) and (5) *gonadotropic* (*follicle* stimulating and luteinizing), and (6) prolactin, or the lactogenic hormone. In addition, the anterior lobe has the following effects, *although no* separate hormones have been isolated: (1) ketogenic (causing a rise in acetone bodies), (2) hyperglycemic, (3) parathyrotropic, and (4) *pancreatropic (stimulating insulin production).*

The posterior lobe produces a pressor substance affecting unstriped muscle. This has a (1) circulatory effect, (2) plain muscle effect, (3) antidiuretic effect, and (4) metabolic effect (hyperglycemia, reduced sugar tolerance, reduced hepatic *glycogen,* and a fall in the basal metabolic rate). Two extracts have been obtained: *pitressin,* which raises blood pressure and is antidiuretic and affects *smooth muscle, and pitocin,* which contracts smooth muscle, especially uterine, and causes hyperglycemia. The only hormone produced by the intermediate lobe is *the melanophore—expanding* principle.

Pathological States of the Pituitary Gland.—

Anterior Lobe.—The chief cause of pituitary dysfunction is the presence of tumors (adenomas). There are two kinds: (1) chromophile adenomas (the cells of which accept stains), which usually cause hyperpituitarism, and (2) chromophobe tumors (the cells of which are not *easily stained*), which by pressure or destruction or altered secretion produce hypopituitarism.

In the group of chromophile adenomas there are again two types: (1) *Acidophilic adenomas,* which are made up of cells which accept an acid stain. If these occur in early childhood, they cause *gigantism; if* in later life, *acromegaly*—large, thick hands, big jaw, enormous tongue, and prominent cheek bones. (2) *Basophilic* adenomas which are made up of cells which take a basic stain. These seem to cause early or premature sex development.

Chromophobe adenomas inhibit the pituitary secretion, and if this occurs in childhood, there is an inhibition of maturity and sex development (*dystrophia,* adiposogenitalis—Fröhlich's syndrome), with deposition of fat. In the male there is a tendency to *female* characteristics, whereas in the female there is sex retardation and obesity, especially about the hips. *The lack of pituitary hormone* in infancy may cause *dwarfism,* producing small adults, normal except for size. *In adult life,* retrogressive sexual changes occur, with deposition of fat. In some forms of pituitary disease other glands *are also involved,* which makes the exact type impossible to diagnose.

Posterior lobe disease gives a confusing picture of polyuria (*diabetes insipidus*), hypertension, and overactivity of *the* parasympathetics. Diagnosis is made from the symptoms and signs, x-ray of the sella turcica, careful checking of *the eye grounds,* and examination by perimetry for bitemporal hemianopia, or obliteration of vision on the nasal half of each

In this chapter we shall consider briefly the pituitary, the pineal, the thymus, the thyroid, the parathyroids, the adrenals, the ovaries, and the testes. The function of the glands of internal secretion is to obtain a general effect. Nature uses the central nervous system for restricted, specific effects, the autonomic nervous system for broad, segmental effects, and the endocrines for widespread mass effect. A ductless gland liberates a hormone which does not affect the organ itself but has a general action. Small amounts of the hormone may be stored, but not for long. Therefore, the endocrine glands produce a continuous secretion.

A hormone is a chemical substance elaborated in one organ and carried by the blood stream to other organs and tissues, where it exerts a stimulating or retarding action. Glands do not produce secretions which act on themselves. If the secretion is introduced as substitution therapy, the gland may be stimulated or put at rest, but the effect is not on the gland.

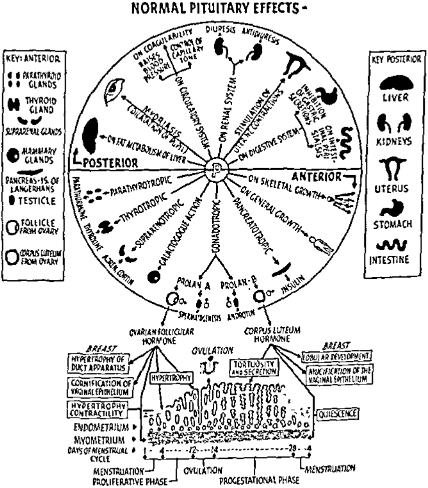

Fig. 382.—Diagram illustrating the normal effects of pituitary and ovarian hormones. Above are represented the pituitary effects and below, the ovarian hormonal activity. The ovarian follicular hormone is also known as folliculin (from the follicle), female sex hormone, theelin (Greek, female), progynon (Greek, before woman), oestrin (estrus-producing agent), menformon (monthly-acting principle), and estrogen. The corpus luteum hormone is also known as progestin, corporin, and progesterone. (Slightly modified from Gregory: A B C of the Endocrines, 1935, Williams and Wilkins Co., and Witherspoon: Clinical Pathological Gynecology, 1939, Lea & Febiger.)

The Pituitary Gland or Hypophysis

This small bilobed gland lies at the base of the brain on the sella turcica, immediately behind the optic chiasm. It is considered by many observers to be the principal gland of the endocrine system. It is composed of an anterior pars distalis (which is

Hypofunction of the pituitary due to chromophobe adenoma and hypopituitary cachexia (Simmond's disease) is accompanied by hypofunction of the thyroid, adrenal cortex, and gonads, as manifested by low basal metabolism, low blood pressure, excessive loss of sodium in the urine by hyponatriumemia, low blood sugar, genital atrophy, amenorrhea. The hypoglycemia was discussed previously in this chapter and was outlined as due to anterior lobe pituitary hypofunction caused by destructive lesions (chromophobe adenomas, cysts), atrophy and degeneration (Simmond's disease), thyroid hypofunction secondary to pituitary hypofunction.

Fig. 384.—Cushing's disease (pituitary basophilism). Basophilic adenoma of the anterior lobe of the pituitary. Note obese abdomen with (purplish) striae. This patient also had hypertension, osteoporosis, acne, polycythemia, frank diabetes, fatigue and changes in carbohydrate metabolism.

Posterior lobe deficiency causes *diabetes insipidus,* or is at least related to its cause. Other factors which have been mentioned as related to its cause are hyperthyroidism, pinealoma (through invasion of the hypothalamus and posterior lobe of the pituitary or involvement of the nerve tract from the hypothalamus to the pituitary which is known to produce the disease when cut or destroyed), and syphilis. The treatment is that of substitution therapy with posterior lobe extracts. Cures have

retina (see Chapter 18). A pituitary tumor, in other words, gives rise to local pressure effects on the brain and the sella (which may be eroded) and systemic hormonal effects as well.

Overactivity of the anterior lobe after maturity causes acromegaly; *before* maturity, gigantism; or it may cause a state of obesity in the trunk, face, and abdomen, with brittleness of the bones, hypertension, hyperglycemia, frank diabetes, changes in carbohydrate metabolism, polycythemia, fatigue, and glycosuria, and atrophy of the testes or ovaries (pituitary basophilism, or Cushing's disease). It is well to remember that certain groups of these symptoms, if not all, may be seen in (1) adrenocortical "hyperplasia," (2) adrenocortical tumors, (3) tumors of the thymus, (4) parathyroid tumors, (5) arrhenoblastoma of the ovaries. *Deficiency of the anterior lobe hormone* causes dwarfism in childhood, retrogressive sexual changes with deposition of fat, extreme emaciation, anemia, low metabolic rate, amenorrhea, and mental deterioration (Simmond's disease, or pituitary cachexia).

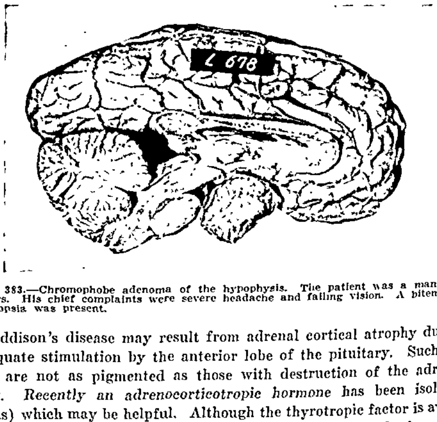

Fig. 383.—Chromophobe adenoma of the hypophysis. The patient was a man aged 44 years. His chief complaints were severe headache and failing vision. A bitemporal hemianopsia was present.

Addison's disease may result from adrenal cortical atrophy due to inadequate stimulation by the anterior lobe of the pituitary. Such patients are not as pigmented as those with destruction of the adrenal cortex. *Recently an adrenocorticotropic hormone* has been isolated (Evans) which may be helpful. Although the thyrotropic factor is available for clinical trial, its effects are evanescent and soon the hormone ceases to stimulate the thyroid gland. The gonadotropic hormone of the pituitary may be given in powder form and will in some cases stimulate the ovary so that menstruation and ovulation will occur where these functions have been absent. The hypothalamus plays a role in the release of the luteinizing hormone of the anterior lobe of the pituitary.

the frontal bone approach as well as the intranasal operation, in which the floor of the sella turcica is removed after a submucous resection, the latter has been largely abandoned now because of the dangers of meningitis. In deficiency states, pituitary extract is administered.

The Pineal Gland

The pineal gland lies on the roof of the third ventricle. It is very small but may be the seat of pinealoma, which may give rise to the symptoms and signs of a brain tumor. The function of the gland is said to be related to growth and sex development.

The Thymus Gland

The thymus gland is derived from each third pharyngeal pouch which toward the end of the sixth week begins to sacculate anteriorly. In the seventh week these sacs or pouches are detached and gradually descend into the mediastinum. The hollow

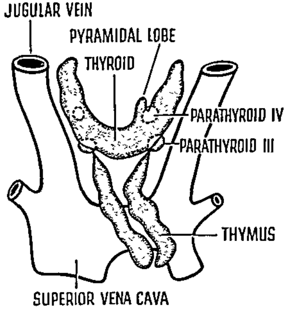

Fig. 386.—Glandular derivatives of the human pharynx. Diagram illustrating the thyroid, parathyroids, and thymi at two months in the ventral view. (After Verdun, ×15). (Redrawn from Arey Developmental Anatomy, Philadelphia, 1942, W. B. Saunders Co.)

pouches are attached to the pericardium at their lower ends, and the upper ends become stretched and thin and finally disappear. By the tenth week the thymic corpuscles appear. They are probably masses of reticulum cells, and by the third month lymphoid tissue has formed and the gland differentiates into cortex and medulla. Lymphocytes then migrate into the bilobed gland from without. The thymus enlarges until puberty, then regresses. Congenital anomalies occur. The upper ends of the thymus may persist, either continuing the thymus from the thyroid down or as separated accessory thymus lobes at the inferior margin of the thyroid. Rarely the thymus originates from the fourth pouch, giving rise to aberrant lobes.

The thymus gland lies in the lower part of the neck and in the superior and anterior mediastina. It is relatively large in infants and may, by pressure, produce

been reported following simple lumbar puncture, x-ray therapy to the pituitary, total thyroidectomy, and x-ray treatment of pinealoma or surgical removal.

Other tumors in the pituitary are: (1) The adamantinomas which occur in children and give the same symptoms as the chromophobe adenomas. X-ray shows calcium deposits and an enlarged sella. (2) The suprasellar cysts which originate in Rathke's pouch and are not rare in children. The cyst may arise anywhere along the stalk. The symptoms and signs are variable. If the cyst is in the upper infundibulum, symptoms of increased intracranial pressure are present; if in the lower part, bitemporal hemianopsia may be present. Choked disc and primary optic atrophy are common. The treatment is surgical excision.

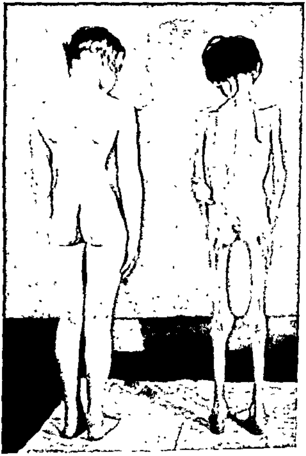

Fig. 385.—Simmond's disease (pituitary cachexia). A normal child of the same age (nine years) is shown on the left. The patient had many attacks of illness from the age of three years. At the age of eight years she had severe attacks of vomiting and diarrhea, with rapid weight loss and extreme emaciation. The patient could stand but not walk, mentality was normal. Blood pressure: 75 systolic, 45 diastolic. Blood sugar range: 60 to 106 mg. The response to anterior pituitary extract was poor and death occurred three months after release from the hospital.

Since anterior lobe dysfunction is usually due to an adenoma, the treatment is the surgical removal of the growth if possible; if not, x-ray therapy is used. The name of Harvey Cushing is indelibly associated with the description and removal of these growths. Although he used

Thymus Enlargements.—The thymus has been found to be enlarged in myasthenia gravis. Moreover the disease is helped by x-ray treatment of the thymus. These observations have led to the performance of thymectomy in selected cases of myasthenia gravis. The gland is difficult to reach. The most direct approach is through the sternum. This is split down the center to within two inches of the xyphoid-sternal junction and then cut transversely, which permits bilateral retraction. A second method is the division of the third and fourth costal cartilages with resection of two to three inches of these structures, and then by incising the perichondrium vertically, the mediastinal pleura may be retracted laterally and the thymus removed. The internal mammary artery is doubly tied and divided. A third approach is the transthoracic one. This is useful in large growths and may be supplemented where necessary by removing a portion of the sternum. Usually the approach is through the bed of the fifth rib.

The Thyroid Gland

The thyroid gets its name from "shield." It is a ductless gland that has two lobes which lie on either side of the trachea and are connected by an isthmus. This lies in front of the trachea just below the cricoid cartilage. The gland tissue is arranged in little units (*acini*), the walls of which are formed by low cuboidal cells, and the lumen of which is filled with a clear, homogeneous, iodine-containing substance known as *colloid*. These irregular sacs or acini are surrounded by connective tissue and blood vessels and lymphatics.

Embryology.—

The thyroid appears as an invagination of the mid-ventral wall of the pharynx in the fourth week of fetal life, between the first and second branchial arches. This constricts off and forms a stalked vesicle. The stalk is the thyroglossal duct. Should this duct fail to obliterate, a cyst forms (thyroglossal duct cyst), which may appear in the midline anywhere from the foramen cecum of the tongue to the isthmus. Aberrant thyroid tissue may be found at the base of the tongue or under the sternomastoid muscles. In the former position this represents all of the thyroid tissue present; in the latter, it is potentially malignant.

This aberrancy is produced by four factors: (1) The median factor may give rise to a pyramidal lobe which results from the retention and growth of the lower end of the thyroglossal duct. (2) The lateral factors are the ultimobranchial bodies which are joined with the adjacent parathyroid IV and set free from the pharynx at about the seventh week. Meanwhile the growth of the thyroid brings its two lobes into contact with the ultimobranchial bodies and the latter disappear or are converted (due to influence of the thyroid environment on a plastic implanted tissue—Arey) into thyroid tissue. Sometimes these "thyroid primordia" remain in a lateral detached position. (3) Malmigration—this factor may cause the thyroid to enter the chest or remain at the foramen cecum as a lingual thyroid. (4) Heterotopia or ectopia—thyroid tissue may be found in the ovary (struma ovarii) or other unpredictable location.

Anatomy.—Beneath the skin are the panniculus adiposus (superficial fascia) and then the panniculus carnosus (platysma). The "ribbon muscles" of the neck (sternohyoid and sternothyroid) lie immediately in front of the capsule. The deep fascia (fascia Colli) may be looked upon as a fibrous sheath which dips in and out of

some interference with breathing (thymic asthma), although this concept is now disputed. This condition is treated by x-ray, which reduces the size of the gland. After *puberty the thymus normally undergoes gradual involution.*

In the neck the gland *lies behind the sternohyoid and sternothyroid* muscles and anterior to the trachea. In the thorax it is covered by the sternum, to which it is attached, and below it is separated from the aortic arch, pericardium, and large vessels by *a thin fascial layer.* Its blood vessels come from the superior and inferior thyroid and internal mammary arteries. Its veins *empty into the thyroid, internal mammary,* and innominat eveins. Its capsule has nerve fibers from the phrenic and descendens hypoglossi, whereas the gland contains branches of the sympathetic and parasympathetic fibers (vagus).

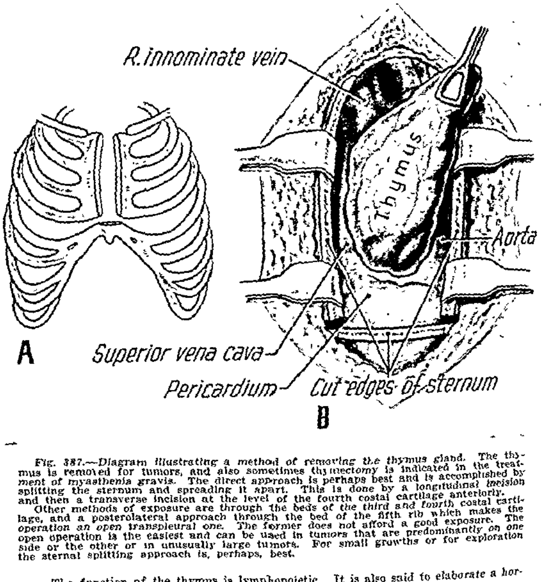

Fig. 387.—*Diagram illustrating a method of removing the thymus gland.* The thymus is removed for tumors, and also sometimes *thymectomy* is indicated in the treatment of *myasthenia gravis.* The direct approach is perhaps best and is accomplished by splitting the sternum and spreading it apart. This is done by a longitudinal *incision* and then a transverse incision at the level of the fourth costal cartilage anteriorly.

Other methods of exposure are through the beds of *the third and fourth* costal cartilage, and a posterolateral approach through the bed of the fifth rib which makes the operation *an open* transpleural one. The former does not afford a good exposure. The open operation is the easiest and can be used in tumors that are predominantly *on one* side or the other or in unusually large tumors. For small growths or for exploration the sternal splitting approach is, perhaps, best.

The function of the thymus is lymphopoietic. It is also said to *elaborate a hormone* which affects *growth and maturation.* The *so* called status thymicolymphaticus, or state in which sudden death in a child has been attributed to an enlarged thymus, probably does not exist.

ate abduction (due to stimulation) and *loss of voice except for a whisper.* Eventual fibrosis of the vocal cords, together with fixation of the arytenoids, results in great narrowing of the glottic space, *making breathing difficult on the slightest exertion.* Injury to one nerve is not so serious because the opposite cord compensates for the inactivity of the injured side.

The thyroid, as seen in microscopic sections, is made up of acini lined with low cuboidal epithelium and filled with colloid. This epithelium becomes enfolded and the cells enlarge, becoming columnar, when hypertrophy and hyperplasia occur. Williamson believes the thyroid to be composed of a number of lymphatic sinusoids, in which are suspended epithelial cords or cylinders. Rienhoff describes the gland as made up of follicles which are not entirely separated from one another by a complete covering of connective tissue. The latter forms a continuous fenestrated meshwork, which grows in from the capsule. The parenchyma is continuous throughout.

Physiology.—

1. *The Relation of the Thyroid to Other Endocrine Glands.*—The thyroid is influenced by the pituitary (through the thyrotropic hormone), by the adrenals (perhaps inhibitory through the pituitary), and by the gonads. The influence of the gonads is very important and is observed clinically during puberty, menstruation, and pregnancy. Often thyroid activity is increased following surgical removal of the ovaries, or at the menopause. In animals, castration leads to reduction in size of the thyroid and depression of the metabolic rate, while the continued injection of estrogenic hormones causes thyroid enlargement, followed by involution. Thyroid feeding inhibits estrus. Menstruation is reduced or absent in thyrotoxicosis. It is increased in myxedema. The pituitary is influenced by the thyroid specifically and by a calorigenic effect. Total thyroidectomy causes hypertrophy of the pituitary, and subtotal thyroidectomy is not followed by compensatory hyperplasia in hypophysectomized animals, a fact which has led to the treatment of hyperthyroidism by x-ray exposure over the pituitary. The adrenal medulla is definitely related to the thyroid. The exaggerated sensitivity of patients with hyperthyroidism to epinephrine is suggestive of its underfunction in this disease. The pancreas and the thyroid may be antagonistic, but the deleterious effect of the severity of diabetes mellitus may not be due to an antagonism between the thyroid and insulin but may be due entirely to the increase in metabolism in hyperthyroidism, which demands more glucose, which in turn is incompletely metabolized due to deficient insulin. We have already observed, in our discussion of hypoglycemia, that the thyroid, pituitary, pancreas, and adrenals are related to sugar metabolism.

2. *Iodine Metabolism and the Thyroid Hormone.*—The thyroid hormone has many interrelated effects; the more prominent are as follows: (1) The regulation of heat production or its equivalent oxygen consumption and carbon dioxide production; that is, the rate of energy exchange or metabolism (calorigenic action). The basal metabolic rate is below normal in starvation and undernutrition, in obesity due to pituitary or hypothalamic disorders, in hypothyroidism, in Addison's disease, in lipoid nephrosis, and in shock. It is above normal in hyperthyroidism, fever, diabetes insipidus, cardiorenal disease with dyspnea, leucemia, and polycythemia. (2) the effect on growth maturation and differentiation of tissue. (3) The distribution of water, salts, and colloids of the body are affected. In hypothyroidism there is a storage of water, salts, and protein. In myxedema the so called "deposit protein" is stored in the body fluids and is quickly oxidized and excreted through the urine when the thyroid is administered. This diuresis is caused by a loss of intercellular fluid is evidenced by the urine's high content of sodium salts. Myxedema is due to the abnormal collection of mucoprotein derived from the cell's ground substance. Myxedematous tissue resembles fetal tissue in its high mucin content. Does this mean that the thyroid provides for a "mature" environment for tissue cells? (4) Carbohydrate metabolism is affected. Glycogen in the liver is depleted in hyperthyroidism and increased in hypothyroidism. Diabetes is aggravated in the former and is less severe in myx-

the principal structures of the neck, forming their covering. The superficial layer encloses the sternomastoid muscle and forms two layers which are attached in front and behind the sternum. The pretracheal layer ensheathes the thyroid and then continues around in front of the prevertebral muscles. Laterally it blends with the carotid sheath, which is also a special part of the cervical fascia. The prevertebral layer lies in front of the prevertebral muscles. The sheath of the thyroid is therefore a part of the pretracheal fascia. This same layer is attached to the larynx, trachea, and esophagus, causing the thyroid to move with swallowing. Behind the sheath lie the parathyroids and the recurrent laryngeal nerve. The latter runs along the groove between the trachea and esophagus. Injury to this nerve causes adductor and abductor paralysis. Removal of the parathyroids causes tetany. The capsule of the thyroid is closely adherent and sends supporting fibrous septa into the stroma. The deep cervical fascia is therefore really composed of two strong sheets, which are attached on the lateral side of the neck, dividing it into three compartments: a posterior or vertebral, containing the muscles of the spinal column, a middle or visceral, containing the great vessels, the esophagus, the pharynx, and the thyroid, and an anterior or muscular, containing the sternomastoid and ribbon muscles.

The normal thyroid weighs about 25 to 40 grams and is a very vascular organ, receiving its blood supply from the superior and inferior thyroid arteries (from the external carotid and thyrocervical trunks, respectively) and often the thyreoidea ima (from the aorta or innominate). If a pyramidal lobe is present, it gets its blood supply from the superior thyroid, usually the left by a special branch. There is a prodigious amount of anastomosis, and the superior and inferior thyroid arteries communicate through an anastomosing trunk on the posterior aspect of the lateral lobes. This trunk is a guide to the parathyroids. Three pairs of veins drain the gland unless accessory veins are present. Typically the upper two, the superior and middle thyroid veins, empty into the internal jugular; the lower or inferior thyroid veins join as a trunk which empties into the left innominate. The veins cover the surface of the gland anteriorly and over the trachea and anastomose freely across the isthmus. The lymph vessels drain into the deep cervical and pretracheal nodes.

The nerve supply comes from the middle and inferior cervical ganglia of the sympathetics and accompanies the blood vessels. In the operation of thyroidectomy, adjacent nerves are encountered which do not supply the thyroid gland but must be recognized. These are the superior laryngeal and the recurrent laryngeals, both branches of the vagus. The former have two branches, an internal, which goes through the thyrohyoid membranes, supplying the mucous membrane of the larynx, and an external, which passes down on the inferior constrictor muscles of the pharynx, supplying this muscle and the cricothyroid. It may be injured in dealing with the superior pole. The recurrent laryngeals are far more important. The right arises from the vagus as it crosses the first part of the subclavian artery. It hooks around the artery, then passes upward and medially behind the subclavian and the common carotid, then more medially behind the inferior thyroid artery and thyroid gland in the interval between the trachea and esophagus. On the left the nerve leaves the vagus as it crosses the aortic arch, which it hooks around lateral to the ligamentum arteriosum, then follows a course similar to the right. Great variations occur in its course upward. The nerves may (1) differ on each side; (2) ascend anterior to the inferior thyroid artery; (3) not descend but cross at a high level and enter the larynx directly; (4) descend to the inferior thyroid artery, then ascend to enter the larynx; (5) hook around the inferior thyroid; (6) divide into abductor and adductor branches at various levels outside the larynx. The importance of these facts becomes even more practical in the surgical treatment of goiter, because the nerve may be compressed against the trachea or into abnormal positions of all sorts. The nerve carries both abductor and adductor fibers, thereby carrying impulses which produce opposing muscle actions of the vocal cords; namely, abduction and adduction. In addition, coordinated impulses are carried which are concerned with speech and breathing. Severance of both nerves results in immedi-

Blood iodine is about 8 to 10 micrograms per 100 c.c. of blood. A small amount of this is due to inorganic iodine, representing exogenous material (nutrition, medication); the rest is due to organic iodine and may represent the amount of circulating hormone. The concentration of iodine fluctuates with diet, exercise, medication, seasons. It is low in myxedema and high in thyrotoxicosis.

The hormone is secreted in two ways: (1) Directly into the blood stream (and this is the predominant way in hyperthyroidism) and (2) into colloid. The normal gland does both—colloid is probably formed in the follicles by action of the cells in four stages, namely, secretion, colloid release, partial collapse, and recuperation, very much as apocrine glands behave elsewhere. Just how colloid gets into the blood stream is unknown, or how thyroglobulin (which has a molecule) diffuses across a living semipermeable membrane is unknown. Perhaps by enzymatic action it is partially broken down into smaller molecules.

The gland then is an independent factory and sets up its own metabolism based upon available iodine, body needs, and other factors. Since thyroxine must be doled out continuously, a store of this material is always available in the colloid unless in abnormal states, where thyroxine is removed as fast as it is made—but in the normal gland a certain amount of thyroid hormone is given to the body and the rest is stored in colloid *to be used as needed. Goiter results if iodine is lacking* when there is an increased demand for thyroxine. Iodine reaches the thyroid as iodide. The thyroid cell changes this and produces a protein thyroglobulin, in which the iodination of tyrosine and subsequent formation of thyroxine takes place. Thyroglobulin is the protein in which thyroxine is stored in the gland. When thyroglobulin splits down as a result of thyrotropin stimulation, thyroid hormone is delivered into the blood stream. The rate of thyrotropin stimulation is set by the amount of thyroid hormone in the blood.

The good effect of iodine in goiter is probably due to endothelial damage by the iodine. Since blood iodine is high in thyrotoxicosis and gland iodine is low, and since this is reversed during remission, we may deduce that the thyroid capillaries leak thyroxine during the exacerbation stage. When the capillaries are sealed, iodine is retained, allowing the gland to store some as colloid. This is the picture seen in remission.

The height of the cells surrounding the acini is related to the amount of colloid which is present. They are cuboidal if much colloid is present, columnar if little is stored. The maximum storage capacity of the gland for iodine is about 5 mg. per gram of dried gland or about 25 to 40 mg. for the normal gland. Whenever the iodine content falls below 1 mg., hyperplasia occurs.

The extractable hormone of the thyroid is iodothyroglobulin. From it, thyroxine is extracted which has most of the pharmacological properties of iodothyroglobulin and is a derivative of di-iodotyrosine. Thyroxin is an integral amino acid which is elaborated at the rate of 0.3 mg. (0.2 mg. of iodine) per day. Tissues other than the thyroid probably are able to elaborate a thyroidlike substance—a condition present in lower forms in the phylogenetic scale.

3. *The Antithyroid Goitrogens.*—These are divided into two classes:

A. Those that act without producing goiter.

(1) Iodine causes a decrease in the size of the gland with deposition of colloid or the return to a resting phase. In toxic goiter whole blood iodine and precipitable serum iodine levels are higher, whereas the iodine content of the thyroid gland is less. With the administration of iodides, blood and serum iodine levels decline and the iodine content of the thyroid increases. This is indicative of lessened thyroid activity and is usually accompanied by a decrease in thyroid hyperplasia.

(2) Radioactive iodine is prepared in a cyclotron by nuclear bombardment of metallic tellurium that becomes transmitted into iodine. This is then dissolved, distilled, and reduced to sodium iodide. The dosage is about 0.5 to 1 mc. of 12 hour iodine per gram of estimated thyroid; 25 to 50 mc. radioiodine causes fibrosis of the gland.

edema; in fact, total thyroidectomy has been suggested for the relief of intractable diabetes. (5) The action on the nervous system is seen in hyperthyroidism with emotional instability, increased irritability, and psychosis, and the reverse more or less in myxedema, although irritability is present. (6) The muscular system is influenced by the thyroid as seen in hyperthyroid states where changes may vary from mild myasthenia to advanced muscular atrophy. Hypotonicity is present in hypothyroidism. (7) The circulatory system is affected through the other effects already mentioned plus increased cardiac irritability in hyperthyroid states and lowered tone in myxedema. (8) The metabolism of vitamins and other foods are regulated by the thyroid. When the rate of metabolism is high, food and vitamin requirements increase, especially proteins and vitamins B and C. (9) Exophthalmos, though frequently associated with hyperthyroidism, is probably not caused by the hormone per se. It is said to be due to the thyrotropic hormone of the pituitary which produces edema and cellular reaction in connective tissues of the body, including the retrobulbar tissue. Exophthalmos is more often associated with myxedema (resulting from postoperative, inflammatory, or spontaneous causes) than with hyperthyroidism. In such cases there is a myxomatous infiltration of the ocular muscles and retro orbital fat, crowding the eyes forward. Other theories are as follows: A true spasm or contraction of Mueller's muscle may be the cause, or it may be due to edema behind the orbit, which occurs due to the dilatation of the orbital venules and the absence of lymphatics in this region to absorb the edematous fluid. Exophthalmos may be increased following thyroidectomy. This may be explained on the basis of increased retrobulbar edema due to ligation and division of vessels. There may also be pseudohypertrophy of ocular muscles with edema degeneration and lymphocytic infiltration. This is explained as follows: The normal thyrotropic hormone stimulates the thyroid to produce thyroxin in sufficient quantity to meet the demands of the body. The thyroid uses up all of the thyrotropin, and pituitary inhibition results. Only small amounts of thyrotropin reach other tissues. In exophthalmic goiter there is excessive thyrotropin in spite of excessive thyroid inhibition. Much thyrotropin reaches the orbit, causing edema of the ocular muscles which weakens their inward pull; this, coupled with an increase of outward push by the edema in the fat and connective tissue, causes the exophthalmos. Exophthalmic ophthalmoplegia is a term used to describe exophthalmos and loss of ocular movements. It may be caused by excessive thyroxin or thyrotropin or both.

A temporary increase in exophthalmos may occur after thyroidectomy. This usually subsides and improvement continues until the eyes are almost normal, although the process may require one to two years. Increasing exophthalmos after thyroidectomy may be anticipated in those patients with mild symptoms and low basal metabolic rates. Some have advised medical treatment or x ray therapy in such cases to avoid this troublesome complication. Should exophthalmos continue with increasing lid pressure, the eyes may be lost due to local chemosis and ulceration. Such cases may be helped by unroofing the orbital canal and incising the orbital periosteum permitting the bulging of retro-ocular fat and muscles (Naffziger). Strabismus may remain in the ordinary case of exophthalmos after thyroidectomy if the eye bulge has been present for a long time. This is corrected by shortening or "tucking" the muscles.

Unilateral exophthalmos may be an early sign in exophthalmic goiter. One usually thinks of other causes for this finding such as (1) intraorbital inflammatory disease (primary or secondary due to paranasal sinusitis), (2) paralysis of extraocular muscles, (3) cavernous sinus thrombosis, (4) congenital anatomical defects, (5) angiomas or aneurysms within or below orbit, (6) neoplasms within or behind orbit.

Every thyroid gland varies in its iodine content from time to time and is affected by seasons, locality, and food habits. Normally about one-third to one-fourth of the total iodine of the body is in the thyroid. The dried gland contains about 0.186 per cent of iodine but varies from 0.05 to 0.45 per cent. Iodine is present in fetal thyroids as early as the third month. The iodine store varies inversely with the degree of hyperplasia.

(3) Thiouracil, propyl thiouracil, methyl thiouracil, thiourea, and the sulfonamides produce goiter by pituitary stimulation and not from direct action by these compounds on thyroid parenchyma. These drugs cause nearly complete disappearance of iodine from the thyroid gland in five days. They therefore interfere with the incorporation of iodine into tyrosine and di-iodotycosine, and formation of thyroxin in the thyroid gland, and thereby cause cessation of hormone synthesis. In addition to preventing iodination and hormone synthesis, they may act as antitoxidants through depression of the enzyme systems. Propyl thiouracil is usually given in doses of 200 to 300 mg. daily, depending on the toxicity of the patient. Toxic reactions include agranulocytosis, sore throat, fever, skin rash, gastrointestinal disturbances, and joint pains. In toxic goiter after the administration of these drugs, blood iodine as well as the amount of iodine in the thyroid gland decreases. When thiouracil is given for toxic goiter, particularly the diffuse hyperplastic type (Grave's disease), there results extreme hyperplasia with heightened epithelium, papillary infolding, and mitosis of epithelial cells.

Abnormalities of Function of the Thyroid Gland

Hypofunction may be (1) primary or (2) secondary. *Primary hypofunction* includes (a) cretinism, which may be sporadic or endemic, (b) hypothyroidism with or without myxedema which may be spontaneous, postoperative, postinfectious, postantithyroid drug administration. Secondary decrease in thyroid activity is seen in hypopituitarism and Addison's disease.

Hyperfunction is seen in hyperplastic (exophthalmic diffuse symmetric) goiter, in nodular toxic goiter (toxic adenoma), and in mixed types.

Congenital Anomalies of the Thyroid Gland

The thyroid may be entirely absent, giving rise to cretinism, or it may be present in various abnormal locations, such as behind the sternum (substernal), in the chest (intrathoracic) or mediastinum, at the base of the tongue (lingual), in the sides of the neck (lateral aberrant thyroids), or in teratomas anywhere (mediastinal, ovarian). Sometimes the thyroglossal duct persists as a sinus, a fistula, or a cyst (see Chapter 15).

Cretinism may be sporadic or endemic, the latter as an end result of untreated endemic goiter lasting over a period of several generations. *Sporadic* cretinism appears in the children of normal parents. Cretinism is myxedema in childhood. Thyroid extract is specific if given early before irreparable brain damage has occurred.

Substernal thyroid may result from *overmigration* of thyroid tissue but is frequently seen in goiter which may have plunged into the superior mediastinum during its enlargement, guided by the middle or visceral compartment of the deep cervical fascia. Its blood supply comes mostly from the inferior thyroid artery, but this is variable, and therefore in its extirpation all vessels are ligated prior to its extraction from the thorax.

Substernal goiters may be complete, with no thyroid tissue above the level of the suprasternal notch; intermittent, which refer to those which are small enough to slip into and out of the anterior compartment of the superior mediastinum; and combinations, in which part of the goiter

B. Those that cause an increase in size of the thyroid gland.

(1) Cyanides (found in cabbage) produce an iodine-deficiency goiter since it can be prevented by giving iodine.

(2) Thiocyanates prevent the synthesis of thyroid hormone at some point distal to the uptake of iodine since the thyroid continues to take up radioactive iodine. The administration of desiccated thyroid prevents or relieves thyocyanate goiter. Thiocyanate goiter resembles neoplasia.

Fig. 388.—Cretin. Clinical photograph of a cretin 8 years of age who has failed to grow or develop physically or mentally. She had not learned to walk, although her mental age was that of a 2-year-old. She presented the following characteristics and findings: weight, 27½ pounds; height, 31 inches; hair scanty and coarse; anterior fontanel open, measuring 3½ cm. in diameter; parietal sutures also open in the anterior portion. head large in proportion to the body; a nonpitting edema over entire body; tongue is thick, and the twenty teeth all deciduous; heart enlarged, and there is a systolic murmur, heard best over the apex; abdomen usually distended; an umbilical hernia is present. X-ray examination of the chest showed cardiac enlargement to the right and left of the midline. There were only two centers of ossification among the carpal bones, whereas normally there should be at least eight. Blood cholesterol was 457 mg. The child was given thyroid extract, ½ grain, three times a day and vitamin B complex.

(3) Thiouracil, propyl thiouracil, *methyl thiouracil, thiourea,* and the sulfonamides produce goiter by pituitary stimulation and not from direct action by these compounds on thyroid parenchyma. *These drugs cause nearly complete disappearance* of iodine from the thyroid gland in five days. They therefore interfere with the incorporation of iodine *into tyrosine and di-iodotycosine,* and formation of thyroxin in the thyroid gland, and thereby cause cessation of hormone synthesis. In addition to preventing iodination and hormone synthesis, they may act as antitoxidants through depression of the enzyme systems. Propyl thiouracil is usually given in doses of 200 to 300 *mg. daily, depending on the toxicity of* the patient. Toxic reactions include agranulocytosis, sore throat, fever, skin rash, gastrointestinal disturbances, and joint pains. *In toxic goiter after* the administration of these drugs, blood iodine as well as the amount of iodine in the thyroid gland decreases. When thiouracil is given for toxic *goiter, particularly the* diffuse hyperplastic type (Grave's disease), there results extreme hyperplasia with heightened epithelium, papillary infolding, and mitosis of epithelial cells.

Abnormalities of Function of the Thyroid Gland

Hypofunction may be (1) *primary or* (2) *secondary. Primary hypofunction* includes (a) cretinism, which may be sporadic or endemic, (b) *hypothyroidism* with or without myxedema which may be spontaneous, postoperative, postinfectious, postantithyroid drug administration. Secondary decrease in thyroid activity is seen in hypopituitarism and Addison's disease.

Hyperfunction is seen in hyperplastic (exophthalmic diffuse symmetric) goiter, in nodular toxic goiter (toxic adenoma), and in mixed types.

Congenital Anomalies of the Thyroid Gland

The thyroid may be entirely absent, giving rise to cretinism, or it may be present in various abnormal locations, such as behind the sternum (substernal), in the chest (intrathoracic) or mediastinum, at the base of the *tongue (lingual),* in the sides of the neck (lateral aberrant thyroids), or in teratomas anywhere (mediastinal, ovarian). Sometimes the thyroglossal duct persists as a sinus, a fistula, or a cyst (see Chapter 15).

Cretinism may be sporadic *or endemic, the latter* as an end result of untreated endemic goiter lasting over a period of several generations. *Sporadic cretinism* appears in the children of normal parents. Cretinism is myxedema in childhood. Thyroid extract is specific if *given early* before irreparable brain damage has occurred.

Substernal thyroid may result *from overmigration* of thyroid tissue but is frequently seen in goiter which may have plunged into the superior mediastinum *during* its enlargement, guided by the middle or visceral compartment of the deep cervical fascia. Its blood supply *comes* mostly from the inferior thyroid artery, but this is variable, and therefore in its extirpation all vessels are ligated *prior to its* extraction from the thorax.

Substernal goiters may be complete, with no thyroid tissue above the level of the *suprasternal notch*; intermittent, which refer to those which are small enough to slip into and out of the anterior *compartment* of the superior mediastinum; and combinations, in which part of the goiter

is in the neck and part has been pushed *down into the mediastinum*. The symptoms and signs of these goiters in addition to their general effects, if any, are those due to local pressure. These may include difficulty in

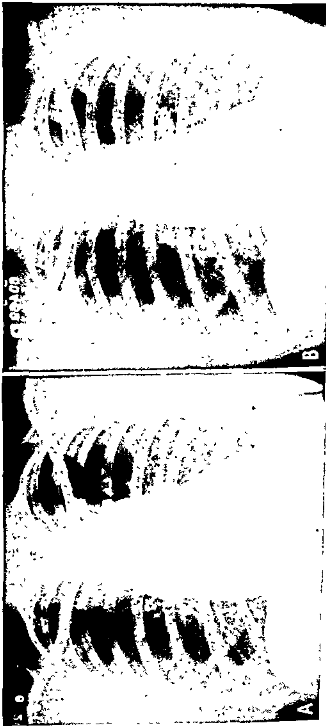

Fig. 389.—X-ray picture of a large intrathoracic "plunging" goiter. The patient was a woman aged 36 years. There was increasing dyspnea, and finally orthopnea, hoarseness, and dysphagia. *A*, Before operation. *B*, After operation.

breathing or swallowing, edema of the face and neck, and pain. In addition, there may be great dilatation of superficial veins of the upper chest and neck due to superior vena caval pressure and hydrothorax.

Diagnosis is made by the symptoms and signs and x-ray studies. The treatment is thyroidectmoy, and this is done through the classical collar incision and after the blood supply has been controlled. If the goiter is too large to be delivered, its capsule may be opened and the growth removed in part; then the capsule may be "peeled" out.

Intrathoracic or *mediastinal* thyroid is due to an overmigration or heterotopia or the inclusion of thyroid tissue in teratomas. Goiters have been found as low as the diaphragm (goiter *plongeant* from *plonger*—a descending or sloping part). Mediastinal goiters do not have the normal relationship to the carotid sheath, the trachea, and esophagus and do not get their blood supply from the thyroid arteries except rarely from the thyroidea ima. Their symptoms and signs are those of a mediastinal tumor (Chapter 20), and the diagnosis is made in the same way as in the care of these neoplasms. The treatment is their surgical removal through a thoracotomy. Thyroids have been found in the trachea and esophagus.

Lingual thyroid is more common than nasopharyngeal, intralingual, sublingual, and prelaryngeal, all of which illustrate a lack of descent of the thyroid tisue to its normal position. Lingual thyroid may be accessory thyroid tissue in addition to the normal gland. In lingual goiter, however, the thyroid at the base of the tongue between the epiglottis and circumvallate papillae is the only thyroid tissue present. The goiter is usually of the adenomatous type and is nontoxic. The symptoms and signs are due to the pressure of a tumor at the base of the tongue which interferes with swallowing, breathing, and speech. In addition, ulceration and infection due to trauma may cause bleeding. Differential diagnosis includes adenoma, angioma, fibroma, lipoma, and nonthyroid cysts; also sarcoma, lymphosarcoma, and carcinoma which may be associated with lingual goiter. Treatment consists of surgical removal either through the oral cavity or, rarely, through the neck in extremely large growths, after preliminary tracheotomy. In small growths transfixion sutures are used before removal, and in larger tumors the lingual arteries are tied. The most common postoperative complication is myxedema. This occurred in the two cases we have seen.

The lateral aberrant thyroids have been explained as arising from the fifth branchial pouch (ultimobranchial body) or from early separation of the aberrant tissue from the main body of the thyroid. These thyroids are usually multiple and are located in front of the sternomastoid muscle beside the internal *jugular vein*. Sometimes they are single. On microscopic examination they resemble a papillary cystadenoma, which, indeed, they are, but of the thyroid, and with the same malignant tendencies as papillary cystadenoma of the breast or ovary or other glandular organs There are few symptoms and signs except for the swelling in the neck They must be differentiated from midline thyroid tumors (undescended thyroids, pyramidal lobe, adenoma of the isthmus, thyroglossal duct cyst) and lateral tumors which are single (branchial

cysts, carotid body tumors, neurofibromas) and multiple (lymph node swellings, inflammatory or malignant, Chapter 17). Treatment consists of surgical extirpation, including the internal jugular vein, overlying muscle, lymph nodes, submaxillary gland, and the thyroid lobe on the affected side if the biopsy of any of the aberrant tissue is malignant. This is followed by x-ray therapy. If not malignant, simple removal is all that is required. Many so-called lateral aberrant thyroid tumors are really metastatic extensions to the deep cervical lymph nodes from a primary carcinoma in the homolateral lobe of the thyroid gland.

Thyroid tissue in *teratomas* has been reported. Their discovery is usually fortuitous, although in the presence of all of the classical symptoms and signs of toxic goiter after thyroidectomy aberrant thyroid tissue activity may be thought of.

Goiter

Not all enlargements of the thyroid gland are of the same nature, even though they are all called "goiter." Therefore, below will be found a simple classification of goiter. First in this list is the so-called *simple goiter.* The thyroid gland is frequently called upon to secrete an increased amount of its hormone (thyroxin). To do this it may undergo hypertrophy, hyperplasia, or both. Having met the emergency, it may return to normal, or it may go into a resting stage (acini filled with colloid), or it may undergo incomplete involution, or it may atrophy. Should it remain enlarged, with or without an excessive or perverted secretion, it forms a goiter. The most common causes for a simple goiter are *compensatory hypertrophy and hyperplasia.* This simply means that the thyroid gland has enlarged, in both the number and size of its cells, to meet an emergency. The smooth fullness in the necks of adolescent girls is a physiological enlargement. In some women this enlargement takes place with every menstrual period; in others, during pregnancy or during the menopause, or in any mental or physical stress or strain. These are all physiological causes of enlargement which is usually relieved by the use of iodine. This condition having occurred, the gland usually lapses into one of three states: (1) normal, (2) colloid rest stage, or involution, (3) atrophy of exhaustion.

During adolescence the body changes and grows rapidly and there is need for increased energy and metabolism. When the increased demand is over, the thyroid gland returns to normal. The same is true during periods of nervous stress and strain.

Classification of Goiter

A. Simple goiter (nontoxic)
   1. Compensatory hypertrophy and hyperplasia, due to physiological causes or acute infections
   2. Simple colloid goiter
      (a) Endemic
      (b) Result of previous hypertrophy and hyperplasia

3. Simple adenomatous goiter
   (a) Diffuse adenosis
   (b) Fetal adenoma
   (c) Combinations

B. Toxic goiter (thyrotoxicosis or hyperthyroidism)
   1. Exophthalmic—acute (crisis) or chronic
      (a) Diffuse hyperplasia
   2. Toxic adenoma (nodular toxic goiter)
      (a) Diffuse adenomatosis
      (b) Fetal adenoma and areas of hyperplasia

C. Infections
   1. Acute thyroiditis—suppurative and nonsuppurative
   2. Chronic thyroiditis
      (a) Riedel's struma (ligneous thyroiditis)
      (b) Struma lymphomatosa (Hashimoto's lymphoid struma)
      (c) Tuberculous thyroiditis
      (d) Syphilitic thyroiditis
      (e) Chagas' disease (*Trypanosoma cruzi*)
      (f) Amyloid disease resulting from infection elsewhere

D. New growths
   1. Benign
      (a) Cysts
      (b) Adenomas
         (1) Embryonal
         (2) Fetal
         (3) Colloid
         (4) Papillary
      (c) Fibroma
      (d) Endothelioma
      (e) Plasmacytoma
   2. Malignant—carcinoma
      (a) Primary carcinoma
         (1) Malignant adenoma
         (2) Papillary
         (3) Adenocarcinoma
         (4) Diffuse carcinoma (small-cell)
         (5) Giant-cell carcinoma
         (6) Hürthle cell tumor
      (b) Secondary carcinoma
         (1) Metastases from other organs (rare)
      (c) Sarcoma
         (1) Fibrosarcoma
         (2) Endothelial sarcoma
         (3) Lymphosarcoma
         (4) Osteosarcoma
         (5) Osteochondrosarcoma
      (d) Melanoblastoma
      (e) Hodgkin's disease
      (f) Teratoma

Simple colloid goiter may result from a previous hypertrophy and hyperplasia; that is, after the great demand is over, the gland may store thyroxin in *colloid* (thyroglobulin) for future use. There is an endemic type of colloid goiter caused by a deficiency of iodine in the water of

certain regions, such as Switzerland, and certain districts of the United States, as the Ohio Valley. Apparently iodine is needed for the synthesis of thyroxine and colloid is needed to store thyroxin. Therefore, in the nontoxic types there is always ample colloid. Since the colloid state is a resting stage in thyroid activity, the administration of iodine sufficient for the gland's requirements causes it to form an ample amount of thyroxin. This is then *stored in colloid for future use. In diffuse* colloid goiter which is untreated, the gland may be so large as to interfere with swallowing and even breathing, although the latter is rare and only occurs when there is great pressure on the trachea or when it has been dislocated by a unilateral enlargement. Interference with vocal cord movement (recurrent laryngeal nerve paralysis) usually implies that a malignant invasive growth is present with the colloid goiter.

Fig. 390.—Large colloid goiter involving chiefly the right lobe. Blood cholesterol, 227 mg.; basal metabolic rate, −25. Removal is indicated because of interference with breathing and swallowing.

Pressure on the acinar cells coupled with insufficient amounts of iodine are apt to produce a hypothyroid state.

The thyroid is the only organ in the human body which requires iodine; apparently no other gland uses it to elaborate a hormone, although it is found in many glands, especially in the pituitary.

The treatment for simple goiter is first its prevention. This may be easily accomplished by administering iodine by mouth during the "stress" periods. This prevents not only colloid goiter, but other types as well. One grain (.065 Gm.) of iodine (marine) per week is usually given during adolescence. The iodine does not eliminate a colloid goiter after it has formed; it does *prevent* it by keeping the gland in a normal

state of activity. The amount of iodine required by the body for thyroid activity is less than 1/1000 of an ounce. Iodine is best administered as iodized salt which will provide for adequate amounts when used for ordinary seasoning of food. If there is associated hypothyroidism, thyroid extract should be given. This medication is useful not only in the prevention of colloid goiter, but also in its treatment when seen early. If the gland is unusually large, unsightly, or interferes with respiration or deglutition, it is subtotally removed (subtotal thyroidectomy). The remaining gland will often return to a normal state if iodine is continued.

Adenomatous goiter is a benign growth of glandular tissue. It may be diffuse, without definite demarcations (diffuse adenosis), or of the so-called fetal type, which is an ingrowth of glandular tissue in a colloid-filled acinus, which looks as though it had a capsule. These areas are probably the involuted forms of previous hyperplasias. True adenomas sometimes occur. In addition to the changes noted, cysts may form due to retention caused by stroma bands or by necrosis due to pressure. Often calcification is observed, making the gland extremely hard. This hardness is observed in chronic thyroiditis and malignancy of the thyroid. However, calcification and malignancy in the same gland are extremely rare. Sometimes the entire gland is necrotic and the gelatinous cystic and hemorrhagic material may be scooped out at operation, leaving only the capsule with its blood vessels.

Embryonal adenomas (undifferentiated fetal adenomas) consist of solid nests or columns of epithelial cells with no acinus formation. This picture is very difficult to distinguish from carcinoma. *Fetal adenoma* (microfollicular adenoma) consists of many small acini containing little colloid and lined with cuboidal cells. The interacinar tissue often is sparse; however, at times, it may be plentiful, resembling hyaline tissue or colloid. The latter picture may resemble an ingrowth of epithelium into a distended colloid-filled acinus. *Colloid adenomas* are common and consist of acini of various sizes filled with colloid. *Papilary adenoma* or *papillary cystadenomas* are full of large acini with papillary projections of tall cuboidal or columnar epithelium resembling papillary cystadenomas in other glandular organs.

Clinically, adenomas are seen ten times more often in women than in men. They are rarely seen in children, occurring mostly after 30 years of age. The only symptoms and signs are those of a nodular swelling in the neck.

Complications include: (1) Carcinoma which is said to occur in 9 per cent of single adenomas and 4 per cent in multinodular goiters. (2) Toxicity which increases with the older age group. (3) Mechanical disturbances by compression and deviation of the trachea and esophagus by retrotracheal, substernal, and intrathoracic extension.

Statistics seem to indicate that carcinoma is more apt to occur in the nontoxic than the toxic nodular goiter. In addition, there are hypothetical grounds for believing that the rule of malignancy concerning in-

certain regions, such as Switzerland, and certain districts of the United States, as the Ohio Valley. Apparently iodine is needed for the synthesis of thyroxine and colloid is needed to store thyroxin. Therefore, in the nontoxic types there is always ample colloid. Since the colloid state is a resting stage in thyroid activity, the administration of iodine sufficient for the gland's requirements causes it to form an ample amount of thyroxin. This is then stored in colloid for future use. In diffuse colloid goiter which is untreated, the gland may be so large as to interfere with swallowing and even breathing, although the latter is rare and only occurs when there is great pressure on the trachea or when it has been dislocated by a unilateral enlargement. Interference with vocal cord movement (recurrent laryngeal nerve paralysis) usually implies that a malignant invasive growth is present with the colloid goiter.

Fig. 390.—Large colloid goiter involving chiefly the right lobe. Blood cholesterol, 227 mg., basal metabolic rate, −25. Removal is indicated because of interference with breathing and swallowing.

Pressure on the acinar cells coupled with insufficient amounts of iodine are apt to produce a hypothyroid state.

The thyroid is the only organ in the human body which requires iodine; apparently no other gland uses it to elaborate a hormone, although it is found in many glands, especially in the pituitary.

The treatment for simple goiter is first its prevention. This may be easily accomplished by administering iodine by mouth during the "stress" periods. This prevents not only colloid goiter, but other types as well. One grain (.065 Gm.) of iodine (marine) per week is usually given during adolescence. The iodine does not eliminate a colloid goiter after it has formed; it does *prevent* it by keeping the gland in a normal

Toxic Goiter (Thyrotoxicosis, Hyperthyroidism).—In addition to enlargement of the thyroid, the gland secretes something that makes the patient ill. Thyrotoxicosis is often referred to as hyperthyroidism; there is perhaps not only hyperthyroidism, but also a perverted secretion (a dysthyroidism). The word thyrotoxicosis implies that a toxemia exists, although no toxic substance has ever been identified. There is a low iodine content in the gland and an increase in blood iodine, but neither of these factors alone or in combination necessarily produce toxic goiter. For example, blood iodine may be elevated in cholecystitis with cholelithiases, essential hypertension, hypertensive cardiac disease, and certain infectious disorders, whereas a low thyroid iodine is seen in colloid goiter. The local changes in the gland are not always the same. Two principal varieties exist: (1) diffuse hyperplasia; (2) variable types of adenoma. The appearance of the gland grossly or microscopically does not indicate its toxicity.

Fig. 393.—Photomicrograph of tissue from a so-called fetal adenoma of the thyroid gland (medium power). This tissue was completely surrounded by a fibrous capsule, a portion of which is shown in the left lower corner. Note the small acini, the great vascularity, and the small amount of colloid. The appearance is that of fetal thyroid tissue.

Graves' disease or *Basedow's disease* is also called *exophthalmic goiter* because, in addition to other symptoms and signs, there is often a protrusion of the eyeball. Microscopically, the picture is one of diffuse hyperplasia. The cause is not known, although there is presumably an overstimulation of the thyroid by the pituitary through the thyrotropic factor of the anterior lobe. The disease is not hereditary but there is a strong familial tendency. Thyrotoxicosis may be induced by the ingestion of thyroid extract (factitial thyrotoxicosis, alimentary thyrotoxicosis). In endogenous thyrotoxicosis, the urinary excretion of radioactive iodine is low compared with euthyroid persons, but it is high in factitial thyro-

active glands holds in the case of the thyroid. If this is true, thiouracil should not be given in a toxic nodular goiter unless as a preoperative measure.

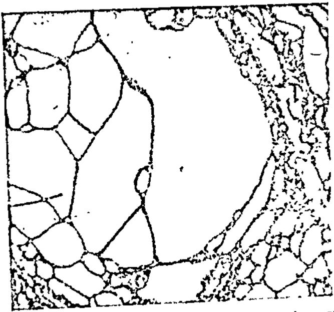

Fig. 391.—Section from a nodular colloid goiter. The section shows one of the nodules in which the acini are distended with colloid. The epithelium is of the low cuboidal type. There were no toxic symptoms.

Fig. 392.—Large adenomatous goiter in a woman aged 74. Pressure symptoms demanded operative removal. This was successfully accomplished.

The treatment for nodular goiter is thyroidectomy whether it produces symptoms or not because of the complications which may ensue, particularly carcinoma. After subtotal thyroidectomy has been done, biopsies should be done, and if carcinoma is found or suspected, total thyroidectomy with excision of lymph nodes is indicated.

Associated Clinical and Pathological Changes in Toxic Goiter.—Almost every organ and tissue in the body is affected more or less in thyrotoxicosis. The more common associated effects are in the brain, eyes, heart and blood vessels, liver, gastrointestinal tract, skeletal system (muscle and bone), endocrine glands, acid-base balance, carbohydrate and protein balance, and basal metabolism.

The psychoses may be due to cerebral edema such as occurs in burn toxemia or the toxemia of pregnancy. Small areas of necrosis may occur. The edema, the cardiac hypertrophy, the high pulse pressure, poor tolerance to hypoxia have been explained by some observers on the hypothesis that the hyperplastic vascular thyroid acts as an arteriovenous fistula. Indeed, they aver that the postthyroidectomy psychosis is due to increased edema because collaterals have not formed around the ligated thyroid vessels and adjustments have not occurred; the same reason is given for postthyroidectomy increase in exophthalmos; also the improvement in cardiac hypertrophy and the return to normal pulse pressure is said to be due to removal of the parasitic circulation (see Chapter 17).

Exophthalmos has been discussed previously under the discussion on Physiology of the Thyroid. The *heart* is often the seat of hypertrophy, and occasionally there may be small areas of necrosis or scars from previous areas or both. The *liver* may contain areas of fibrosis or necrosis as seen in severe burns or toxemia of pregnancy. Acute and chronic hepatitis and altered hepatic function are observed and may be discovered by liver function tests as previously described. These observations have led to the use of a high carbohydrate-protein and low fat diet with liberal amounts of vitamin B complex. There is a striking resemblance between some of the clinical features of hyperthyroidism and thiamine deficiency (tachycardia, cardiac hypertrophy, dyspnea, palpitation, edema, fatigue, lowered muscular strength, etc.). Hyperthyroidism increases the rate of cell metabolism, thus calling forth a higher requirement for food and an increase in the breakdown and resynthesis of metabolites. Thiamine is important in the latter processes. Pyruvic acid is an important intermediary in carbohydrate breakdown, and perhaps in the interconversion of protein, fat, and carbohydrate, and it is elevated in thyrotoxicosis. When there is an increased cellular metabolism, there will be a need for more thiamine and a relative deficiency in this vitamin. A high vitamin B diet delays the appearance of liver damage in thyroxine-treated dogs and decreases the level of pyruvic acid. Therefore, vitamin B complex is useful in the utilization of pyruvic acid, and this in turn makes for more complete breakdown and utilization of carbohydrates and protein which are needed to prevent further liver damage. There is good experimental evidence to show that hepatic injury is much more apt to occur in hyperthyroid animals who are anoxic than in hyperthyroid controls. The low serum proteins sometimes found may be due to the excessive utilization and breakdown of protein with increased nitrogen excretion, the fact

toxicosis. The cause is unknown, since the causative substance in the blood that is responsible has never been identified. Some of the contributory causes are understood; namely, the constitutional type, emotional stress, and autonomic imbalance. Sympatheticotonic symptoms are the tachycardia, exophthalmos, increased metabolism, fever, perspiration, and lessened gastric secretion. Increased peristalsis is vagotonic. The rapid pulse is thought by some to be due to a shunt across the greatly dilated capillary bed in the thyroid, which is comparable to an arteriovenous fistula.

Fig. 394.—Exophthalmic goiter in a girl aged 11 years. There were severe thyrotoxic symptoms, a basal metabolic rate of +35, and a blood cholesterol of 92 mg. Thyroidectomy was performed and was followed by an amelioration of symptoms. The gland showed diffuse hyperplasia. The exophthalmos is not pronounced.

Pathology.—The gland is enlarged, smooth, and beefy red (symmetric toxic goiter). The cells have enlarged and multiplied until the acini are full of tall cells with practically no colloid. The gland is red because its blood supply is greatly increased. Apparently the body takes away the thyroid secretion faster than the gland can produce it. The thyroid in primary thyrotoxicosis is poor in iodine and colloid. It has lost its power of retaining thyroxine in the colloid and discharges it in excess into the circulation.

The size of the thyroid or its microscopic picture is not in any way indicative of the presence or degree of thyrotoxicosis. There is no evidence that the cells produce an abnormal secretion.

Thyroid extract may produce a remission by relieving the gland of some of its work, thereby allowing capillaries to constrict and impeding the mechanism for the discharge of thyroxin. Once iodine is retained, a remission may occur. Blood from a thyrotoxic patient will cause tadpoles to metamorphose, but so will iodine.

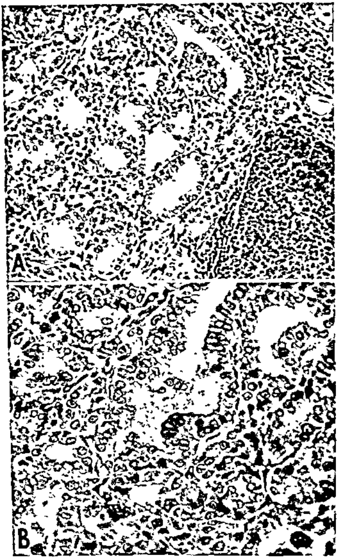

Fig. 396.—Tissue from an exophthalmic goiter. *A*. Medium power. Note the infolding of the epithelium into the acini, which are not large and contain very little lightly stained colloid. The lymphoid tissue in the right lower corner is a characteristic finding. *B* High power. The columnar cells are clearly shown, as is also their infolding in o the acini. This patient received iodine for a long period of time without remission of symptoms. Thyroidectomy was successfully accomplished in stages.

Symptoms and Signs.—Clinically, the disease is usually seen in young women who have had an unusual period of stress. It seems to occur in those with a "constitutional thyroid tendency," usually in individuals of the linear rather than the lateral type. There are heat intolerance and loss of weight in spite of enormous appetite. The patient

that there is impaired liver function interfering with the synthesis of serum albumin and fibrinogen, and the usual diet of thyrotoxic patients which is notoriously poor in protein. This combination of decreased intake, increased loss, and deficient synthesis is a vicious circle because hypoproteinemia causes liver impairment and vice versa.

The gastrointestinal tract exhibits changes in thyrotoxicosis which are more or less characteristic. These are (1) achlorhydria, (2) delay in gastric emptying, (3) increased small and large intestine tone and motility.

Fig. 395.—Exophthalmic goiter in a woman aged 28 years. The goiter is rather large and smooth. The exophthalmos is very pronounced. The anxious expression is typical.

Skeletal muscle may be atrophic and *bone* may show demineralization, imperfect calcification, or osteomalacia. There is an increased loss of calcium in the urine. Spontaneous fractures have been reported. The cortical portion of the *thymus*, the *pituitary*, the *spleen*, and *lymph nodes* shown hypertrophy. Disturbances in acid base balance may result in acidosis due to ketosis which is promptly relieved when liver glycogen is restored to normal. The profuse sweating, diarrhea, and vomiting are apt to cause dehydration with loss of electrolytes, especially in thyroid crisis.

Basal metabolism is greatly increased and the rate is high, plus 70 to 90 or more. Whole-blood *iodine* is elevated to about twice the normal (8 micrograms per 100 c.c.). The protein-bound (acetone-insoluble) blood iodine is presumably thyroglobulin in nature and is increased in hyperthyroidism and is decreased after the administration of gastrogenic drugs. Curtis believes that the basal metabolic rate and the protein-bound iodine determination are useful in detecting early cases of hyperthyroidism, especially in nodular goiter. If the BMR exceeds +10 per cent and the iodine is 1.2 micrograms, hyperthyroidism is suspected.

Therefore, it is better to give iodine only preoperatively in this type of goiter. How iodine acts is unknown. Iodine seems to have an inhibiting action on the excessive discharge of thyroxin. This is manifested not only by a return to normal histological architecture (accumulation of colloid, flattening of epithelium) and an increase in total iodine, but chiefly by an increase in the thyroxine iodine in the thyroid. Thus it seems that iodine does not exert its influence peripherally in the tissues but through the thyroid. Since the anterior pituitary shows relatively large amounts of iodine, this may also exert an inhibiting action by checking the production and secretion of the thyrotropic hormone. (Elmer.)

Fig. 397.—Toxic adenoma (nodular goiter) in a woman aged 69 years. This is the so-called exhaustion type of thyrotoxicosis, with emaciation, general weakness, loss of muscle tone, anorexia, and cardiac decompensation.

Some believe iodine acts on the thyroid by encouraging the formation of colloid, which decreases the activity of the gland by pressure. It may be that its good effect comes from the edema that iodine is known to produce in the capillaries or in the intima of the arterioles. This is especially true in new capillaries or young cells anywhere. This decreases

complains of palpitation, shortness of breath, and muscular weakness. The pulse is rapid and bounding. There are a high systolic and low diastolic pressure (large pulse pressure). Often there is exophthalmos, with lid lagging (von Graefe), or widened palpebral fissure (Stellwag). The enlarged gland is smooth and even. There are emotional instability, nervousness, tremors, and inability to sleep. There may even result what is known as a crisis (acute thyrotoxicosis); nausea, vomiting, diarrhea, and high fever, with delirium or coma.

The "thyroid storm" is a part of the disease and may occur not as a complication but during the course of thyrotoxicosis. It is a sudden exaggeration of all of the morbid and perverted functions of the central nervous, cardiovascular, and hepatorenal systems, and it may result in death from pulmonary or cardiac complications. It is seen in severe thyrotoxic patients and is apt to be initiated by (1) infections such as pneumonia or postoperative wound infection; (2) anoxemia from any cause whether anoxic (injury to recurrent laryngeal nerve, postoperative edema of trachea or its partial collapse, hemorrhage with pressure on the trachea), anemia from severe hemorrhage, stagnant from dehydration; (3) postoperative exacerbation; (4) following prolonged x-ray therapy without preparation; (5) hemorrhage and the necessity for secondary suture. It is more often seen in those patients who do not respond well to preoperative preparation. Acute thyrotoxicosis, or a crisis, may occur after thyroidectomy or after other operations if a goiter is present. Therefore, operation to remove the goiter usually takes precedence.

Exophthalmic goiter in children (juvenile exophthalmic goiter) is a familiar disease. It manifests itself as in adults but is much more severe. However, it is often overlooked because it is apt to occur during the adolescent period of childhood and the symptoms are attributed to physiological adjustments.

Treatment.—The disease goes through cycles of remissions and exacerbations, and in the treatment an attempt is made to produce a remission. Lugol's solution or iodine in any form, even by inhalation, is given for ten days. This and rest should produce an amelioration of symptoms, though it does not produce a permanent remission or cure. This may usualy be accomplished by the surgical removal of four-fifths or more of the gland.

Thus the treatment of thyrotoxicosis associated with diffuse hyperplasia resolves itself into producing a remission which is permanent. To achieve this, three lines of treatment have been pursued: (1) medical, (2) irradiation, (3) surgical. Usually a combination of medical preparation followed by adequate surgery is the surest method of producing a permanent amelioration of the disease.

MEDICAL TREATMENT.—

a. Iodine does not make a goiter nontoxic but does produce a remission long enough for the surgeon to perform an operation. If given over a long period of time, its ability to produce a remission is decreased.

in (1) those patients who refuse surgery, (2) those patients who have had surgery with recurrence but without a discernible goiter, or who cannot tolerate further surgery, (3) severe thyrocardiacs, (4) patients in whom a satisfactory remission cannot be obtained with the drug, with Lugol's solution, or x-ray therapy, (5) perhaps those in whom malignant exophthalmos is feared, although there is a difference of opinion concerning thyroidectomy in such cases; (6) the adolescent age group which may be tried on small doses because of the frequency of recurrence after thyroidectomy and the problem of deciding how much thyroid to remove; they must be carefully watched; (7) severe mental cases.

Thiouracil and its allied products are contraindicated (a) in those who are hypersensitive to the drugs, (b) in blood dyscrasias of all kinds, (c) in infections where granulocytes are needed, (d) in severe, long-standing exophthalmos, (e) over long periods of time in adolescence, (f) in toxic nodular goiter because of the danger of cancer, (g) in severe liver, kidney, or adrenal disease, (h) in pregnancy, (i) in large cervical, retrosternal, retrovasal, or retrovisceral goiter because increase in size may produce pressure symptoms and make surgery more difficult.

c. Radioactive iodine may be used in severe hyperthyroidism because the radioactive material goes to the most actively proliferating and hyperplastic cells, resulting in their necroses and replacement with fibrous tissue. Reports indicate that there are few side effects when doses ranging from 50 to 60 mc. are employed. The results are encouraging.

d. Irradiation of the thyroid gland may induce a remission by causing a decrease in blood supply and subsequent fibrosis. This is variable and unpredictable but useful in those patients who will not submit to thyroidectomy or in whom surgery is inadvisable or has been ineffective. Before x-ray treatment is given, patients should be prepared as for thyroidectomy, and if surgery is to follow, the surgeon must expect to encounter many adhesions between the gland and its capsule.

e. Irradiation of the pituitary gland to depress the secretion of thyrotropin has been suggested. The poor results and the danger of injury which might interfere with other functions of the pituitary have limited its use.

f. Miscellaneous medical treatment includes those measures which will improve the patient's general condition and help bring about a remission. (1) the diet should be high in calories. We have kept a caloric requirement curve in our thyrotoxin patients; as a remissoin occurs, the caloric needs and desires fall preceptibly, in severe cases, from 8,000 to 10,000 calories to 2,000 calories per day. Vitamins must be supplied, especially B complex, D, and C. (2) The administration of calcium and phosphorus in small doses is indicated. (3) Digitalis should be administered where necessary. (4) Quinidine should be given in fibrillation.

the blood supply and cuts down activity of the thyroid by retaining the iodine in the thyroid gland and preventing its excessive and perhaps premature loss into the blood stream. Iodine does not neutralize anything in the blood.

If iodine and thyroid extract are administered at the same time to experimental animals and man, hyperthyroid symptoms occur just the same. The chemical effects of iodine are well known. Tryptic ferments are present in the tissues and are normally inhibited by the unsaturated fatty acids. These may be converted into saturated fatty acids, thereby releasing tryptic ferments for autolytic action. The histologic effects of iodine are not well known. Diseased tissues or very young cells take up more iodine than normal adult tissues. The cells become swollen.

b. Thiouracil, Thiobarbital, and propylthiouracil decrease the synthesis of thyroid hormone within the gland. The amount of iodine within the gland and the blood is greatly decreased. The thyroid is enlarged and more vascular. However, the histological picture remains about the same; that is, there is the high columnar type of cell, with infolding in the acini, which contain very little colloid. Apparently these changes remain in the face of a decrease in the metabolic rate and abolition of the symptoms of hyperthyroidism due to the continuation of an excess of thyrotropic hormone. Thiouracil is given in 0.6 to 0.8 Gm. doses daily for about two weeks; then it is decreased. Thiobarbital is said to have ten times the antithyroid effect of thiouracil and is therefore given in much smaller daily doses, 50 to 60 mg. Propyl thiouracil may be administered in daily amounts of 200 to 300 mg. It is the least toxic of this group. However, in all there must be careful daily supervision lest severe side reactions occur, particularly granulopenia. Although some observers prefer to treat primary hyperthyroidism with these drugs, our observations have led us to employ them for preoperative preparation only, except in such cases in which surgery is contraindicated because of severe cardiac failure, mental derangement, or other causes. The reason for this is the great number of recurrences following the medical treatment described above. Since preparation with these drugs is accompanied by thyroid enlargement and an increase in vascularity, we discontinue the drugs after remission is apparent and then give Lugol's solution for eight to ten days to cause a recession in the size and vascularity of the gland, thereby making surgery easier. In some cases both drugs are used for a two-week period prior surgery, but even here we use iodine alone during the final preparatory period, with sulfadiazine for twenty-four to forty-eight hours prior to operation, particularly in extreme thyrotoxicosis.

Propyl thiouracil is not advocated as a routine preparatory measure, being used chiefly in extreme cases of thyrotoxicosis, or in thyrocardiac cases, or in those patients who do not tolerate iodine and who require a long period of preparation. The drug is used for prolonged treatment

in (1) those patients who refuse surgery, (2) those patients who have had surgery with recurrence but without a discernible goiter, or who cannot tolerate further surgery, (3) severe thyrocardiacs, (4) patients in whom a satisfactory remission cannot be obtained with the drug, with Lugol's solution, or x-ray therapy, (5) perhaps those in whom malignant exophthalmos is feared, although there is a difference of opinion concerning thyroidectomy in such cases; (6) the adolescent age group which may be tried on small doses because of the frequency of recurrence after thyroidectomy and the problem of deciding how much thyroid to remove; they must be carefully watched; (7) severe mental cases.

Thiouracil and its allied products are contraindicated (a) in those who are hypersensitive to the drugs, (b) in blood dyscrasias of all kinds, (c) in infections where granulocytes are needed, (d) in severe, long-standing exophthalmos, (e) over long periods of time in adolescence, (f) in toxic nodular goiter because of the danger of cancer, (g) in severe liver, kidney, or adrenal disease, (h) in pregnancy, (i) in large cervical, retrosternal, retrovasal, or retrovisceral goiter because increase in size may produce pressure symptoms and make surgery more difficult.

c. Radioactive iodine may be used in severe hyperthyroidism because the radioactive material goes to the most actively proliferating and hyperplastic cells, resulting in their necroses and replacement with fibrous tissue. Reports indicate that there are few side effects when doses ranging from 50 to 60 mc. are employed. The results are encouraging.

d. Irradiation of the thyroid gland may induce a remission by causing a decrease in blood supply and subsequent fibrosis. This is variable and unpredictable but useful in those patients who will not submit to thyroidectomy or in whom surgery is inadvisable or has been ineffective. Before x-ray treatment is given, patients should be prepared as for thyroidectomy, and if surgery is to follow, the surgeon must expect to encounter many adhesions between the gland and its capsule.

e. Irradiation of the pituitary gland to depress *the secretion of* thyrotropin has been suggested. The poor results and the danger of injury which might interfere with other functions of the pituitary have limited its use.

f. Miscellaneous medical treatment includes those measures which will improve the patient's general condition and help bring about a remission. (1) the diet should be high in calories. We have kept a caloric requirement curve in our thyrotoxin patients; as a remissoin occurs, the caloric needs and desires fall preceptibly, in severe cases, from 8,000 to 10,000 calories to 2,000 calories per day. Vitamins must be supplied, especially B complex, D, and C. (2) The administration of calcium and phosphorus in small doses is indicated. (3) Digitalis should be administered where necessary. (4) Quinidine should be given in fibrillation.

(5) Thyrotoxicosis and diabetes produce a "symbiotic" picture because the thyroid speeds metabolism, demanding fuel, while the diabetes prevents proper utilization of glucose. Both diseases cause the patient to demand more and more food while he continues to lose weight rapidly. Therefore, insulin must be given along with propyl thiouracil and iodine. (6) Thyrotoxicosis and tuberculosis are a not uncommon combination; both diseases cause loss of weight and weakness. Iodine is not contraindicated in the preparation of the patient for surgery, which should be done as soon as feasible. (7) Children require special consideration. Surgery is deferred if possible because of the strong probability that a recurrence will take place. Furthermore, the surgeon does not like to remove too much gland since severe upsets in endocrine balance may ensue. This in itself ensures recurrence because the regenerative qualities of glandular tissue and especially the thyroid are greater in children than adults. If a remission can be maintained by propyl thiouracil, this should be done. If not, thyroidectomy which is less radical than for adults, is indicated.

SURGERY.—The treatment of choice in the great majority of cases is *thyroidectomy*. Two facts must be emphasized concerning thyroidectomy:

1. Thyroidectomy does not remove the cause of exophthalmic goiter, because it is not known definitely that the enlarged and hyperplastic thyroid gland is the determinant of the syndrome. It takes a link out of the chain of events. It is the best procedure to produce a permanent remission of symptoms, although it rests on an empirical basis.

2. Surgery is more apt to produce a permanent remission than any other method of treatment, although nature may accomplish this by atrophy (burning out of the disease). This is dangerous because heart, liver, brain, and other complications may occur during the waiting period, although some believe that organic heart disease is not caused by thyrotoxicosis.

Thyroidectomy should be performed after *adequate preparation.* Iodine does not always produce a remission. Remission is recognized by (1) the stabilization of the pulse, (2) the fall in the basal metabolic rate, (3) the stabilization of all emotional symptoms, (4) the gain in weight and strength. Other important circumstances which minimize the surgical risks are: the patient must have been given iodine for at least ten days, no fever or intercurrent infection must be present, the heart must be in compensation. Sometimes operations must be done in stages to avoid a "crisis." The first operation may consist of tying the superior thyroid arteries to produce a remission; then one or both lobes may be removed at the next procedure. This is not necessary as a rule.

Technique for Thyroidectomy:

This is done by making a "collar" incision in the neck, separating the "ribbon" muscles, and dissecting each lobe out of its capsule. The blood vessels are clamped and divided and the gland is partially removed, leaving the portion which lies next to the

trachea and esophagus (where the recurrent layngeal nerve lies) and the posterior part (where the parathyroids are situated). In toxic goiter almost the entire gland is removed. (See Fig. 398.)

Varations in technique: (1) Two-stage operations are done in very large goiters, doing one side at a time, because of the dangers inherent in removiing great pressure suddenly, with the consequent readjustments of organs and edema and interference with function as a result of these effects. Thus interference with breathing when both sides are removed is not only due to tracheal collapse but also to the enormous edema that comes from release of pressure. Thrombosis and embolism is also more apt to occur. (2) Two-stage operations in toxic goiter are now much less commonly done because remission can usually be produced by drugs. (3) Dissections may be done by first dividing the isthmus, then ligating the vessels and dissecting laterally, or first ligating the vessels and removing the lobe medially, but in every instance the blood supply is controlled by individual tying of each vessel by transfixed ligatures. (4) Identification of the recurrent laryngeal nerves is necessary when there is great displacement of structures and is done routinely by some surgeons. (5) The parathyroids are identified instead of being pushed aside with the capsule. (6) The ribbon muscles are divided transversely instead of being separated in large goiters.

Postoperative Complications of Thyroidectomy: The more common postoperative complications which may occur are (1) nerve injuries, (2) hemorrhage, (3) infection, (4) crisis, (5) parathyroid insufficiency, (6) respiratory difficulty.

Injury to the recurrent laryngeal nerve on one side results in homolateral paralysis with the vocal cord fixed in the midline. This results in a temporary change of voice, but in the presence of edema it may cause respiratory difficulty. When both nerves are injured, there is early loss of voice and then fixation in the midline of both vocal cords. This usually demands tracheotomy. But if oxygen is given, this may not be necessary, especially when the paralysis is temporary and the result of edema rather than injury. Great relief for bilateral cord paralysis is afforded by widening the space between the two vocal cords. This is done by dislocation and fixation of one of the arytenoid cartilages (King).

Hemorrhage is prevented by careful hemostasis and individual ligation of all vessels by transfixed ligatures. It is easily detected postoperatively when it appears on the dressings but is frequently overlooked when it is trapped in the thyroid bed (especially when large glands have been removed) and is unnoticed until respiratory stridor appears. The treatment is immediate surgery with reopening of the wound, removal of clots, and then, under Pentothal sodium or other anesthesia, careful ligation of the bleeding vessel.

Infection occurs rarely and when it occurs, it is usually the result of excessive postoperative bleeding. When tracheotomy or secondary surgery is necessary, the complication is more apt to occur. Penicillin and, if necessary, streptomycin are given and the pus evacuated when localization occurs.

Crisis has been discussed previously. Its treatment consists of (1) supplying sufficient oxygen to satisfy the increased metabolism; it is more effective in controlling the nervousness than sedatives; (2) replac-

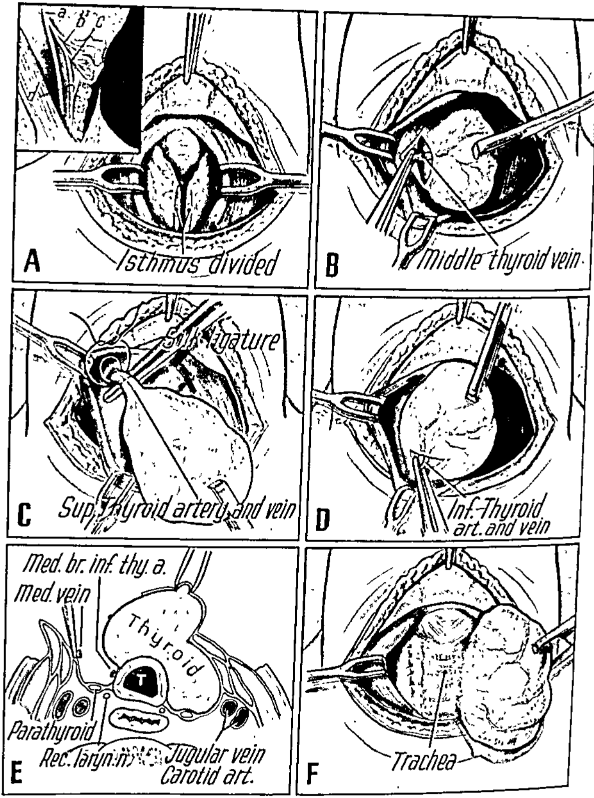

FIG. 398.—Thyroidectomy (subtotal).— *A.* A transverse incision has been made. The skin, subcutaneous tissue, and platysma have been divided. The ribbon muscles have been split longitudinally. The isthmus is divided between clamps, thereby converting the operation into two halves. Insert shows the related nerves: *a*, vagus, *b*, superior laryngeal nerve internal ramus), *c*, superior laryngeal nerve (external ramus); *d*, re-

(Continued on opposite page)

ing water and electrolytes which are lost by sweating, diarrhea, and vomiting; (3) supplying plasma and whole blood as indicated; (4) sulfadiazine and penicillin to combat infection, (5) glucose and vitamin B complex to protect the liver; (f) iodine and thiouracil should be continued. (g) Miscellaneous aids—lipocaic for the diarrhea, calcium gluconate to provide for the negative calcium balance, cold sponges for the excessively high fever.

Parathyroid insufficiency is rare and first manifests itself by numbness of the hands, general weakness, difficulty in focusing the eyes, and, later (after two to three days), carpopedal spasm. The blood calcium is lowered and inorganic phosphates raised. Treatment consists of large doses of calcium lactate orally or calcium gluconate intravenously. Dehydrotachysterol is given orally, 1 c.c. per day.

Respiratory difficulty may be caused by paralysis of the vocal cords, one or both, hemorrhage, infection, edema of the glottis, tracheal collapse, and tetany. If severe the condition may require tracheotomy before the cause is corrected in order to save life. All large goiters and substernal thyroids are removed under endotracheal anesthesia. At the conclusion of the operation the trachea is inspected with the bronchoscope and aspirated.

Sequelae to Thyroidectomy:

1. Hypothyroidism with or without myxedema occurs in a small group of patients. This late result may be treated with thyroid extract.

2. Recurrences are bound to occur since thyroidectomy is an operation which removes one of the manifestations of the disease and probably not its primary cause. The reasons for recurrence are (a) insufficient removal of the gland, (b) long duration of the disease before surgery, (c) persistence of social and economic problems, nervous shock. The treatment of recurrence is the treatment of the primary condition. However, propyl thiouracil with iodine may completely control the symptoms. X-ray treatment is occasionally effective. Operation may be necessary.

3. Persistent and progressive exophthalmus. This has been discussed under Physiology of the Thyroid. The thyroid-stimulating hormone is known to be an important factor in the formation of edema, including retrobulbar edema. Thyroxin is its antagonist, possessing de-

---

current laryngeal. *B.* The middle thyroid vein is identified, clamped, and dissected loose from the lateral aspect of the thyroid gland and tied with a silk ligature. *C.* The superior pole is identified and the superior thyroid artery and vein are doubly ligated with transfixed ligatures. *D.* The inferior pole is freed and the inferior thyroid artery and vein are divided and ligated Care is taken to preserve the parathyroid glands. *E.* Transverse section showing the thyroid removed from its bed and the recurrent laryngeal nerves, parathyroid glands, and other important structures in the neck. *F.* The completed operation on one side The lobe is out and the remaining thyroid tissue, if any is left, is reconstructed by interrupted chromic 00 catgut sutures. The process is then repeated on the opposite side and the ribbon muscles are closed with interrupted sutures and the skin is also closed with interrupted silk sutures Usually, one drain is left in place for twenty-four to forty-eight hours to take care of any exudate or transudate that might accumulate beneath the ribbon muscles.

Carcinoma of the thyroid if limited to one lobe requires total lobectomy and radical neck dissection as shown in Fig. 136 if diffuse total thyroidectomy must be done.

hydrating and diuretic properties. Yet the administration *of thyroxin to relieve the exophthalmus is not often successful. Recently the adreno-corticotropic hormone has been tried with promising results.*

Toxic adenoma, or so-called **nodular goiter,** occurs in older people. These adenomas are the "tombstones" of a previous hyperplasia; perhaps the disease started earlier in life as a diffuse hyperplasia and then involutional changes occurred, producing a diffuse adenomatous goiter with some reactivated areas of hypertrophy and hyperplasia. The process is probably as follows: hypertrophy and hyperplasia; involution, with fibrosis, making more *divisions of the acini into groups resembling adenomas (as in adenosis of the breasts in involution). Some believe that thyrotoxicosis* in such glands is due to hyperplasia and hypertrophy of "unaffected" portions of parenchyma. As a rule, both pictures are present: hyperplasia and so-called adenosis. There is no evidence that the cells of an adenoma produce an abnormal secretion. They do appear to be autonomous, producing a small amount of thyroxin and dicodotyrosine, and, therefore, should be removed along with the rest of functioning gland. Carcinoma occurs more frequently in the single adenoma (about 9 per cent) than in multinodular goiters (about 4 per cent). The symptoms are not as severe as in exophthalmic goiter. It is not seen *often in young people. Frequently it occurs after the menopause.* The *treatment is the same. Rest in bed, propyl thiouracil,* and iodine usually *bring about a remission; then thyroidectomy is done.* Long-continued use of propyl thiouracil is contraindicated *because of the threat* of malignancy.

INFECTIONS OF THE THYROID GLAND

Infection in the thyroid gland is known as *thyroiditis.* It may be *acute or chronic. The acute varieties are caused* by the streptococcus, *staphylococcus, pneumococcus, typhoid bacillus, and* paratyphoid bacillus. Usually the infection *reaches the gland by the* blood stream (pneumonia, typhoid fever, puerperal *sepsis, influenza) but may* occur after injuries or by contiguity or by the lymphatics (*pharyngitis,* tonsillitis, Ludwig's angina). The symptoms are those *of an acute* inflammation with pain, swelling, tenderness, and even redness *of the skin;* there are chills, fever, leucocytosis, cough, dyspnea, and dysphagia *in the* more severe types. Complications are perforation of an abscess *into the* larynx or trachea, descent into the mediastinum with mediastinitis, pyemia. *The treatment consists of rest in* bed, penicillin and/or streptomycin, drainage of an abscess if this occurs. Late sequelae include hypothyroidism and myxedema.

Chronic thyroiditis may result from *specific* infections such as syphilis, tuberculosis, actinomycosis, trypanosomiasis (Chagas' disease) or it *may be nonspecific,* such as Riedel's struma (struma fibrosa, woody or *ligneous* thyroiditis), struma lymphomatosa (Hashimoto's lymphoid *struma),* giant-cell thyroiditis (pseudotuberculous of de Quervain).

Lastly, there may be amyloid deposits in the thyroid which result from chronic infections elsewhere. The specific varieties do not differ in their pathological appearances from the diseases elsewhere in the body. The nonspecific types are peculiar in their reactions. *Riedel's* struma is rare (about 0.3 per cent of all thyroidectomies). The gland becomes enlarged and very hard and is fixed to the capsule, which also becomes thickened. Microscopic examination discloses diffuse fibrosis in and around the lobules. Later, hyaline replaces much of the parenchyma. The acini becomes smaller, colloid decreases and becomes granular and watery, the epithelial cells are tall columnar with eosinophilic cystoplasm or cuboidal; some are degenerated. Giant cells, plasma cells, lymphocytes, and definite lymph follicle formation are seen. Clinically there is much pain with dyspnea, dysphagia, and some dysphonia. The patient is nervous and has a goiter, but the basal metabolic rate is normal. When limited to one lobe, the diagnosis between this condition and carcinoma is difficult and cannot be made without histological study. Treatment consists in bilateral subtotal thyroidectomy. This is done to establish the diagnosis and relieve constriction. The latter is served best when the isthmus is removed. Radical removal is not necessary and it is dangerous because the adhesions prevent careful protection of the parathyroids of recurrent laryngeal nerves. Since much of the functioning gland is destroyed, hypothyroidism and myxedema may follow thyroidectomy.

Struma lymphomatosa (Hashimoto's lymphoid struma) consists of an enlarged thyroid due to excessive amounts of lymphoid tissue. This frequently leads to decreased thyroid function and myxedema. The gland is smooth and enlarged and is hard. The lymphoid infiltration is either in the form of single cells or well-defined follicles with germinal centers. Most of the epithelial cells are low or tall cuboidal; some are larger with pale eosinophilic cytoplasm and are identical with Hürthle cells. There is not much increase in connective tissue, and the blood supply is normal. Clinically it is usually seen in women at or near the menopause. The thyroid is diffusely enlarged and causes *some pressure symptoms*. The patients usually complain of symptoms which are more or less typical of myxedema. The basal metabolic rate is often subnormal. Treatment is usually conservative thyroidectomy to relieve pressure symptoms and above all to establish the diagnosis.

Giant-cell thyroiditis (pseudotuberculosis, de Quervain's) has been accepted as an entity by some pathologists who say it does not evolve into any other type. Others have not been willing to call it tuberculosis, although the granulation tissue closely resembles the tubercle formation of this disease, because tubercle bacilli have not been found, preferring to classify it rather as a stage or stages in the evolution of any varieties of chronic nonspecific thyroiditis. In favor of the latter concept is the fact that the typical pictures as described in Riedel's and Hashimoto's struma are the end results. Almost any combination of reaction to in-

jury by the stroma or the epithelium may be *encountered in the early stages.* Clinically there are *pain, dysphagia, and low-grade fever. The thyroid is diffusely enlarged and very tender.* The patients are weak and *nervous with tachycardia,* but the basal metabolic rate is usually *normal.* The *diagnosis is suspected* in many cases, and the disease may be *successfully treated with x-rays.* However, most surgeons prefer *limited thyroidectomy* to be sure of the diagnosis as well as to relieve *symptoms.*

Tumors and Cysts

The thyroid acini rarely become cystic. Follicular cysts are due to hemorrhage into the follicles. They contain some colloid, degenerated blood, and often cholesterol. The wall is made of the follicle and gland capsule which also has new connective tissue. Adenomatous cysts are due to necrosis in the center of an adenoma with subsequent softening and hemorrhage with blood pigment which is absorbed later, leaving clear fluid which is yellow in color. The wall is made of the adenoma capsule and neighboring compressed gland. Calcification often occurs.

Benign tumors are chiefly epithelial but may be made of any of the gland's constituents. The more common varieties are adenoma, fibroma, endothelioma, and plasmacytoma. Of this group the adenomas are of prime importance. They vary greatly in their microscopic appearance and in their function as previously described in this chapter.

Malignant tumors may be primary or metastatic. Primary carcinoma is more common than was formerly thought, occurring in about 3 per cent of surgically removed goiters. About 35 per cent of carcinomas are said to arise in pre-existing adenomas or in situ. Furthermore, they are more apt to occur in the nontoxic varieties, or at least hyperthyroidism or thyrotoxicosis is found in only about 3 per cent of thyroid malignancies. Since thiouracil produces changes of a hyperplastic nature, and since it also decreases function, it should be used cautiously in toxic adenoma. As we have seen in Chapter 15, an anaplastic tumor retains less of the normal function of its constituent cells as the degree of anaplasia advances, although hyperthyroidism may be an adjunct of malignant neoplasia. Various types of carcinoma are seen. Those of low grade are the malignant adenoma (probably the so-called benign metastasizing goiter belongs in this group), papillary carcinoma, and Hürthle-cell carcinoma. The moderately malignant is the adenocarcinoma, whereas the highly malignant are the small-cell carcinoma and the giant-cell (and spindle-cell) carcinoma. The microscopic picture is extremely variable in its architecture and cell types as well as its size, which may be extremely small or very large. However, if the epithelial growth invades the capsule or blood stream, it is malignant regardless of its microscopic appearance, and perhaps the reverse is true for benign tumors. *Clinically* the lesions are insidious and occur at any age, even in children; usually, however, they occur between 45 and 70 years. The

growths are discovered in what is thought to be a benign adenoma, or, because of the age, recent rapid growth of the goiter, and its firmness, the lesion may be suspected and found localized in its capsule. The more highly malignant carcinomas may be associated with symptoms of hyperthyroidism. This is not often the case in lower grade carcinomas. The explanation for this is not clear.

Another group will show early involvement of the recurrent laryngeal nerve or trachea, indicating extension. Late cases show x-ray evidence of bone metastasis. These already have lymph node involvement and often the lungs as well. There observations clearly show the routes of spread by both blood and lymph channels. Indeed, many of the so-called lateral aberrant thyroid tumors are lymph nodes filled with carcinoma from the homolateral lobe. *Treatment* consists of radical excision (total) of the lobe involved, together with nodes, along the carotid sheath and superior mediastinum in the less malignant types, whereas in late cases or the more malignant varieties, total thyroidectomy and removal of nodes on both sides is indicated. In all cases, x-ray treatment is given postoperatively. Radioactive iodine is useful for diagnosis and treatment of bone and other metastases. The prognosis in the early and less malignant types is excellent. In the diffuse varieties or in those of the less anaplastic types which have spread or in the mixed types, the prognosis is poor. Frequently the lone lesion leads to the diagnosis. In such cases the bone metastasis and the primary growth must be removed. X-ray treatment should follow.

Secondary malignancies of the thyroid are rare; however, hypernephromas, malignant melanomas, and carcinomas from the lungs and gastrointestinal tract have been reported. The explanation for this infrequency of metastasis is conjectural. Two theories have been advanced: (a) the rich arterial supply inhibits the lodgment of emboli in the gland and (b) chemical factors such as the high oxygen and high iodine content may be inhibitory factors in contrast to the low oxygen content in the liver. Neoplastic cells need very little oxygen.

Other malignancies include sarcomas (fibrosarcoma, endothelial sarcoma, lymphosarcoma, osteosarcoma, osteochondrosarcoma), melanoblastoma, Hodgkin's disease, and teratoma. These tumors are not diagnosed preoperatively as a rule. Wide excision with subsequent x-ray therapy is the treatment. If one lobe is involved as is often the case, total lobectomy and radical neck dissection as described in Chapter 16 should be done. If there is wider involvement, total thyroidectomy is indicated with radical neck dissection.

Insufficient Thyroid

Sometimes myxedema (cachexia strumipriva or thyreopriva) is caused by removing too much of the thyroid gland. The causes of insufficient thyroid secretion are congenital absence of the thyroid, infec-

tion, atrophy, atrophy with nodules which are functionless or cystic, large colloid goiter (due to pressure on the functioning cells), and postoperative deficiency. Not all hypothyroid states produce myxedema, which is probably a late phase. Myxedematous patients are edematous and torpid but may still be "nervous." The edema is not a true collection of fluid in the skin and subcutaneous tissues unless there is associated cardiac damage. The deposit of a semifluid albuminous substance (like the white of an egg—13 per cent protein) in the skin resembles edema. A pure carbohydrate diet diminishes it and a diet rich in protein increases it. This is thought to be due to the great osmotic pull of the tissue fluid and an increased permeability of the capillaries. (See Chapter 6.) Clinically the skin is dry and scaly, the hair falls out, the voice is coarse, and physical and mental activities are depressed. The basal metabolic rate is low, and the blood cholesterol is high. There is anemia (macrocytic) and achlorhydria in many cases. The patient thus becomes a hibernating animal.

Other changes are as follows: (1) The blood (decrease in plasma volume, increase in plasma protein, decrease in water and chlorides, and increase in bicarbonate); (2) circulation (decrease in minute volume and prolongation of circulation time—the opposite of hyperthyroidism; myxedematous changes in heart muscle); (3) edema (increase in *intracellular* water; in cardiac edema the increase in *intercellular*); (4) cerebrospinal fluid (increase in protein concentration—the opposite from hyperthyroidism); (5) calcium (excretion diminished and bones more dense—the opposite from hyperthyroidism); (6) menses (usually but not always prolonged—the opposite from hyperthyroidism); the treatment is the administration of thyroid extract.

The Parathyroid Glands

The parathyroid glands (epithelial bodies, parathymic glands, branchiogenic glands) are yellowish brown spherelike structures measuring about 10 to 20 mm. in diameter. From the dorsal part of pharyngeal pouches III and IV come the parathyroids which at the 20 mm. stage are detached along with the thymic and ultimo branchial bodies. The pair from the third pouches is drawn down by the migrating thymus to the lower level of the thyroid gland. The pair from the fourth pouches does not shift much and becomes the upper parathyroids. The two upper glands are, therefore, distinguished by the number IV and the two lower by the number III. Parathyroid IV is usually embedded in the tunica propria of the thyroid and lies on its posterior side at about its middle (lower level of cricoid cartilage), whereas parathyroid III lies in a similar position at the inferior part of the thyroid. The best guide to them is the anastomosing channel connecting the inferior and superior thyroid arteries which give off branches (superior or inferior or the anastomosing channel) to supply the glands. The normal parathyroid gland weighs 30 to 40 mg. and measures 6 to 7 mm. by 3 to 4 mm. by 1 to 2 mm. Variations do occur. The largest glands will measure 15 by 6 by 3 mm. and weigh up to 100 mg. Usually four glands are present (80 per cent); sometimes there are six or more (6 per cent) and sometimes less than four (14 per cent). When more than four are present, the supernumerary glands are situated in the immediate vicinity of the normal glands. When less than four are present at operation, there is likelihood that they have been missed. The gland is soft,

oval, and smooth. Its surface appears finely granular due to minute vessels beneath the capsule which enter at the hilus. Before puberty the color is coffee brown (due to chief cells). After puberty fat appears and the color is more of a yellowish-brown. Sometimes the gland lies in a pod of fat.

Congenital Anomalies of the Parathyroid Glands.—Sometimes in the course of development, the parathyroid primordia divide into many parts, giving rise to eight to twelve glands. All segments from the third pouch are numbered III and those from the fourth are numbered IV. Parathyroid IV may be found behind the pharynx and esophagus, in the fibrous tissue at the side of the larynx above the level of the thyroid gland, on its anterior surface behind any part of the homolateral lobe of the thyroid gland, or embedded in the thyroid substance (internal parathyroid). Parathyroid III may be found near the bifurcation of the common carotid, the sides of the trachea, behind any part of the homolateral lobe in the superior mediastinum, or in the thorax.

The normal parathyroid is made up of chief or principal cells up to puberty, which probably give rise to the oxyphile cells and the water-clear cells (wasserhelle). The latter are in some normal glands after puberty, whereas oxyphile cells are found in increasing numbers with age.

Physiology.—The parathyroid hormone has a great influence on the metabolism of calcium and phosphorus. Practically all of the body's *calcium* is in the form of a calcium phosphate calcium carbonate compound which is found in the matrix of bone and teeth and in body fluids. In the blood it is mostly in the form of calcium ions and calcium proteinate. When the calcium ion is low, the parathyroids are stimulated and regulate the level of calcium ions. Calcium is lost chiefly in the urine and feces and, to a lesser extent, in the lactating breast and placenta. Deficits are made up by the mobilization of calcium from the bones and perhaps the teeth—excess amounts are stored in these structures. Serum calcium remains constant (10 to 12 mg. per 100 c.c.).

Phosphorus is also found in bones and teeth just like calcium in a ratio of about 2 to 1 and in small amounts in body fluids. In the serum phosphorus an inorganic phosphate is found in amounts of 3 to 5 mg. per 100 c.c. (lower in adults, higher in children). Organic phosphates (phosphoprotein, phospholipids, various phosphate esters) liberate phosphate ions on hydrolysis, though these do not necessarily reach the bones.

In the absence of parathyroid secretion there is a decrease in phosphorus excreted in the urine, an increase in serum phosphorus level, a decrease in serum calcium and its diminished excretion in the urine. When parathyroid extract is given to a normal person, the reverse of the above is true.

A reciprocal relationship exists in the blood between calcium and phosphorus concentrations. Phosphate retention or injection causes a fall in serum calcium; conversely a rise in the calcium of the serum tends to depress the inorganic phosphorus of the blood. If too much parathyroid extract is administered to the experimental animal, "parathyroid poisoning" may ensue, with calcium deposits in the alveoli of the lungs and mucous membranes of the stomach and the kidneys. The sequence of events is a high level of serum calcium, an acute failure of the kidneys to excrete phosphates with a rise in serum phosphorus, and, at the same time, a high serum calcium and high serum phosphorus, a precipitation of calcium phosphates into the tissues, and chemical death (Albright).

Functional Derangements of the Parathyroid Glands

Hypoparathyroidism usually occurs as a result of the inadvertent removal of the parathyroids during thyroidectomy or, more commonly, through interference with their blood supply. Sometimes the condition occurs idiopathically or even more rarely due to congenital absence of most of the parathyroid tissue. Hypoparathyroidism causes a fall in the

serum calcium from 10 to 12 mg. per cent (normal) to 7 or 8 mg. per cent and a rise in serum phosphorus from 5 mg. per cent (normal) to 6 to 8 mg. per cent. No calcium is secreted in the urine. Clinically the syndrome known as *tetany* is exhibited. The chief symptoms are neuromuscular excitability which is dependent on hypocalcemia. This irritability is manifested as carpopedal spasm, Chvostek's sign (tapping of facial nerve, causing facial muscle spasm), Trousseau's sign (obstructing circulation of arm by cuff, causing hand spasm—accoucheur's hand), Erb's sign, increased excitability of muscles to galvanic current, laryngeal spasm, epileptiform seizures in long-standing cases. Cataracts, brain calcification, and increased bone density have been described. In the acute state there is rapid breathing (which intensifies the clinical symptoms due to alkalosis), high fever, tachycardia, salivation, and fibrillary twitchings, and death may ensue.

Differential diagnosis. Tetany may be caused by a number of conditions other than parathyroid deprivation. The following is a list of some of the more common causes. In some cases, a combination of causes may be causal.

1. Calcium deficiency
   a. Diminished intake or insufficient amounts as in pregnancy; excessive loss as in lactation (milk fever of cows)
   b. Lack of adequate absorption (sprue, celiac disease, diarrhea)
   c. Metabolic deficiency; defective utilization and assimilation of calcium due to lack of vitamin D, as in rickets and osteomalacia, "laryngismus stridulus" and spasmophilia in general.
   d. Abnormal control due to parathyroid deficiency
   e. Renal insufficiency with phosphorus retention and compensatory lowering of serum calcium.
2. Alkalosis (calcium normal, phosphorus increased)
   a. Chloride deficit from vomiting or continuous gastric suction
   b. Excessive bicarbonate from ingestion of soda bicarbonate
   c. Carbonic acid deficit from hyperventilation may explain "freezing at the sticks" in aviation, "cramps" in cold water swimming
3. Miscellaneous causes (experimental)
   a. Magnesium deficiency
   b. Intravenous injection of alkaline phosphate (not acid phosphate)

The treatment of parathyroid tetany includes the administration of dehydrotachysterol (like vitamin D, it is a photochemical derivative of ergosterol), about 3 c.c. per day, until calcium appears in the urine; calcium and vitamin D; a diet rich in calcium and low in phosphorus. Parathyroid extract is available and effective for short periods.

Other types of tetany are treated by first correcting the cause and then giving calcium if there is a deficiency in the form of gluconate or lactate. Alkalosis tetany demands relief of hypochloremia, increased CO_2, or administration of acidifying salts such as ammonium chloride, depending on the cause (see Chapter 12).

Hyperparathyroidism may be primary (more parathyroid hormone produced than needed) or secondary (more parathyroid hormone than normal produced for compensatory purposes as in rickets, osteomalacia, and renal insufficiency). The *causes* of hyperparathyroidism are (1) neoplasms (adenoma usually and rarely carcinoma) and (2) hypertrophy and hyperplasia.

Adenomas may be present in one (usually) or more of the parathyroids. The lower glands are the seat of adenomas in about 80 per cent of the reported cases. In 10 per cent the parathyroids were in an abnormal portion (60 per cent of this group were in the mediastinum, 30 per cent in the substance of the thyroid, and 10 per cent behind the esophagus). The size varies from 10 to 3,500 times the normal, but the average will be about 3 by 2 by 2 cm., weighing about 7 grams. The only way the surgeon can distinguish between adenoma and hyperplasia grossly is by the fact that in the latter instance all glands will be uniformly enlarged. Histologically adenomas present a mixture of chief, water-clear, and oxyphilic cells together with transitions between these forms.

Hypertrophy and Hyperplasia.—In hypertrophy the amount of parathyroid tissue is greatly increased due to an enormous increase in the volume of the normal cell. In hyperplasia there is a uniform replacement of the normal gland with large-sized water-clear cells.

Abnormal Physiology.—The serum calcium is high (up to 18 mg.). Serum calcium exists in two forms: (1) nondiffusible, which is bound to serum protein (chiefly albumin) and constitutes about 45 per cent of the total serum calcium; that is, about 4-5 mg. per 100 c.c.; (2) diffusible, which exists in an ionized form and represents about 55 per cent of the serum calcium (5-7 mg. per 100 c.c.). Because of the large amount of nondiffusible calcium which is normally present, a serum protein determination should be done. If this is low, the total serum calcium may be normal, yet the calcium ions which are high in hyperparathyroidism would be greatly increased. Serum phosphorus is low (3 mg. or less unless renal damage is present). Calcium and phosphorus excreted in the urine are both increased. If the hyperparathyroidism leads to bone disease (which is not always the case if the patient gets enough calcium in his diet), the phosphatase level is increased (20 to 30 Bodansky units).

Symptoms and signs are usually of three general variieties: (a) those due to bone disease—*osteitis, fibrosa cystica generalisata,* (b) those due to renal disease; (c) those due to the hypercalcemia.

Bone disease is seen as an increased amount of absorption with an increase in the number of osteoclasts. Bones are easily injured, but the reparative powers are unimpaired and osteoblasts are plentiful. With the increase in osteoblastic activity, there is an increase in serum phosphatase which, in the absence of hepatic disease, is evidence of bone building. Bone matrix laid down around the osteoblasts is calcified, and

there is an increased amount of stroma in the bone marrow with fibrosis. Solid or semisolid tumors are sometimes seen which are made up of osteoblasts and osteoclasts; these are known as benign *giant-cell tumors* or osteoclastomas. In the jaw this kind of tumor is known as epulis. The bone cysts filed with fluid and lined by fibrous tissue are due to secondary degenerative changes and may be found anywhere in the body—generalized osteitis fibrosa cystica (von Recklinghausen's). (See Chapter 21.) Spontaneous fractures and vague pains in the back or legs are often the first manifestations of the disease. The bone disease must be differentiated from osteoporosis due to other causes such as: osteomalacia, osteitis deformans (Paget's disease), multiple myeloma, metastatic malignant neoplasms, osteitis fibrosa disseminata (polyostitic fibrous dysphasia), a regional disease with increased density and porosity occurring in young females, xanthomatosis, Gaucher's disease, lymphoma, hemangioendothelioma, osteogenesis imperfecta (osteopsathyrosis), chronic radium poisoning. The diagnosis is established by x-ray studies, biopsy, and blood and urine studies.

Rickets and *osteomalacia* are due to vitamin D deficiency and interference of absorption of calcium from the gastrointestinal tract. This causes a low serum calcium which in turn stimulates the parathyroids to increased activity with the production of more hormone which leads to a decrease in serum phosphorus. The glands hypertrophy to meet the demands. The final result is a normal serum calcium and a low phosphorus level. If the parathyroids do not hypertrophy, the calcium is low and the phosphorus normal; if both values are low, the glands have not kept pace with the hypocalcemia. This type of hyperparathyroidism is *secondary* and not primary

Renal disease is due chiefly to the excretion of increased amounts of calcium and phosphates in the urine with the formation of calcium phosphate or calcium oxalate *calculi*. Calcium salts may be deposited in the pyramids (nephrocalcinosis), leading to renal insufficiency. Polyuria and polydipsia are as common in hyperparathyroidism as in diabetes mellitus and insipidus.

Renal insufficiency may give rise to *secondary* hyperparathyroidism, "renal rickets," or may result from primary hyperthyroidism. In the former there is retention of nonprotein nitrogen and also retention of serum phosphorus with tendency toward low serum calcium and hyperplasia of the parathyroids to correct the low calcium level. In some cases it may be accompanied by osteitis fibrosa cystica, "renal osteitis fibrosa cystica"—Albright. The secondary hyperparathyroidism probably prevents tetany in these cases.

The renal damage resulting from parathyroid adenoma and hyperparathyroidism leads to phosphate retention and low calcium, and the body demands for parathyroid hormone may equal the increased amount secreted by the secreting adenoma. Thus in all types of hyperparathyroidism with renal insufficiency less parathyroid tissue is removed.

Hypercalcemia induces decreased neuromuscular excitability, decreased blood coagulation time, fall in inorganic phosphorus, and high plasma phosphatase increase in urinary calcium. Many diseases may be confused with hyperparathyroidism; namely, acute osteoporosis, hypervitaminosis D, sarcoidosis, myelomatosis, carcinomatosis with extensive bone involvement, polyostotic fibrous dysplasia, renal osteitis fibrosa generalisata, and osteomalacia. When associated with hypercalcemia and renal damage, differential diagnosis may be difficult. Hypercalcemia without hypercalciuria or decrease is serum alkaline phosphatase, and accompanied by calcinosis and renal insufficiency, may result from prolonged intake of milk and alkali.

The treatment for primary hyperparathyroidism is the removal of the adenoma or adenomas or in the secondary varieties the removal of some of the excessive parathyroid tissue. A few rules to follow in parathyroidectomy as follows: (1) A methodical search should be made beginning with the left superior, then the left inferior, the lower levels of the inferior thyroid veins, then the other side. (2) Biopsy is not taken until all parathyroid tissue has been inspected. (3) Normal parathyroid should not be removed because it will not help the condition and, if later on, adenoma is found and removed, tetany may occur. (4) If a parathyroid is not found in the normal position, further search is necessary in the region of the missing gland. If it is the superior, search is made from the lipoid bone to below the thyroid (all around the superior pole, between the thyroid and trachea, trachea and esophagus, behind the esophagus around the carotid). If the inferior is missing, one must *search the anterior superior mediastinum and posterior superior mediastinum* all along the inferior vessels. If there is none found and if the thyroid is nodular, a lobe of this gland may be removed in the hope that the parathyroid is embedded. (5) Anterior superior mediastinal exploration should not be done at the same time that the neck is explored. If the missing gland and adenoma have not been found, several weeks should elapse to see whether the patient is improved; then exploration should be done by splitting the sternum. Even thymectomy may be indicated. (6) Complete removal of the adenoma is indicated because of the possibility of carcinoma. (7) Sometimes postoperaive tetany ensues for a while. However, in the presence of hyperparathyroidism, the diet should be low in calcium lest "parathyroid poisoning" occur.

Primary carcinoma of the parathyroid is rare. It grows expansively and metastasizes to the regional nodes and lungs. It may or may not be endocrinologically active, usually not. The diagnosis is very difficult in the early stages and can only be established by biopsy. However, these glands are apt to be more firm, adherent, and invasive. Therefore, all parathyroid tumors should be widely removed, and if microscopic study shows any malignant change, lymph node biopsies should be taken. If metastases are present, a wide dissection of the involved side of the neck is indicated. X-ray treatment appears to be ineffectual.

The Adrenal Glands

The adrenal or suprarenal glands lie at the upper pole of the kidneys. The two glands together weigh about 10 to 12 grams. They are richly supplied with blood by the superior suprarenal artery (from the inferior phrenic branch of the aorta), the middle suprarenal (directly from the aorta), and the inferior suprarenal (from the renal artery). The capsule contains the arteries, a nerve plexus, and some collections of sympathetic ganglion cells and sends a fine network of reticular fibers into the cortex, along with the capillaries. The capillaries empty into anastomosing sinusoidal blood spaces, which in turn drain into the central veins, which unite and emerge as a single vein. This empties into the inferior vena cava (right) and the renal vein (left). The sinusoids in the cortex are lined with endothelial cells and macrophages. About twenty to thirty nerves enter each gland, most of them coming from the celiac sympathetic plexus, some from the greater splanchnics, and a few from the vagus.

The glands are divided into a cortex and medulla. The latter contains chromaffin and sympathetic ganglion cells. The cortex develops from the mesoderm of the Wolffian ridge; the medulla from ectoderm, which gives rise to the sympathetic ganglion cells.

The medulla elaborates adrenaline (epinephrine, adrenin, or suprarenin). The effects initate those of stimulation of the sympathetic nervous system and are, therefore, said to be sympathomimetic. The sympathetic fibers liberating an adrenaline-like substance (sympathin) are said to be adrenergic, that is, postganglionic fibers to the heart causing cardioacceleration and to blood vessels causing vasoconstriction, etc., as distinguished from those fibers of the parasympathetic and sympathetic (to sweat glands, vasodilators, and to adrenal medulla) which liberate acetylcholine and are called cholinergic (see Chapter 18). Some of the more important actions of adrenaline are: (1) Blood vessels are affected in different ways, depending on their location. Arterioles and capillaries of the skin, mucous membranes, splanchnic viscera (except the intestinal vessels) are constricted; the vessels of skeletal muscles, the coronaries, and the intestines are dilated. (2) The heart is slowed by adrenaline, but since this effect is produced through the carotid sinus and aortic nerves as a result of elevated blood pressure, it cannot occur where there is a great loss of blood volume. (3) Plain muscle is inhibited (stomach, intestine, bronchiole, wall of urinary bladder) so that intestinal movement is inhibited, bronchioles are dilated, and the urinary bladder does not contract, whereas the trigone and sphincter do sometimes, causing urinary retention. Muscles of the gall bladder, ureter, and pyloric, ileocolic, and anal sphincters are excited. Skeletal muscle shows a delay in fatigue. (4) Respirations are increased in rate and depth. (5) Carbohydrate metabolism is increased and hyperglycemia and glycosuria result due to mobilization of sugar from the liver, decreasing its glycogen as well as that of muscles. (6) General metabolism is also increased. The adrenal medulla is not essential to life. Dibenamine hydrochloride (dibenzyl beta-chloroethylamine hydrochloride) is an adrenolytic drug blocking the effects of adrenaline and is therefore useful in the diagnosis and treatment of diseases of the medulla producing excessive amounts of adrenaline, such as the pheochromocytomas. Any of the benzodioxan derivatives are useful as indicators of excess epinephrine since they lower the blood pressure due to this hormone but do not lower it in essential hypertension. The injection of .05 mg. histamine intravenously will precipitate a hypertension crisis in pheochromocytoma perhaps due to the vasodilation and increased amounts of adrenaline thrown into the circulation.

The emergency theory of epinephrine secretion holds that since it is secreted in greater amounts during nervous excitation, it is needed to make the body more efficient (in energy spending) during such crises (Cannon). The tonus theory assumes that the sympathetic nerve endings are being stimulated continuously, thus keeping up

the vascular tone and the blood pressure. Epinephrine is secreted in small quantities and is rapidly destroyed in the blood stream.

The cortex is necessary to life. If most of it is destroyed, as in Addison's disease, death follows unless prevented by replacement (cortin). Completely adrenalectomized animals have loss of appetite, vomiting, diarrhea, weight loss, weakness, low body temperature, and low basal metabolic rate. They may be maintained without any other medication for months if given large amounts of salt, that is, NaCl, or sodium citrate. Some observers believe that this is more important than the administration of cortin in Addison's disease. With the sodium ion decreasing in the blood because of its increased excretion through the kidneys, there is commonly also a drop in bicarbonate ion, as well as in the chloride ion. Because of this, Wilder and Allers have felt that a sodium salt without a fixed acid radical should be administered in addiiton to the sodium chloride. Therefore, sodium citrate or sodium bicarbonate is given with the sodium chloride. One-tenth of the gland is sufficient to maintain life in experimental animals. During adrenal insufficiency there is an increased excretion of sodium by the kidneys, and there are increased amounts of potassium and nonprotein nitrogen in the blood.

Crystalline compounds extracted from the cortex are oxygenated steroid derivatives. Of the identified steroids is one with the property of male sex hormone (dehydroisoandrosterone), a beta ketosteroid that is closely related to the male sex hormone androsterone, an alpha ketosteroid. Also female sex hormones are secreted—estrone and progesterone. Androgens and estrogens are found in the urine of small children of both sexes. In normal adults the estrogens decrease in males and the androgens decrease in females. Other steroids have effects on salt and water metabolism, permeability of the capillaries, regulation of carbohydrate, fat and protein metabolism, renal function, capacity of muscle response, and resistance to stress. Desoxycorticosterone is useful in deficiency states but has no demonstrable effect upon carbohydrate metabolism; that is, the hypoglycemia seen in cortical atrophy or destruction by granuloma or neoplasia.

Active compounds isolated from the adrenal cortex and their effects are listed in Table XXVII.

TABLE XXVII

(Slightly modified from Walters and Sprague: J. A. M. A., 1949.)

EFFECT	COMPOUND
Salt and water	Desoxycorticosterone
Carbohydrate, protein metabolism; antiarthritic?	17-hydroxy-11-dehydrocorticosterone (Compound E)
	11 dehydrocorticosterone (Compound B)
	17-hydroxycorticosterone (Compound F)
Fat metabolism	11 dehydrocorticosterone (Compound A)
	Corticosterone (Compound B)
Androgenic effect	Androstenedione
	11-hydroxy iso-androsterone
	17-hydroxyprogesterone
Estrogenic effect	Estrone
Progestational effect	Progesterone

The adrenal cortex is related to the sex glands and thyroid as well as the pituitary. The cortex hypertrophies during pregnancy. Hypertrophy of the cortex causes sexual precocity in children and virilism in girls. There is a very close relationship between the thyroid and the adrenals. Hypophysectomy causes atrophy of the cortex, and injection of hypophyseal extracts causes an increase in the mitoses in the glomerular and outer fascicular zones. The cortex is rich in ascorbic acid (vitamin C).

Higgins and Scott have performed bilateral adrenalectomy in prostatic cancer in four patients who survived 1½, 1½, 11, and 116 days with adequate therapy of adrenal cortical extract desoxycorticosterone acetate and plasma transfusions given frequently

The Adrenal Glands

The adrenal or suprarenal glands lie at the upper pole of the kidneys. The two glands together weigh about 10 to 12 grams. They are richly supplied with blood by the superior suprarenal artery (from the inferior phrenic branch of the aorta), the middle suprarenal (directly from the aorta), and the inferior suprarenal (from the renal artery). The capsule contains the arteries, a nerve plexus, and some collections of sympathetic ganglion cells and sends a fine network of reticular fibers into the cortex, along with the capillaries. The capillaries empty into anastomosing sinusoidal blood spaces, which in turn drain into the central veins, which unite and emerge as a single vein. This empties into the inferior vena cava (right) and the renal vein (left). The sinusoids in the cortex are lined with endothelial cells and macrophages. About twenty to thirty nerves enter each gland, most of them coming from the celiac sympathetic plexus, some from the greater splanchnics, and a few from the vagus.

The glands are divided into a cortex and medulla. The latter contains chromaffin and sympathetic ganglion cells. The cortex develops from the mesoderm of the Wolffian ridge; the medulla from ectoderm, which gives rise to the sympathetic ganglion cells.

The medulla elaborates adrenaline (epinephrine, adrenin, or suprarenin). The effects imitate those of stimulation of the sympathetic nervous system and are, therefore, said to be sympathomimetic. The sympathetic fibers liberating an adrenaline-like substance (sympathin) are said to be adrenergic, that is, postganglionic fibers to the heart causing cardioacceleration and to blood vessels causing vasoconstriction, etc., as distinguished from those fibers of the parasympathetic and sympathetic (to sweat glands, vasodilators, and to adrenal medulla) which liberate acetylcholine and are called cholinergic (see Chapter 18). Some of the more important actions of adrenaline are: (1) Blood vessels are affected in different ways, depending on their location. Arterioles and capillaries of the skin, mucous membranes, splanchnic viscera (except the intestinal vessels) are constricted; the vessels of skeletal muscles, the coronaries, and the intestines are dilated. (2) The heart is slowed by adrenaline, but since this effect is produced through the carotid sinus and aortic nerves as a result of elevated blood pressure, it cannot occur where there is a great loss of blood volume. (3) Plain muscle is inhibited (stomach, intestine, bronchiole, wall of urinary bladder) so that intestinal movement is inhibited, bronchioles are dilated, and the urinary bladder does not contract, whereas the trigone and sphincter do sometimes, causing urinary retention. Muscles of the gall bladder, ureter, and pyloric, ileocolic, and anal sphincters are excited. Skeletal muscle shows a delay in fatigue. (4) Respirations are increased in rate and depth. (5) Carbohydrate metabolism is increased and hyperglycemia and glycosuria result due to mobilization of sugar from the liver, decreasing its glycogen as well as that of muscles. (6) General metabolism is also increased. The adrenal medulla is not essential to life. Dibenamine hydrochloride (dibenzyl-beta chloroethylamine hydrochloride) is an adrenolytic drug blocking the effects of adrenaline and is therefore useful in the diagnosis and treatment of diseases of the medulla producing excessive amounts of adrenaline, such as the pheochromocytomas. Any of the benzodioxan derivatives are useful as indicators of excess epinephrine since they lower the blood pressure due to this hormone but do not lower it in essential hypertension. The injection of .05 mg. histamine intravenously will precipitate a hypertension crisis in pheochromocytoma perhaps due to the vasodilation and increased amounts of adrenaline thrown into the circulation.

The emergency theory of epinephrine secretion holds that since it is secreted in greater amounts during nervous excitation, it is needed to make the body more efficient (in energy spending) during such crises (Cannon). The tonus theory assumes that the sympathetic nerve endings are being stimulated continuously, thus keeping up

of high fever, rapid respiration, purpura, convulsions, cyanosis, vomiting, and diarrhea the adrenals may be suspected.

Inflammations of the adrenals may be due to syphilis or tuberculosis, giving rise to Addison's disease if extensive. In the presence of severe septicemia from any cause but particularly from the meningococcus, hemorrhagic phenomena occur which include hemorrhage into the adrenal as well as the skin and other organs. The symptoms and signs resemble those of hemorrhage in the adrenals of infants and is known as the Waterhouse-Friderichsen syndrome. The symptoms are probably due to shock and overwhelming sepsis rather than to adrenal insufficiency.

Tumors of the Adrenal Glands

Neoplasms of the *adrenals* may be primary or secondary. The latter are very rare and occur as a result of metastases or invasion from the adjacent organs. Primary neoplasms may be derived from the various constituent tissues of the adrenal such as connective tissue (fibroma), fat (lipoma), nerves (neuroma, neurofibroma), muscle (myoma), blood vessels (hemangioma), lymph vessels (lymphangioma), and malignant tumors such as sarcoma and melanoma.

A second group of tumors peculiar to the ectodermal sympathetic nerve system are derived from the *medulla* of the gland. They are classified according to the type cell from which they are derived: (1) sympathoblastomas from embryonic cells; (2) ganglioneuromas from mature ganglion cells; and (3) pheochromocytomas from pheochromocytes or paragangliomas from mature chromaffin cells which are functionally active and which produce epinephrine. A third group of tumors originate from the adrenal cortex and are hyperplasias, adenomas, or carcinomas. They may occur (1) with no recognizable hormonal changes, (2) from changes due to hormonal influence or secondary sex characters (adrenogenital), (3) from changes due to hormonal influence on various metabolic processes (adrenometabolic tumors) (Cushing's syndrome), (4) from a mixture of (2) and (3); cortical tumors may occur in accessory adrenals (Marchand's bodies) which may be in the perirenal fascia or retroperitoneal fascia within the broad ligament attached to the ovary or testes.

Benign and malignant tumors from the framework of the adrenal are difficult to diagnose and are apt to be missed unless they are large enough to be felt. Malignant neoplasms may give no localizing signs or symptoms. A gradual loss of weight and strength, a progressive unaccountable anemia, and loss of appetite make one think of malignancy. In the absence of any demonstrable change, the retroperitoneal space with its adrenal may be the hidden site of the cancer.

Tumors of the Medulla.—The sympathogonia or the primitive cell of the sympathetic nervous system may differentiate into the sympathoblast, the sympathetic ganglion cells, and also the chromaffin cells (pheochromoblast and pheochromocyte). The whole group of tumors from

in large amounts. Inadequate therapy resulted in hyperpyrexia, hypotension, and addisonian pigmentation. There were also a reduction of 17-ketosteroids and urinary androgens as measured by the cock's comb growth technic, but a continued excretion of small amounts of estrogen.

Operations such as denervation, unilateral extirpation, bilateral subtotal resection, and irradiation of the adrenals have been done for such conditions as hypertension and other circulatory disorders, diabetes, peptic ulcer, hirsutism in the female, epilepsy, hyperthyroidism, Raynaud's disease, neurocirculatory asthenia, etc. The rationale is not clear, and the results in most cases are questionable.

Tests of Adrenal Cortical Function

The *ketosteroids* have been used as indicators of adrenal gland activity. Of those steroids found in the adrenal, those which have a keto group on carbon 3 are the ones which possess adrenal cortical function. The adrenal ketosteroids that have action on sexual characteristics are those with a distinctive side chain on carbon 17. These are known as the 17-ketosteroids and are derived from the adrenal cortex and the gonads, two-thirds from the former and one-third from the latter. The normal amount in a twenty-four hour specimen of urine for a child up to 10 years of age is 1 mg.; at puberty, in the male, 10 to 20 mg.; in the female, 9 to 15 mg. If the 17-ketosteroids is 30 mg. or over, the lesion is probably adrenocortical carcinoma. If above normal but under 30 mg., a diffuse or nodular hyperplasia of the adrenal is present. If there is evidence of associated hyperpituitarism, it is probably a hyperplasia. In the presence of a feminizing tumor of the male adrenal cortex, there is no increase in the 17-ketosteroids but estrogenic substances are increased.

The 17 ketosteroids have been divided into alpha and beta fractions, and data have been collected upon the relative importance of the beta fraction which is greatly increased in adrenal cortical adenoma or carcinoma. This is a great help in those cases of masculinizing changes. The 11-oxycorticosteroids with a 17-hydroxyl group are an index of the rate of secretion of adrenal cortical hormones influencing protein and carbohydrate metabolism. They are excreted in large amounts in patients suffering from burns, Cushing's syndrome, and adrenal cortical virulism.

Pituitary adrenocorticotropic hormone, when injected into normal persons (25 mg.), causes a decrease in circulating eosinophiles and a rise in excretion of uric acid. Patients with adrenal cortical disease fail to show these changes. Expressed as a ratio between uric acid and creatinine, a decrease of 50 per cent or more indicates adequate adrenal cortical reserve.

Sex homones. In the adrenogenital syndrome an excess amount of male hormones (androgens) has its effect on the secondary sex organs as shown in the masculinization of females (adults and children) and male maturity in male children. Hyperplasia and tumor cells may elaborate excessive amounts of steroids with female hormone activity (estrogens), causing femininism in males and early maturity in females.

The use of *air insufflation* in the perirenal area for x-ray studies and the retrograde pyelogram may help find a tumor of the adrenal (medulla or cortex) which cannot be felt. Thus with a careful clinical study of symptoms and signs in addition to the demonstration of a tumor in the region of the adrenal gland, a diagnosis may be made. The tests for function will help to differentiate the particular type of disease or neoplasm of the adrenal.

Diseases and Injuries of the Adrenal Glands

Injuries to the adrenal gland occur at birth and rarely in adult life. At birth, hemorrhage into the adrenal may result in death and the diagnosis is made at autopsy in almost every case, although in the presence

photungstic and acid hematoxylin stain. The growths are usually seen in the first few years of life and are often not recognized until metastases have occurred. Sometimes a tumor may be felt in the loin before metastases have occurred. In such instances a Wilms' tumor is also thought of. Intravenous pyelograms and even retrograde pyelograms may help make the diagnosis. Since the adrenal is outside and the Wilms' tumor inside the kidney, a greater distortion of the kidney, pelvis, and calyces is seen in the latter. In either case the treatment is complete removal of the adrenal and kidney (which may be invaded) through a transabdominal approach which is the best method of treatment. This permits preliminary ligation of the blood vessels before handling so that malignant cells may not be dislodged. The prognosis is poor and the cells are not radiosensitive.

The *ganglioneuromas* and *neurocytomas* arise from the adrenals, ganglions, Zuckerkandl's organ, coccygeal and carotid body. They vary in malignancy but are usually benign. They are symptomless and are discovered accidentally during physical examination. They should be removed surgically.

Pheochromocytoma (chromaffinoma) are hormonal tumors of the adrenal medulla. They arise in chromaffin cells anywhere, and though usually single, they may be multiple. Microscopically the tumors show excess of pheochrome cells with increase of interstitial stroma and ganglion cells. They may be benign or malignant. Clinically the neoplasms are seen in young or middle adult life, but no age is immune. The usual symptom complex is described as paroxysmal hypertension which is thought to be due to a temporary release of excessive amounts of epinephrine; in severe and sustained release of pressor substance, the symptoms resemble essential hypertension. The symptoms come on after excitement or physical stress or may at times be produced by massage of the tumor. Attacks start with palpitation, headache, epigastric pain, coldness of the hands and feet, and a fear of impending death. The systolic and diastolic blood pressures are increased but fall to normal after the attack. After the attack there is fatigue, perspiration, and exhaustion. Blood and urine tests show hyperglycemia and glycosuria which do not respond to the usual treatment of diabetes. The diagnosis depends on the history and clinical findings; additional evidence includes a mass which is often felt; symptoms and signs of pheochrome syndrome in so-called essential hypertension; reduction of blood pressure by an epinephrine antagonist such as benzodioxan; precipitation of an attack by histamine and evidence of the tumor if it cannot be felt by pyelography or scout films or perirenal air insufflation. The syndrome must be differentiated from hyperthyroidism, diabetes, and psychoneurosis. The treatment is surgical removal by the transabdominal route. This permits exploration for other unrecognized tumors and, more important, it allows for preliminary ligation of all vessels before manipulation is started. If the diagnosis of adrenal tumor is certain, a lumbar

the sympathogoma are the most common neoplasms of the abdominal cavity in childhood. There are four types: (1) sympathogonioma from the embryonic sympathiogonia—extremely malignant; (2) sympathoblastoma or neuroblastoma sympatheticum, the most common of the group; also highly malignant; (3) the benign ganglioneuroma; and (4) the chromaffinoma or pheochromocytoma which is an adrenaline secreting tumor.

Fig. 399.—Carcinoma of the adrenal cortex. Woman aged 33 years. Note the virilism and hirsutism.

The *sympathoblastomas* occur in either sex and may arise not only from the adrenal glands, but also from the retroperitoneal or retropleural sympathetic ganglion and even the cervical region. Their rapid growth and rapid spread by the lymphatics and blood stream permits early invasion of the liver (Pepper syndrome), the skull and orbits (Hutchinson syndrome), or any organ or tissue in the body. The microscopic picture is one of a highly cellular and infiltrative neoplasm with cells not unlike large lymphocytes forming occasional rosettes, with the nuclei peripherally placed. Neurofibrils can be seen with the phos-

Hormonal tumors (Cahill) are divided into those which produce changes due to (1) excess androgens—in a girl toward adult masculinity; in a boy toward adult masculinity; (2) excess estrogens—in a man toward femininity. Androgenic tumors in a girl cause changes described as pseudohermaphroditism. Usually the cause is bilateral hypertrophy of the adrenal cortex rather than unilateral tumor. There is a hypertrophy of the clitoris, hair on the genitals, deep voice, good muscular development. Older girls do not menstruate, have hirsutism, a deep voice, and early closure of the epiphyses. *In women there is a suppression of*

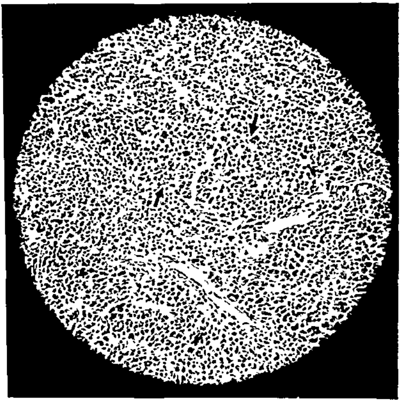

Fig. 401 —Carcinoma of the adrenal cortex. Arrows point to an area showing neoplastic cells.

female characteristics and the appearance of male secondary sex patterns: hirsutism, enlarged clitoris, cessation of menses, acne, low voice, recession of breasts, labia, and uterus. These changes are known as the adrenogenital syndrome. Laboratory studies show increase of androgens in the urine and also the 17-ketosteroids. *X-ray* with *insufflation* of air in the perirenal space may reveal the tumor, although this is not an innocuous procedure. The tumors may be adenomas or adenocarcinomas. The excessive granular-cell cytoplasm has given the name of "granular-cell tumors" to this group. The treatment is surgical extirpation if tumor is present and the results are usually good.

incision may be used. This may be bilateral if the diseased gland is not found on the first side exposed. If exposure is inadequate through the ordinary incision used for operations on the kidney, the eleventh and twelfth ribs may be resected. Still more room may be obtained by resecting a portion of the tenth rib. The pleura may be pushed forward and the diaphragm incised. In this way, the pleural cavity is not opened. After removal there is an immediate fall in blood pressure, requiring the use of epinephrine. Recurrences are due to incomplete removal, the presence of other tumors, and functionating metastases.

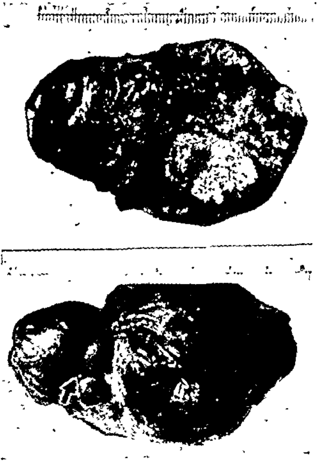

Fig. 400.—Carcinoma of the adrenal cortex. Arrow points to a groove between the normal gland on the left and the tumor on the right.

Tumors of the Adrenal Cortex.—*Nonhormonal tumors* are encapsulated but usually malignant. They are irregular and yellowish, and the large vacuolated cells that are found do not contain steroids as a rule. They are usually silent and are not discovered until they are felt on routine examination or until, because of their size, they produce pain. If malignant, metastases may be recognized first. Often they are mistaken for tumors of the tail of the pancreas. The treatment is complete removal by a transperitoneal approach. Since they are usually encapsulated, their removal is not difficult as a rule.

gastric or pelvic plexus, the ovarian plexus, and the uterine nerves. Afferent impulses from the ovary reach the central nervous system through the posterior root fibers of the tenth thoracic nerves. The ovaries present a pock-marked appearance due to the fact that the ovum develops in the germinal epithelium of the ovarian cortex within the *Graafian follicle.* The germinal epithelium sends small groups of cells into the ovarian stroma. One cell of the group is the *primordial follicle* which migrates deeper into the stroma which in turn produces two layers of cells to surround the follicle—the fibrous outer theca externa and the inner vascular and more cellular theca interna. The follicle ruptures and extrudes the ovum during the middle third of the menstrual cycle. The small pit which remains fills with *luteal* cells and fibroblasts, forming what is known as the *corpus luteum,* which may be true *(corpus luteum verum)* if pregnancy occurs, or false *(corpus albicans),* ending in fibrous tissue after ten days if the ovum has not been fertilized. Some animals do not have a corpus luteum (monotremes, such as the platypus, or duckbill). If the corpus luteum is removed in the early months of pregnancy, abortion usually follows. This is not true if it is removed in the later months. The granulosa cells of maturing Graafian follicles and also the cells of the corpus luteum give rise to a hormone (the *follicular hormone* or *female sex hormone, oestrin*) which is concerned with the initiation of menstruation and the secondary sex characteristics; the lutein cells of the corpus luteum gives rise to the hormone *progesterone,* which induces changes in the uterine mucosa preparatory to ovum implantation, helps in the formation of the placenta, stimulates growth of the mammary glands, and suppresses menstruation and ovulation during pregnancy. Progesterone has also been termed the "nidification" hormone, because after implantation of the ovum, the hormone of the corpus luteum is necessary for the development of the maternal "placenta" (the decidua). Oral temperatures vary during phases of the menstrual period, being low during the first part of the month, dropping to a minimum about the time at which ovulation occurs, and rising to a relatively high level until the next menses, when it drops abruptly. If conception occurs it remains at the high postovulation level. One hypothesis for the phenomenon is that the rise is brought about by ovulation and the elevated basal temperatures are maintained by corpus luteum activity. It is important to note that the ovaries are in intimate relationship with other endocrine glands. This is especially true of the pituitary (anterior lobe), which may, through its gonadotropic hormone, stimulate the follicle (prolan A) or the corpus luteum (prolan B) into activity and secretion and stimulate the secretion of milk by the hormone *prolactin,* the lactogenic hormone. Androgenic hormones from the adrenal cortex oppose and perhaps also act as pacemakers to the female sex hormones.

Diseases of the Ovaries

Congenital anomalies of the ovaries, unlike the rest of the reproductive system, are not common. There may be absence of one or both ovaries, or they may be hypoplastic, giving rise to incompletely developed secondary sex characteristics. The ovaries may fail to descend, or there may be accesory ovaries. Rarely there is inclusion of aberrant glandular tissue such as thyroid or adrenal, and still more rare is the inclusion of testicular tissue (ovatestes).

Inflammations of the ovary (oophoritis) are due usually to an extension of the fallopian tube inflammations. These may be acute or chronic; the former are initiated usually by the gonococcus, streptococcus, and staphylococcus, the latter by the tubercle bacillus, the spirochete, and actinomyces (see Chapter 23).

In a boy there is early puberty (pubertas praecox) with early enlargement of the genitals, hair on the face, great muscular development (infant Hercules). Sometimes there is a mixed picture with obesity and redness of the face (Cushing's type). If a tumor is found, it should be removed, but substitution therapy may be necessary for a while because the opposite adrenal is usually atrophied. The results are good.

Excess estrogens in a man due to adrenocortical tumors cause a decrease in size of the genitals, enlargement of the breasts and nipples, and impotence. The tumors are usually carcinoma and should be removed. *Cushing's syndrome* has been described previously in this chapter under basophilic adenoma of the pituitary. Adrenal tumor may also cause it. (Symptoms and signs are painful obesity of the face, neck, and abdomen with purple striae on the abdomen and thighs, acrocyanosis, hirsutism, polycythemia, glycosuria, muscular weakness, osteoporosis, amenorrhea in women, impotence in men. The syndrome is usually seen in women and is usually due to bilateral adrenocortical hypertrophy "foam cell adrenals." Tumors may be the cause and are usually adenomas. Operative removal is indicated, but it may be followed by acute adrenal insufficiency because the opposite gland is atrophic. The preoperative preparation includes adrenocortical extract (20-50 c.c.) the day before surgery, and this is repeated in the morning before operation. In addition, 1000 c.c. of physiological saline with vitamin C is given intravenously. Sodium citrate has been advised to fix the salt. This treatment is continued for several days after surgery. Sometimes desoxycorticosterone acetate (5-10 mg.) is also given by intramuscular injection.

The surgical approach may be through the abdomen or by the lumbar route as described under Pheochromocytoma. If the diagnosis of adrenal tumor is fairly certain, the latter is preferable and may be bilateral if the incorrect side has been explored first.

Ovaries

The ovaries are derived from the embryonic genital glands (gonads) which in the male give rise to the testes. At six weeks the sexless gonads consist of a superficial germinal epithelium and an internal epithelial mass. At eight weeks the gonads begin to assume the characteristics of testes or ovary. Although in the embryo the ovaries lie rather high in the abdomen, they descend later to their permanent position, due to the gubernaculum of Hunter (round ligament), which fails to keep pace with the growth of the rest of the body. This results in such traction on the ovary that it pulls it down into the pelvis. The ovaries are bilaterally situated in the pelvis, are held in place by the tubo-ovarian ligaments, and are nourished by the ovarian arteries, which are branches of the abdominal aorta. The ovarian veins anastomose freely, forming the pampiniform plexus, finally forming two veins which accompany the corresponding ovarian artery, ultimately fusing into one vein which empties into the vena cava on the right and the left renal vein on the left. The lymph vessels of the ovary join with those from the upper part of the uterus and end in the precaval and laterocaval nodes on the right and the lateroaortic and preaortic nodes on the left. The nerves are derived from the hypo-

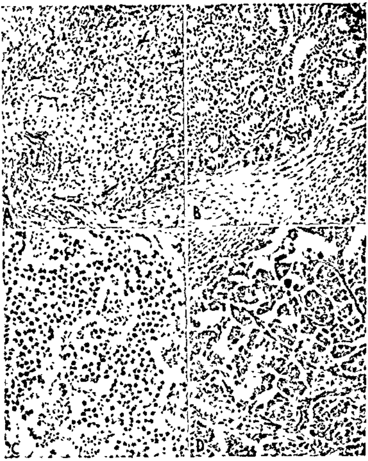

Fig. 402.—Photomicrographs of solid tumors of the ovary. *A*. Theca-cell tumor. Cells are derived from the theca interna. Most of the cells resemble those of connective tissue. Areas such as are shown are yellow spots in which the cells have *undergone luteinization* and produce an excess of progesterone. *B*. Arrhenoblastoma of the ovary. *Note* the adenomatous arrangement of the tumor, which is surrounded by connective tissue. *C*. Dysgerminoma of the ovary. Note the lack of differentiation in the cells, which are polygonal in shape and contain many mitotic figures and *very little stroma*. *D*. Carcinoma of the *ovary*. *Note the ad*enomatous arrangement of the growth, which has very little stroma and much variation in size and shape of its cells.

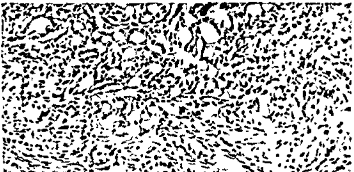

Fig. 403.—Krukenberg tumor of the ovary. This section resembles glandular tissue (adenocarcinoma). Note "signet ring" cells.

Tumors and Cysts of the Ovary

Tumors and cysts of the ovary are discussed in Chapter 23.

Here we shall enumerate the various types of new growth in the pluripotential ovaries and discuss those which stimulate the ovary to incomplete or perverted function, which decrease the natural secretion, or which increase or revitalize the depressed function.

A. Cystic ovarian tumors
  1. *Simple cysts*
    a. *Graafian follicle*
    b. *Theca luteum*
    c. *Corpus luteum*
    d. *Endometriosis* (chocolate cysts are not all due to endometrioses but are more often due to hemorrhagic follicle or corpus luteum cysts)
    e. Germinal inclusion (very small cysts beneath the germinal epithelium and lined by cells similar to those covering the ovary)
  2. Cystadenomas
    a. Serous (bilateral in 30 per cent of the cases; papillary types are apt to become malignant)
    b. Pseudomucinous (usually unilateral papillae in about 6 per cent and malignant degeneration in about 5 per cent of the cases; intraperitoneal transplants produce pseudomyxoma)
  3. Dermoid cysts (containing skin, hair, teeth, nails) and teratomas which may contain any tissue or organ; malignant transformation may occur (epithelioma and even melanoepithelioma in dermoids and almost any type in termatomas)

B. Solid tumors
  1. Nonfunctioning
    a. Fibroma
    b. Brenner tumor
    c. Adenocarcinoma
    d. Sarcoma
    e. Teratoma
    f. Krukenberg tumor (usually from stomach)
    g. Mesonephroma (resembling mesonephric tissue)
    h. Secondary tumors (carcinoma, sarcoma)
  2. *Functioning*
    a. *Granulosa cell*
    b. *Arrhenoblastoma*
    c. *Dysgerminoma*
    d. *Theca-cell*
    e. *Aberrant*
      (1) Adrenal adenoma—masculinovoblastoma; the tumor resembles adrenocortical tissue and gives symptoms like arrhenoblastoma plus hypertension, polycythemia, and a tendency to diabetes and obesity
      (2) Thyroid tumor of the ovary—struma ovarii—probably from a teratomatous growth; usually found as an adenoma and may become malignant
    f. Metastatic chorionepithelioma from uterus (or primary in ectopic pregnancy of tube and ovary or in teratoma)

The granulosa-cell tumor arises from fetal rests of *granulosa* cells and becomes a firm encapsulated growth. If it occurs *before* puberty, it may cause *sexual precocity;* if after the menopause, rejuvenation. Dur-

TABLE XXIX

SOLID TUMORS—COMPARATIVE DATA ON SOME OF THE MORE COMMON "NONFUNCTIONING" TUMORS OF THE OVARY
(Modified from Dockerty: Proc. Staff Meet., Mayo Clin., 1941)

	PRIMARY ADENOCARCINOMA	SARCOMA	TERATOMA	KRUKENBERG'S TUMOR	FIBROMA	BRENNER TUMOR
Histogenesis	Probably begin as cystic tumors (cystadenomas)	60% from fibromas; 40% from stroma of ovary	Mutation of cells or rests (?)	Always metastatic; stomach (80%), jejunum, colon, gall bladder, breast, hepatic duct, uterus	Ovarian stroma	Embryonic rests (?), teratomatous origin (?), mutation of cells (?)
Age	Any age	Any age—usually earlier than carcinoma	Any age—usually less than 10 or more than 40 years	Usually less than 45 years	100% after puberty	70% after menopause
Characteristic symptoms or syndrome	Rapidly growing tumor; cachexia; frequently ascites	Nonspecific	Nonspecific	Often gastric	Slow-growing tumor; ascites in 10% with large tumors; occasionally also hydrothorax*	Symptoms not characteristic
Unilateral or bilateral	50% bilateral	20% bilateral	15% bilateral	25% bilateral (small tumors); 85% bilateral (large tumors)	90% unilateral	95% unilateral
Gross appearance	Solid, brown, often adherent; often necrotic and cystic	Not diagnostic	Variety of tissues found	Solid smooth surface; cut surface becomes concave	90% solid, white	70% solid, resembling fibroma; 30% solid nodules in walls of pseudomucinous cysts
Microscopic pattern	Malignant cells with tendency to formation of glandular spaces	Usually fibrosarcoma	Heterogenicity of tissues	Often signet-ring cells	Cellular and fibrous types; small fibroblastic cells	80% fibrous stroma; 20% squamous cells in islands with cystic centers; mucus
Prognosis	Malignant	Malignant	Sometimes malignant	Malignant	Benign (if not fibrosarcoma)	Benign
Hormone elaborated	No hormones	No hormones	?	No hormones	No hormones	No hormones

*This also may occur with other large tumors of the pelvis.

TABLE XXVIII

SOLID TUMORS—COMPARATIVE DATA ON SOME OF THE MORE COMMON "FUNCTIONING" TUMORS OF THE OVARY
(Modified from Dockerty: Proc. Staff Meet., Mayo Clin., 1941.)

	FEMINIZING	MASCULINIZING	NEUTRALIZING	FEMINIZING
	GRANULOSA-CELL TUMOR	ARRHENOBLASTOMA	DYSGERMINOMA	THECA-CELL TUMOR (THECOMA)
Histogenesis	Granulosa cells	Testicular "rests"	Undifferentiated sexual cells	Theca of follicle
Age of patients	40 to 60 years (60%)	20 to 40 years (90%)	5 to 20 years (70%)	80% after menopause
Characteristic symptoms of syndrome	Precocious menstruation, early development of secondary sexual characteristics, postclimacteric menstruation, feminization	Sterility, hirsutism, atrophy of breasts, hypertrophy of clitoris, voice changes, amenorrhea, masculinization	Pseudohermaphrodism (can have normal menstruation and pregnancy), hypo plasia of genital organs	Often periodic postmenopausal bleeding (as in granulosa-cell tumors)
Unilateral or bilateral	Unilateral (95%)	Unilateal (100%)	Unilateral (65%)	100% unilateral
Gross appearance	Solid, granular, homogeneous	Solid, multicentric nodules	Solid; consistency of brain	Solid, yellow, fibrous; uterus large
Microscopic pattern	Folliculoid, cylindroid, diffuse	Tubular, cylindroid, and diffuse with interstitial cells	Undifferentiated cells, giant cells, lymphocytes; all neoplasms, grade 4	Fibroblastic cells laden with fat; hyaline bands
Five-year survival	95 per cent	75 per cent	60 per cent	Sometimes malignant
Hormone elaborated	Estrogen and progestin?	Male sex hormone	No hormones	Estrogens; so much that gonadotropic hormone of pituitary inhibited and no prolan B

ductules. These pierce the tunica albuginea and enter the caput epididymis where after much twisting the little canals finally open into the duct of the epididymis. This duct is 19 to 20 feet long, beginning in the head of the epididymis and after a tortuous course ending at the tail, becoming the ductus deferens. The testis is supplied by the internal spermatic artery which is a branch of the aorta. The veins form the pampiniform plexus which finally pours into the spermatic vein which ends in the inferior vena cava on the right and the left renal vein on the left side. The lymph vessels pass upward in the spermatic cord and empty into the right and left lateroaortic and preaortic nodes also the external iliac nodes. The nerves are derived through the aortic and renal plexuses from the tenth thoracic segment of the spinal medulla. Afferent fibers from the epididymis reach the spinal medulla through the posterior roots of the eleventh and twelfth thoracic and first lumbar nerves. The arteries and nerves and lymphatics communicate with those of the lower part of the ductus deferens (artery of the ductus and nerves of the hypogastric plexus). The descent of these organs from within the abdominal cavity into the scrotum is discussed in Chapter 20. Here it was pointed out that (1) the gubernaculum descends first, "pulling" the testis down, and (2) as the gland descends, it pulls the layers of the abdominal wall and peritoneum with it, and these, together with the peritoneum (tunica vaginalis), form the covering of the cord and testis, respectively.

The seminiferous tubules are coiled and twisted. They are lined by several layers of epithelial cells derived from germinal epithelium. These cells give rise to the spermatozoa. The epithelial lining of the tubules corresponds to the stratum granulosum of the Graafian follicle. *The youngest cells (spermatogonia)* lie near the basement membrane, and next, toward the lumen, are the *spermatocytes*, which divide to form the *spermatids*, which are transformed into the *spermatozoa*.

The anterior pituitary, through its gonadotropic hormone, stimulates the spermatogenic cells. The cells of Sertoli, lying among the spermatogonia, are supporting and nourishing cells. The interstitial cells (cells of Leydig) are supposed to elaborate the male sex hormone and in turn are said to be stimulated by the luteinizing hormone of the anterior pituitary.

The male hormone *(testosterone, androsterone)* has been isolated and can be obtained in crystalline form. Chemically it belongs to the sterols. It stimulates the formation of secondary sex characteristics.

Another hormone, *inhibin*, is supposed to exert an inhibitory effect on the prostate by acting on the pituitary and causing the latter to decrease its effect on the interstitial cells of the testes. As the testes undergo atrophy, inhibin is decreased, and consequently the gonadotropic hormone is liberated in greater amounts and causes a hypertrophy of the prostate.

A hormone does not stimulate the gland which secretes it and therefore testosterone does not stimulate the interstitial cells. It does have a salutary effect, however, in underdevelopment of the sex organs, and increased libido following its administration has been reported. The anterior pituitary-like hormone derived from pregnancy urine has also been used with reported success in cryptorchidism, sterility, and underdevelopment.

Congenital Anomalies

Congenital anomalies of the testicles are common. Among the more common are as follows: (1) Cryptorchidism (see Chapter 20) or nondescent; may be associated with hernia. If present on one side, it is known as monorchism; if both sides, anorchism. Cryptorchidism, if bilateral, gives rise to hypogonadism because the seminiferous tubules degenerate (perhaps as a result of the high intra-abdominal temperatures, but the interstitial cells remain. Therefore, subjects with an-

ing the menstrual life of a woman, *metrorrhagia* may occur. In other words, it stimulates the formation of the female sex hormone (the follicular hormone, or oestrin).

Arrhenoblastomas exert a "masculinizing" effect (virilism). They develop from potentially testicular cells present in the rete ovarii, and through their hormonal effects override the feminine influence of the ovary. These growths are unilateral as a rule and of low-grade malignancy. Removal of the growth may cause complete disappearance of symptoms (hirsutism, amenorrhea, bass voice, hypertrophied clitoris, etc.).

Dysgerminoma corresponds to seminoma of the testis. It is highly malignant and leads to an arrest of secondary sex characteristics.

Tables XXVIII and XXIX set forth comparative data on the more common solid tumors of the ovary.

The treatment of ovarian neoplasms is surgical for the following reasons: (1) In benign growths to prevent twisting, great increase in size, or malignant transformations; (2) in functioning growths to alleviate "hormonal" symptoms as well as the reasons given in (1); (3) in malignant growths to prevent spread and metastases. Functioning neoplasms require the opposite ovary to restore normalcy after their removal; therefore only the affected side is removed, leaving also the uterus and tubes. Carcinomas require extensive removal, including the opposite ovary, tubes, uterus, and nodes of the first echelon. X-ray treatment should be used in cases with peritoneal implant or lymph node involvement. Androgenic hormones may be helpful in the relief of pain.

Testes

The embryological development of the testes is the same as that of the ovary until about eight weeks; then the male genital glands become more compact and the original broad attachment to the mesonephros becomes the mesorchium or the gonadal mesentery. There appear in 14 mm. embryos branched anastomosing strands of cells—testes cords; also a layer of tissue between the germinal epithelium and the centrally located testes cords which will become the tunica albuginea or fibrosis capsule. The testes cords converge toward the mesorchium as the primordium of the rete testis. Soon the rete primordium becomes a network of strands which unite with the testes cords, each of which will split into three or four daughter cords to form the forerunners of the seminiferous tubules which do not canalize until about the seventh month. The testis of the newborn shows hypoplasia perhaps due to maternal hormones during pregnancy.

Beneath the serous tunica vaginalis the testis is covered by the tunica albuginea, which sends strands (septula testis) into the organ, dividing it into wedge shaped lobules (lobuli testes) and joining posteriorly to form the mass of fibrous tissue known as the mediastinum testis (corpus Highmori). This structure is traversed by the rete testis, arteries, veins, and lymph vessels. The parenchyma is made up of the convoluted seminiferous tubules (tubuli seminiferi contorti). There are three to four tubules to each lobule (a total of 600 to each gland); after a course of about two feet, they end in straight fine canals (tubuli seminiferi recti) and empty into the rete testis. Secretion of the seminiferous tubules is carried from the rete to the canal of the epididymis through from fifteen to twenty tubules called ductuli efferentes testis or efferent

Tumors of the Testicle

1. Supporting structure
   a. Hemangioma
   b. Fibromas
   c. Lipoma
   d. Neurofibrosarcoma
   e. Melanoblastoma
   f. Lymphosarcoma
2. Tumors of germ-cell origin
   a. Semenoma
   b. Undifferentiated or adenocarcinoma
   c. Trophocarcinoma from cytotrophoblast
   d. Chorioepithelioma from syncytotrophoblast
   e. Teratoma with undifferentiated carcinoma or adenocarcinoma
   f. Teratoma with trophocarcinoma
   g. Teratoma with chorioepithelioma
   h. Teratoma (adult type)
3. Tumors of the interstitial cells of Leydig
4. Metastatic neoplasms

Fig. 404.—Teratoma of testicle in a man aged 25 years. There were metastases in lungs and retroperitoneal tissues. The Aschheim-Zondek test was positive: 500 mouse units of prolan A per liter.

Neoplasms of germ cell origin comprise 90 per cent of all testicular neoplasms ordinarily encountered and therefore deserve special consideration.

Semenoma is seen in older men, in persons with cryptorchidism, and in persons with atrophic testes. It metastasizes by the lymphatics and by permeation. The tumor is radiosensitive, and the prognosis is therefore hopeful. Treatment consists of orchiectomy by first tying the cord vessels. The radical operation is not necessary and often not feasible. X-ray therapy should be used following surgery.

orchism are sterile but are sexually otherwise normal. Malignant tumor formation is more common in undescended testicles than in those in the normal position. (2) Aplasia or hypoplasia. (3) Supernumerary testicle. (4) Adrenal or splenic inclusions. (5) Ovarian inclusion—ova-testis. (6) Hydrocele. Hydrocele is due to failure of the tunica vaginalis to obliterate. The cavity, which becomes filled with fluid, often communicates with the peritoneal cavity (hernia). The treatment of this is operative. In the congenital type it is best to wait until after 5 years of age because spontaneous obliteration sometimes occurs. After this age the tunica vaginalis is split, "turned inside out," and sutured (bottle operation).

Spermatocele is probably a retention cyst and, if large, should be excised. Varicocele is a dilatation of the spermatic veins in the pampiniform plexus. Excision often leads to "painful cord." If there is no obstruction above (from a renal tumor or pressure from other cause on the renal vein), scrotal support is used.

Injuries of the Testes

Injuries may be due to trauma or to torsion of the appendix, of the testes, or of the spermatic cord. A blow or crushing injury leads to hemorrhage and rupture of the tunica albuginea. It may be followed by infection or may result in scar formation so extensive that atrophy ensues. The relationship between injury and neoplasia is conjectural. Torsion is due to a long spermatic cord and gubernaculum in a capacious tunica vaginalis. Undescended testes may undergo torsion. The exciting cause is usually a strain (cough, sneeze, heavy lifting), but may occur without any known cause. If the torsion persists, venous return will be impeded and ultimately, when venous pressure equals arterial pressure, circulation ceases and gangrene occurs. The clinical symptoms and signs resemble an acute epididymitis or incarcerated hernia if the torsion is outside the tunica vaginalis. Prompt surgery will avert serious trouble. The operation is simple and requires only untwisting of the cord.

Inflammations of the Testes

(1) Acute nonspecific orchitis (from epididymitis, mumps, trauma, generalized infection); (2) tuberculosis—practically always secondary to tuberculosis of the epididymis; (3) syphilis—practically always primary in the testes (4) filariasis—affects the testes in more than 50 per cent of the cases; (5) actinomycosis—rare. Treatment consists of first the treatment of the primary disease. Locally, cold relieves pain in the acute inflammations. Penicillin and streptomycin are useful in all of the infections, the latter especially in tuberculosis. Aureomycin is also useful. Orchiectomy may be necessary in refractory cases with irreversible changes.

positive. They are radioresistant. Orchiectomy is done but the radical operation is usually not indicated because of distant metastases.

Teratocarcinomas may be monodermal or tridermal since they arise from totipotent sex cells. This group may include semenoma, embryonal carcinoma, choriocarcinoma, chorioepithelioma, or adult embryoma or teratoma. The treatment in this group is radical orchiectomy. X-ray treatment is ineffective.

Interstitial cell tumors are usually benign. Orchiectomy should be done, and if a study of the permanent section shows malignancy, radical resection may be done as a second stage operation.

Metastatic neoplasms are extremely rare. The presence of a painless mass in the testes should suggest new growth. In the *chorioma testis,* and perhaps in other teratomas, the Aschheim-Zondek or Friedman test may be positive. Although the growths mentioned, as well as those affecting the interstitial cells, should stimulate or decrease the function of these cells, it is extremely rare to find a growth affecting secondary sex characteristics as tumors of the ovary do.

Adenocarcinoma or *undifferentiated* carcinoma grows rapidly and metastasize to the retroperitoneal nodes. It is not so radiosensitive and requires radical orchiectomy. This is done through an oblique incision extending from the costovertebral angle to the external inguinal ring. The internal spermatic vessels which lie between the transversalis fascia and peritoneum are ligated at their origins and terminations (aorta and vena cava and left renal vein). The dissection is carried down to where the vas turns down to pass along the posterior surface of the bladder. Nodes may be encountered along the spermatic cord, at the internal ring on the external iliac artery, at the bifurcation of the hypogastric artery, and between the common iliac artery and the genitofemoral nerve. On the right side nodes may be found on the anterior surface of the vena cava, between the vena cava and aorta, and at the junction of the spermatic vein and the vena cava. On the left side nodes may be found lateral to the aorta and at the junction of the spermatic vein and renal vein. Sometimes the kidney is sacrificed on the left to remove all metastases.

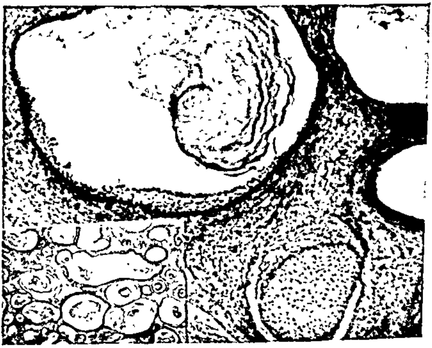

Fig. 405.—Teratoma of the testicle. Note the cystic areas as seen in the low power (lower left). Under high power, some of these are found to be lined with squamous epithelium (large upper cyst); others show cartilage (lower). Very little glandular structure is seen in this section.

Trophocarcinoma from the cytotrophoblast, which is the precursor of the syncytotrophoblastic cells of *chorioepithelioma*, constitutes a rapidly growing tumor which metastasizes early by the blood stream and the lymphatics.

Chorioepithelioma is composed of Langhans' cells and syncytium. There is rapid growth and early metastases by the blood stream and lymphatics. The Aschheim-Zondek and Friedman tests are frequently

Chapter 23

REPRODUCTIVE AND URINARY SYSTEMS

The reproductive and urinary systems are closely related developmentally, anatomically, and functionally, also in their susceptibility to certain infections such as gonorrhea. Moreover, in the female, injuries to the birth canal frequently affect the bladder support, and pregnancy may interfere with normal kidney function. In both sexes congenital anomalies of either system may occur, thereby affecting the other. For these reasons the two systems are considered together in this chapter.

THE FEMALE REPRODUCTIVE SYSTEM

The female reproductive system is composed of ovaries, Fallopian tubes, uterus (body and cervix), vagina, and vulva. A description of the ovaries and their function is found in Chapter 22, Glands. Diseases and abnormalities of this system make up the special field of *gynecology* (literal meaning, "the study of women").

The two Mullerian ducts give rise to the uterine tubes (Fallopian tubes), the uterus, and the vagina. Congenital anomalies occur if these ducts fail to fuse (double uterus), if they only partially fuse (uterus bicornate), or if they fail to develop (congenital absence of vagina and uterus). In the indifferent stage of the embryo (both the male and the female), there are a pair of genital glands, a pair of mesonephric or *male* ducts, a pair of Mullerian or *female* ducts, and a genital tubercle bearing the phallus. Fig. 406 illustrates the changes which occur in the development of these structures in the male and the female. If nature errs in the sex development, true or false hermaphroditism may occur. The former is extremely rare and implies the presence of both ovarian and testicular tissue. The latter is not uncommon and implies the presence of one type of sex glands (either male or female) and the opposite type of secondary sex characteristics. (See also Fig. 410.)

The Fallopian tubes join the uterus on either side and are held in position by the tuboovarian ligaments. The ovum is fertilized in the tube and then descends into the uterus. This organ is held in position by three sets of ligaments: the broad ligaments, which are most important, the round ligaments, and the uterosacral folds. In front of the uterus lies the bladder, which is closely attached to its anterior surface. Behind is the rectum, separated from it by a space covered with peritoneum, called the pouch of Douglas. The *cervix uteri* extends into the vagina, and its external opening (external os) is easily seen with the speculum and is felt upon bimanual examination. The vulva is composed of the labia (major and minor) enclosing the vaginal orifice, just anterior to which is the urethral meatus. The blood supply of the ovaries is from the ovarian arteries (from the aorta); that of the round ligaments, from the arteries of the round ligaments (from the external iliacs). The uterus is supplied by the uterine arteries which arise from the hypogastrics (internal iliacs). These cross the ureters near the cervix and ascend toward the fundus.

The lymphatics of the cervix empty into the middle or medial groups of the external iliac chain; the hypogastric and common iliac nodes and the nodes of the promontory; those of the corpus terminate in the latero aorti nodes, the preaortic nodes in the vicinity of origin of the inferior mesenteric artery, in the nodes of the middle group of the external iliac chain, and sometimes in the superomedial superficial inguinal nodes.

The nerve supply is somatic (sensory and motor) by way of the lumbosacral plexus and visceral by way of the superior hypogastric (presacral) plexus which becomes the middle hypogastric plexus below the promontory, becoming, at the level of the first sacral vertebra, the inferior hypogastric plexus. Fibers from the sacral plexus which join the latter represent the parasympathetics and are known as the nervi erigentes. These are the source of parasympathetic innervation of the uterus, tubes, ovaries, and the walls and internal sphincters of the bladder and rectum. The plexus of the pelvis located on the posterior surface of the base of the broad ligament supplies sympathetic fibers to the uterus, bladder, vagina, and rectum, whereas the aortic plexus supplies fibers which run along with the ovarian arteries to the ovaries.

The uterus is composed of an external mesothelial layer (serosa), a middle layer composed of bundles of smooth muscle (myometrium), and an inner layer (endometrium). The vaginal portion of the cervix is stratified squamous epithelium, but at the external os it becomes nonciliated columnar epithelium which lines the cervical canal to the internal os and sends projections to form its compound racemose cervical glands.

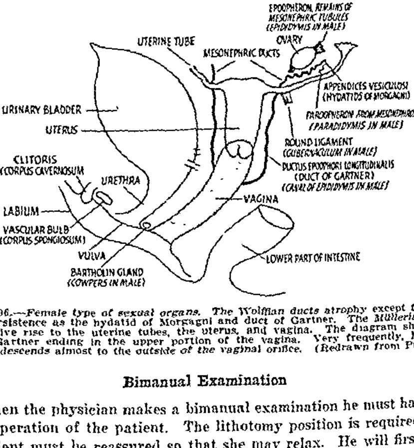

Fig. 406.—Female type of sexual organs. The Wolffian ducts atrophy except for occasional persistence as the hydatid of Morgagni and duct of Gartner. The *Müllerian ducts* fuse to give rise to the uterine tubes, the uterus, and vagina. The diagram shows the duct of Gartner ending in the upper portion of the vagina. Very frequently, however, this duct descends almost to the outside of the vaginal orifice. (Redrawn from Prentiss.)

Bimanual Examination

When the physician makes a bimanual examination he must have the full cooperation of the patient. The lithotomy position is required, and the patient must be reassured so that she may relax. He will first note the consistency of the cervix, whether hard and smooth (normal), soft and smooth (pregnancy), or hard and friable (neoplasm); also whether there are tears or neoplasms. Next he will palpate the lateral fornices for masses or swellings in the adnexa, then the posterior cul-de-sac for abscess or retroversion. Finally, he will note the position and mobility of the uterus. The speculum enables him to inspect the cervix, to take smears for bacteria or tumor cells, and, when necessary, to take tissue for biopsy.

Menstruation

Menstruation may be of the ovulatory or anovulatory (especially at the menopause) type. The latter shows no secretory changes in the endometrium. We have seen in Chapter 22 that the anterior lobe of the pituitary secretes a hormone which causes stimulation and maturation of the follicle and another which causes its luteinization after it ruptures. After menstruation, as the Graafian follicles begin to mature, estrogen is secreted and one follicle reaches maturity while the rest degenerate. The corpus luteum which forms secretes estrogen and progesterone. Estrogen alone causes proliferation of the endometrium; however, estrogen and progesterone cause differentiation or secretion and inhibit ovulation. When the corpus luteum degenerates menstruation ensues.

Menstruation is divided into the following phase: (1) Proliferative phase (follicular or interval phase) which corresponds with the ripening of the follicles and ends with ovulation (in twenty-eight day cycle occurs about fourteenth day). After menstruation the endometrium consists of thin basilar layers and a portion of the spongiosa. Soon epithelium develops from the underlying glands, which later changes from a few small straight structures to numerous elongated tortuous glands. The blood vessels are small, numerous, and engorged toward the end of the proliferative phase. (2) Secretory phase (differentiative, progravid, or progestational phase) which is due to the action of the corpus luteum secretion (fourteenth to twenty-sixth day of cycle). The endometrium *shows a basilar layer*, a spongiosa *(tortuous and dilated portion of* glands), and a compact layer where the glands are straighter and narrower. (3) Ischemic phase which occurs one to two days before menstruation and is due to a constriction of the special vessels that pass between the basilar and spongiosa layers. (4) Menstrual phase which is due to degeneration, necrosis, and rupture of vessel walls.

Abnormalities of Menstruation.—Although menstruation is normally established in this climate at the age of 12 to 15 years, the age of onset is very variable. In its establishment during the adolescent period, many irregularities occur which are looked upon as functional, due perhaps to deranged or unestablished internal secretions (see Chapter 22). Catamenia normally ceases at about 45 to 50 years of age. At this age, also, there are irregularities, associated with vasomotor disturbances (hot flashes) and with psychic states or neuroses. The menstrual irregularities both of adolescence and the menopause are transient: In youth, regularity of menstruation soon becomes established, and in the fifth or sixth decade menstruation ceases entirely. Symptomatic treatment consists of glandular therapy (oestrin). Should gross and persistent changes *occur, they signify disease.*

Menorrhagia means a menstrual flow (occurring at regular intervals) which is prolonged or profuse or which has an interval of less *than twenty*-eight days. It may be "glandular" or functional in origin (due to too

much estrogen from persisting ovarian follicles or to too little progesterone, the inhibiting hormone of the corpus luteum), but the physician should make a careful examination for *fibroid tumors*, cervical or corporeal polyps, myomas, adenomyomas, and ovarian tumors or *inflammatory disease* of the adnexa (salpingitis, oophoritis, and tuberculosis).

Metrorrhagia means bleeding between menstrual periods. It usually means new growth, *carcinoma of the cervix* or *uterus*, or *polypoid growths in the cervix.*

Dysmenorrhea means painful menstruation, the cause of which often rests on a *neurotic* background.

Amenorrhea means absence of menstruation and usually denotes *pregnancy* or *menopause.* In ectopic pregnancy, where signs may not be clear, the Aschheim-Zondek or Friedman test (rabbit) or Xenopus (frog) test for pregnancy is used but is not always positive. *In order to obtain a positive test for pregnancy, an excess of chorionic gonadotropin must be present in the blood or urine. Since in ectopic pregnancy there may be* a poor development of the trophoblast or the chorionic villi plus a poor connection with maternal tissue, the test is apt to be negative (about 25 to 30 per cent).

Oligomenorrhea means scanty menstruation. It occurs in unmarried women more frequently than in married and is associated with painful breasts. It is normal at the menopause. It is thought to be due to insufficient oestrin hormone and is helped by its administration.

Uterine bleeding may not conform to any abnormal type or combinations such as menometrorrhagia or continuous hemorrhage. *The causes are varied and may include bleeding from* retained gestational products after abortion or full-time delivery and tubal pregnancy, cervicitis with erosion, cervical or corpus carcinoma, systemic causes such as purpura (see Chapter 22).

Every case of abnormal menstruation demands careful bimanual examination, inspection, through the vaginal speculum, smears, and scrapings for cancer cells. If the diagnosis is not positive, diagnostic curettage and cervical biopsy should be done.

Congenital Anomalies

Congenital anomalies may occur in the uterus or vagina. If the Müllerian ducts fail to fuse, a double uterus or double vagina may occur, or there may be an atresia of the cervix or vagina, which prevents the egress of menstrual blood, causing pain and swelling. If the obstruction is at the vaginal orifice, the vagina fills with blood (hematocolpos); also the uterus and the tubes. Other common anomalies are congenital absence of the vagina (and usually with this an absence of the uterus), imperforate hymen, pseudohermaphroditism. Often there are associated anomalies in the kidneys or bladder.

Treatment for a double uterus (bicornis unicollis, didelphys, septatus, arcuatus, etc.) is not often necessary. Complications during pregnancy may require surgery. A double vagina frequently demands a plastic reconstruction. Congenital absence of the vagina necessitates surgery if marriage is contemplated. This is accomplished by bowel transplants, labial grafts, pedicle grafts from the thigh, free split-thickness grafts held in place by a plastic mold, simple pressure against the perineum with a rounded mold over a long period, or simple reconstruction by incision and insertion of a plastic mold until epithelialization occurs. The latter method is easiest and gives fairly good results. Imperforate hymen requires incision. Pseudohermaphroditism is a difficult problem. Adults should be left in the sex in which they have been reared. Gonads should not be removed unless diseased or for diagnosis. The psychological management is important.

Malpositions of the Uterus

We have noted previously that the uterus is held in its normal position by (1) the round ligaments which draw the uterus forward, especially after it has been displaced backward by bladder distention or by pregnancy; (2) the uterosacral ligaments which are part of the endopelvic fascia lying beneath the peritoneum and entering from the cervix to the sacrum—they hold the cervix back and aid in holding it up; (3) the bases of the broad ligaments (cardinal ligaments, ligamentum transversalis colli, Mackenrodt) which are part of the endopelvic fascia and are attached to the intra-abdominal portion of the uterine cervix and the lateral pelvic wall; (4) the fascia *lying between the anterior vaginal wall* and the bladder (subvesical fascia or pubovesical fascia) stretching from the symphysis pubes beneath the bladder to the anterior wall of the cervix; (5) the fascia lying between the posterior vaginal wall and the rectum which is the posterior part of the fascial cylinder encasing the vagina; it is extremely difficult to demonstrate the so-called fascia enumerated in (4) and (5); most authorities now believe that this fascia is really the muscular coat of the vagina; (6) the muscular floor of the pelvis (pubococcygeal fibers of the levator ani muscles). The normal position of the uterus when a woman is standing is approximately horizontal. This position is called one of *anteversion.* Should the entire uterus be tilted backward on an axis at the internal os, it would be in *retroversion.* This is said to be of the first degree when the long axis of the uterus coincides with the long axis of the vagina, of the second degree when the cervix points in the direction of the vaginal orifice, and of the third degree when the cervix points anteriorly. *Lateroversion* means a turning of the uterus to the right or to the left. *Flexion* of the uterus means an angulation of the body of the uterus on the cervix; this may be forward *(anteflexion),* backward *(retroflexion),* or lateral *(lateroflexion).* There may also be combinations of versions and flexions and therefore such terms

as *retroversioflexion*, etc. *Prolapse* of the uterus means a permanent descent of the organ toward the vaginal introitus. There is always some degree of prolapse with retroversion. *Procidentia* means extreme prolapse in which the cervix protrudes from the vaginal orifice. *Complete procidentia* denotes extrusion of the entire uterus from the vaginal orifice. *Torsion* of the uterus means a twisting of the body on the cervix in the vertical axis. *Inversion* means the turning inside out of the entire organ. This is extremely rare.

Most of these conditions are intimately related to the effects of childbirth, although malpositions may be congenital or acquired due to congenital weakness such as procidentia in the nulliparous woman. The uterus is normally held in position by its ligaments and by the pelvic musculature below. Should these structures become relaxed, or should the uterus change its position due to an increase in size or weight, or

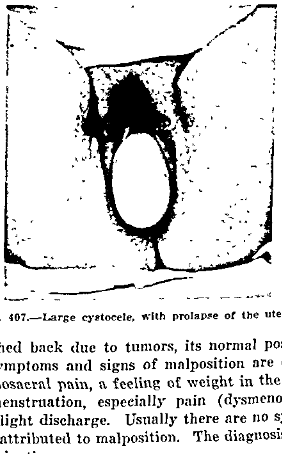

Fig. 407.—Large cystocele, with prolapse of the uterus.

should it be pushed back due to tumors, its normal position would be changed. The symptoms and signs of malposition are of reflex origin and include lumbosacral pain, a feeling of weight in the pelvis, and abnormalities in menstruation, especially pain (dysmenorrhea). Sometimes there is a slight discharge. Usually there are no symptoms which can be definitely attributed to malposition. The diagnosis is easily made by bimanual examination.

The prevention of malpositions may be briefly summarized in the phrase "good obstetrical care." In the minor degrees of retroversion, treatment is unnecessary. In the major degrees with marked symptoms, and in procidentia, surgical treatment is indicated. Many procedures have been devised. In younger women of childbearing age these consist of suspensions by the round ligaments in various manners and the repair of the pelvic floor from below (q.v.). Women with associated organic

lesions require hysterectomy. Older women who are no longer of childbearing age and younger women with complete procidentia demand fixation of the uterus to the anterior abdominal wall, or parametrial fixation. (Vaginal hysterectomy and plastic repair are advised by some.) Childbearing is impossible after this operation, and therefore in the latter group sterilization by salpingectomy is necessary. These operations are also combined with perineal repair. In severe or recurrent cases, complete closure of the vagina (colpocleisis—Le Fort operation) may be indicated. Palliative measures, such as pessaries and tampons, are used where operation is contraindicated.

It is beyond the province of this book to describe each surgical procedure in detail. This information may be obtained from the many excellent textbooks on operative gynecology. However, the number and variety of operations is good evidence that no one form of repair is applicable to all cases and that none are entirely satisfactory. In general they may be grouped as follows:

1. Operations which seek to restore normal position without interfering with the childbearing function by repairing normal structures (plication of round ligaments, drawing them out through the inguinal canal or fastening them to each other in front of the rectus muscles or behind uterus—Olshausen, Alexander, Gilliom, Baldy Webster, etc.; plication of uterosacrals; repair of perineum).

2. Procedures which retain the uterus to act as a supporting structure without retaining its childbearing function (fixation to anterior abdominal wall, interposition or transposition of the uterus under the bladder—ventral fixation; Watkins, etc.).

3. Operations which preserve the uterus but which eliminate the cervix and permit shortening of the cardinal ligaments—Manchester, Fothergill.

4. Excision of the uterus with preservation of the cervix and anchorage of this structure to the round ligaments or anterior abdominal wall.

5. Excision of the uterus and cervix by vaginal hysterectomy and approximation of the round and broad ligaments and reconstruction of pelvic floor.

6. Obliteration of the vaginal canal so that descensus cannot occur. (Le Forte colpocleisis). The particular type of procedure will depend upon: (1) the age and general physical condition of the patient; (2) the desirability of preserving functions—(a) menstruation, (b) childbearing, (c) sexual; (3) The condition of the cervix and corpus uteri; (4) The presence of associated conditions—(a) cystocele, (b) rectocele or enterocele; (5) The degree of descensus.

Infections

One of the most common infections seen in the female genital tract is gonorrhea. This disease is caused by the gonococcus *(Neisseria gonorrhoeae)* and is acquired by contact If affects mucous membranes and

therefore may involve the vulva and vagina (vulvitis and vaginitis), the urethra (urethritis), Skene's glands or the paraurethral glands (skenitis), Bartholin's glands (bartholinitis), the endocervix (endocervicitis), the endosalpinx (salpingitis), the ovaries (ovaritis), and the pelvic peritoneum (pelvic peritonitis). It may also involve the eyes (conjunctivitis) in the newborn or in the adult as a result of carelessness. In children, gonorrhea takes the form of a vulvitis or vaginitis. Children acquire the disease through uncleanliness on the part of adults who are afflicted; adults acquire it by sexual contact. The chief symptoms and signs are a purulent discharge, pain and burning on urination, and, if the tubes and ovaries are involved, pelvic pain, fever, distention, and abdominal muscle rigidity. Bimanual examination reveals fullness in the fornices or the cul-de-sac, fixation of the uterus, and extreme tenderness. Rarely, the infection invades the blood stream, causing gonorrheal arthritis and even endocarditis. The diagnosis is made by urethral and cervical smears which show the gram-negative, intracellular diplococci. The *treatment* consists of bed rest and application of heat locally. The Elliott treatment is the application of intravaginal heat by means of a rubber bag with two tubes through which hot water is allowed to enter and exit. In addition, penicillin is given intramuscularly with sulfonamides by mouth. Formerly, extensive pelvic operations were done in cases with salpingitis and tubo-ovarian abscess. Today, conservative management is the rule. Should an abscess form, it may be drained through the posterior cul-de-sac. Residual tuboovarian abscess may require surgery.

Tuberculosis may involve the tubes and ovaries, causing a tuberculous salpingitis and peritonitis. About 7 per cent of all pelvic infections requiring surgery are said to be due to tuberculosis. Pelvic tuberculosis is usually secondary to infection in the lungs, intestinal tract, or lymph nodes. Skene's glands, Bartholin's glands, the vagina, and cervix are rarely involved. The Fallopian tubes are involved in almost every case of pelvic tuberculosis, the endometrium in about one-half the cases, and the ovaries in about 33 per cent (see Chapter 8). The diagnosis is made from a history of contact and from signs of tuberculosis elsewhere. The local symptoms and signs resemble those of a mild gonorrheal salpingitis. The treatment is, first, the general care of the tuberculosis supplemented with streptomycin in doses up to 1½ Gm. per day. Later, operation may be performed with removal of the diseased tubes. The surgeon must use extreme gentleness to avoid tuberculous fistulae of the intestines. No drainage is employed because secondary infection is feared.

Nonspecific infections are common in the cervix after childbirth. This condition is known as a *cervicitis* or *endocervicitis*. It gives rise to an annoying discharge of a semipurulent character. Treatment is directed at the cause; namely, small, infected cervical tears. Cauterization destroys the infected tissue and the compound racemose glands of the cervix.

Another type of infection is acute and is caused by the *streptococcus*. It occurs after induced abortions and (rarely, now) after delivery. This

dangerous infection spreads to the tubes, ovaries, broad ligaments, and pelvic cellular tissue, causing *parametritis* and *pelvic peritonitis*. Septic emboli may be released from the thrombosed veins of the broad ligaments, causing a septicopyemia and death. Treatment consists of bed rest, ample fluids, repeated blood transfusions, penicillin, the sulfonamides, and *no* surgery unless a localized abscess forms.

Other infections in the cervix are *syphilis, granuloma pyogenicum* and rarely *granuloma inguinale* (Chapter 7). Parasitic infestations are common. *Trichomonas vaginalis* is a parasite which may cause an annoying vaginitis with frothy irritating discharge and pruritus vulvae. The best treatment is careful cleansing and carbarsone or Devegan locally. *Monilia infection* produces a "cheesy" exudate and intense pruritus. It responds quickly to 3 per cent aqueous solution of gentian violet. Actinomycosis and bilharziasis have been reported. *Pruritus vulvae* or persistent itching about the vulva is a common complaint. The cause may be local (trichomonas, vaginalis vaginitis, moniliasis infections, kraurosis vulvae, leucoplakia, senile or atrophic vaginitis, eczema) or general (diabetes, Hodgkin's disease, leucemia, severe neurosis). Treatment is directed against the cause, and, in addition, symptomatic treatment to relieve the itching. In kraurosis or severe leukoplakia vulvectomy may be necessary. "Senile" vaginitis responds well to the estrogens.

Injuries Due to Childbirth

We have seen that malpositions of the uterus may occur following delivery due to relaxation of the supporting structures. We must not infer that every woman will have such changes after the birth of her baby. Nor are *injuries* during childbirth by any means invariable. As the cervix uteri stretches to permit extrusion of the fetal head, small lacerations occur. These are usually inconsequential and heal spontaneously. Large *lacerations* of the cervix may occur under the following conditions: (1) disproportionately large fetal head, (2) precipitate labor, (3) instrumentation. The alert obstetrician will repair these immediately after delivery so that they may heal. If this is not done, they fill in with granulation tissue, and healing by second intention may occur. Frequently, however, they remain as infected, unhealed areas of granulation tissue which protrude into the vagina as an everted red granular mass, commonly called an erosion as distinguished from an ulcer which occurs away from the endocervix with more or less normal epithelium between the ulcer and the external os. The latter are thought to be associated with carcinoma more commonly than the former. In an erosion the surface epithelium is destroyed and the glands are hypertrophied and hyperplastic and secrete a copious amount of mucus. The surrounding tissue is usually edematous and cystic (Nabothian cysts) but may be sclerotic. Inflammatory cells are present in large numbers, and there is a change of the columnar and glandular epithelium to stratified squamous type produced locally from

basal cells and known as *squamous metaplasia*. This process is also seen in respiratory and other epithelium where a "protective" mechanism is invoked by the surface epithelium, changing it to the stratified type. The lesion resembles and must be differentiated from carcinoma, a distinction not always easy since the basement membrane may be intact and only an occasional cell may show loss of polarity and variation in size, shape, and staining quality—"carcinoma in situ." *The lesion causes a profuse* vaginal discharge, which is annoying. Furthermore, carcinoma *may arise* in such areas of chronic ulceration if they are left untreated. Biopsy must be done. The infected areas are excised and sutured (trachelorrhaphy), or, if they are small, *cauterization of the cervix* is done. *The* uterine cervix is frequently obstructed, giving rise to many symptoms such as dysmenorrhea, delayed menses, prolonged bleeding, leucorrhea, infertility. *There may ensue hematomelia, hematosalpinx, pyometra*,

Fig. 408.—Combined rectovaginal and vesicovaginal fistulae. This was in a woman aged 29 years who had had a septic abortion. Subsequently she began to have a temperature up to 105° F. About three weeks after entrance into the hospital it was noted that following an enema the water returned through the vagina. Also the patient complained that there was a constant drainage of urine from the vagina. The diagnosis was a vesicovaginal and rectovaginal fistula, due to gangrenous vaginitis following streptococcic infection induced by septic abortion. The patient had twelve attempts at surgical repair of the fistulae in various hospitals. None of them were successful. In addition to direct attacks upon the fistulous tracts, a panhysterectomy was done and finally a colostomy was established. As a last resort to bring relief to the unfortunate woman, a colpectomy was performed as illustrated in the diagrams. *A*, The condition prior to operations. *B*, The final result. This shows the completed obliteration of the vaginal canal and the bladder draining its contents into the bowel. (Case of Dr. Carl Habich.)

endometriosis as a result of the damming back of menstrual flow. *The* causes are congenital atresia, infections (*vaginitis, cervicitis, syphilis*), *trauma* (*postdelivery, abortion, instrumentation*, cauterization which is followed by dilation, conization, amputation, trachelorrhaphy, hysterotomy, caustic medicaments, foreign bodies), radium and x-ray, neoplasms (carcinoma of cervix or carpus, myomas), senile contracture. *The treatment* depends on the cause.

The perineum is frequently torn or lacerated, especially in primiparas. Anticipating this, most obstetricians perform *an* episiotomy and

then suture the incision after delivery. The purpose is twofold: (1) the wound is an *incised* instead of a *lacerated* one; (2) the extent and direction of the wound is controlled. Lacerations of the perineum may extend to the sphincter ani (incomplete) or into it (complete). In any event, these must be carefully repaired by the obstetrician immediately after delivery. Relaxations or incomplete repairs of the perineum allow the rectum to bulge forward into the vagina, causing a *rectocele.* An overstretching of the fascial layer between the bladder and the vaginal wall *permits the bladder to herniate into the vagina,* causing a *cystocele.* Both conditions may produce annoying symptoms. A cystocele is often accompanied by urgency, frequency, and sometimes incontinence. A rectocele interferes with defecation, causing a bulging, with pain and incomplete evacuation. The treatment consists of restoring the normal position of the uterus (since malposition is usually a causative factor), repair of the anterior vaginal wall (anterior colporrhaphy), and repair of the torn levator ani muscle (perineorrhaphy) and of the posterior vaginal wall (posterior colporrhaphy). These operations must be accompanied by normal placement and fixation of the uterus. Rarely, as a result of injudicious forceps deliveries, horrible tears occur, extending into the bladder. This accident, if not recognized and repaired immediately, results in a *vesicovaginal fistula.* (This is also seen as a result of carcinoma or prolonged radium implantation.) The symptoms of this annoying condition are constant dribbling of urine through the vagina and excoriation about the vulva. The *treatment* consists in carefully denuding the fistulous tract of its lining epithelium and then suturing the bladder and vagina separately by inversion sutures. A catheter is usually placed in the bladder through the urethra and anchored so that there will be no retention of urine. In addition, some surgeons prefer that the patient be kept in the prone position for about one week. In difficult cases the fistula may be closed through a transvesical approach. If all methods fail, ureteral-intestinal anastomosis may be indicated.

Complicated Pregnancy

Ectopic pregnancy refers to pregnancy outside the uterus (extrauterine). The ovum may become implanted in the tube, in the ovary, or in the abdominal cavity. If it becomes implanted in the uterine end of the tube, it is known as **interstitial pregnancy.** After the ovum leaves the ovary it begins its journey into the fimbriated end of the tube and downward into the uterus. Impregnation occurs normally in the tube and then the fertilized ovum continues into the uterus. Should this passage be obstructed because of inflammation or constriction, the fertilized ovum would be arrested at this point and begin its development. The more common causes for such obstructions are gonorrheal salpingitis, puerperal and tuberculous infections of the tubes and ovaries, and congenital malformations.

Normally the ovum grows in the uterine cavity. The uterus is capable of sufficient enlargement to accommodate the fetus until term. When a fertilized ovum is implanted in the tube, it is sure to be destroyed. Under growth, the tubal wall stretches and finally ruptures (tubal rupture), allowing blood and fetal contents to spill into the peritoneal cavity. More commonly, just the fetal capsule ruptures (tubal abortion), and the blood spills into the tube, causing a hematosalpinx.

The symptoms and signs during the first six weeks are those of early pregnancy, with slight enlargement of the uterus. When rupture occurs, there is sudden, severe abdominal pain, with signs of shock, and a slight vaginal bleeding. Cullen's sign is a discoloration about the navel. Although the color is usually blue or greenish-yellow, other colors (red, purple, tan) have been reported. It is not pathognomonic of ectopic pregnancy since it may appear in intra-abdominal bleeding from any cause and also in acute hemorrhagic pancreatitis or any disease causing bloody exudate. Discoloration may occur on the abdomen in such cases not only about the umbilicus, but also in surgical scars, at the sites of perforating vessels, and over hernias. Rarely, a decidual cast is sloughed. Bimanual examination reveals a soft swelling (blood) in the pouch of Douglas or in one fornix. The Friedman test is usually, but not always, positive.

The treatment is immediate operation and removal of the ruptured and bleeding tube. Preparations for transfusion are made and this is given during the operation. Should shock be extreme, operation is impossible, and if transfusions do not bring about a reaction, the surgeon must wait for one. This frequently occurs after a short time and is accomplished by using several veins at once and transfusing under positive pressure. By referring to Chapter 14, the student will see that the three maxims expressed are obeyed in the treatment of ectopic pregnancy. The first one is "treat the patient for shock first;" the second, "never operate in profound shock;" and the third, "there is no operation that has merit enough to be used on a patient who cannot possibly stand it."

Abdominal pregnancy requires long and watchful care. The surgeon *waits* for the fetus to die (this usually occurs later than in tubal pregnancy but rarely does the fetus reach the stage of viability, and if it does it is usually malformed) and for thrombosis of the placental veins to occur. (The placenta is of fetal origin and may be attached anywhere. There is no direct communication between mother and fetus, but in intrauterine pregnancy, infections and toxins may spread to the placenta through the uterine wall.) Operation is performed, the fetus and membranes are removed, and, if the placenta is attached to a tube, ovary, or the omentum, it may also be removed. If attached to a solid organ, removal is impossible because of hemorrhage. In this instance, it is left in situ and the abdomen is closed without drainage.

Cesarean Section.—The surgeon may be called upon to deliver a baby through an abdominal *section*. The indications for this procedure are few but vary with different surgeons. In general, it is indicated when the *life of the mother is endangered*—certain abnormal positions of the fetus with contracted pelvis in the mother, or a great disproportion between the size of the baby and the birth canal, making normal delivery impossible, placenta praevia centralis, and previous section (because of possible rupture of the uterus). Preparations are made for laparotomy and, in addition, for care of the infant. The abdomen is opened through a low midline or oblique incision; then the uterus is opened and the baby delivered. The placenta is next removed and the uterus and abdomen are closed. Three methods are available for Cesarean section: (1) classical method—intestines packed away, uterus opened by longitudinal incision, and then closed by three tiers of sutures; (2) the low-segment or low-cervical method employs a transverse incision of the peritoneum at the uterovesical junction and then a longitudinal (or transverse) incision in the uterus. Closure of the peritoneal flaps gives added security against rupture and postoperative adhesions; (3) extraperitoneal method uses an incision in the paravesical fascia, pushing the bladder down, the peritoneum is stripped upward from the lower uterine segment, and then the uterus is entered through a curved incision. If the peritoneum is inadvertently torn, it is closed before the uterus is opened. This is the safest operation in potentially contaminated cases.

Neoplasms

New growths occur in the female generative organs more commonly than anywhere in the body. New growths of the ovaries have been discussed in Chapter 22.

Solid growths of the ovary are rare (Chapter 22). *Cystic growths* are very common. *Dermoids* containing hair and teeth fragments have already been mentioned. *Teratomas* are not uncommon. These are to be expected in the ovary or testis, for here are the most pluripotent cells of the body—cells from which, in fact, the entire body is derived. The large *pseudomucinous cystadenomas* are usually unilateral and tend to be benign. Rarely, they rupture and cause a pseudomyxoma peritonei, in which the entire peritoneal cavity becomes filled with a jellylike substance. The *serous cystadenomas* are bilateral and may become malignant because of the proliferating papillary outgrowths within their lumen (invertans). These outgrowths finally come through the wall of the cyst (evertans) and are transplanted over the entire peritoneal cavity (proliferating papillary cystadenocarcinoma), causing death.

Endometriosis is the presence of endometrial tissue in abnormal location. The condition is said to be due to a reflux of endometrial cells from the uterus into the tubes during menstruation or a metaplasia of mesodermal tissue or proliferation of congenitally misplaced Müllerian

duct tissues. The term endometriosis interna or adenomyosis (adenomyoma) refers to the lesion in the wall of the uterus and endometriosis externa when it involves other tissues (bowel wall, ovary, tubes, pelvic peritoneum, abdominal wall, bladder, ureters, umbilicus, vagina, vulva, cervix, abdominal and mediastinal lymph nodes, rarely the linings). If large, the lesions are removed and castration is done either by x-ray or bilateral oophorectomy. Small areas regress after castration.

Fig. 469.—Cysts of the ovary. *A.* Dermoid cyst of the ovary showing epithelium and sebaceous glands. *B.* Serous cystadenoma of the ovary. The cyst was filled with clear fluid. Note the deep-staining cuboidal cells which line the cavity. *C.* Pseudomucinous cystadenoma of the ovary. Note the columnar cells which surround the cavities containing pseudomucin. *D.* Corpus luteum cyst of the ovary. Note the crenated edge and the large luteal cells.

Some cysts contain blood (Sampson's cysts, or chocolate cysts). These are due to the presence in the ovary of congenitally misplaced endometrial cells, which bleed with each menstruation, filling the cysts with blood. If the cells migrate into the pouch of Douglas or anywhere else in the pelvis, the same phenomenon occurs (endometriosis), giving rise at times to bizarre symptoms, *made worse at menstruation.* Rarely, such cells are transplanted during an operation into the abdominal

wound. Should these cells survive and ovarian function remain, they, too, would bleed periodically. Bleeding from the umbilicus in infants is usually due to a patent omphalomesenteric (vitelline) duct containing aberrant gastric mucous membrane on which forms peptic ulcer. Rarely this type of bleeding occurs in an adult in whom the condition has been present since birth. In women during the menstrual period, bleeding may occur from endometriosis (the aberrant implantation of edometrial cells).

Still rarer growths of the ovary are the *theca-cell* and *granulosa-cell tumors* which cause a marked change in the secondary sex characteristics, causing young girls to mature at any early age and old women to regain a primitive menstrual function. Also in this group of rarer growths are the *arrhenoblastomas* and the *embryomas* (see Chapter 22).

The physician may suspect the exact type of ovarian lesion present. As a rule, he will make the diagnosis of a solid or cystic ovarian tumor by bimanual examination. Such a finding warrants abdominal operation and the removal of the diseased ovary. Should the cyst be small, it may become twisted on its pedicle, thereby interfering with the ovarian blood supply and demanding an emergency operation because of pain and the possibility of its rupture.

The *Fallopian tubes* and uterine ligaments rarely contain neoplasms. The following varieties have been reported: (1) from epithelium—carcinoma occurring as a primary growth in about 0.25 per cent of all primary malignant growths of the female genital tract; secondary carcinoma may occur from ovarian or uterine carcinomas; (2) from embryonic elements—hydatids of Morgagni (dilated blind ends of Gartner's ducts), para-ovarian cysts (Gartner's ducts dilated and covered with Fallopian tube); (3) from connective tissue—fibroma; (4) from muscle—myoma; (5) from muscle and fibrous tissue—fibromyoma; (6) mesenchymal tissues sarcoma; (7) from chorionic elements—chorioepithelioma; (8) from reticulum cells—plasmacytoma; (9) from endometrium—endometrioma. New Growths of the tubes produce vaginal discharge, pelvic pain, and a tumor. The diagnosis is rarely made with accuracy prior to operation. Surgery consists of bilateral salpingo-oophorectomy with panhysterectomy.

The Uterus and Cervix.—Benign growths such as *polypi*, which are grapelike adenomas of the cervix, are common. They manifest themselves by intermenstrual bleeding. *Papillomas* are occasionally seen near the vaginal orifice. The *urethral caruncle* is a red, pouting tumor (mucous polyp) of the urethra, which causes pain on urination, frequency, and urgency. *Fibromyomas of the uterus* (fibroids) are extremely common. They are multiple and may be intramural, subserous, or submucous; that is, they may be beneath the peritoneal coat, where they cause few or no symptoms except for peritoneal reaction they may excite or symptoms due to their large size, they may lie between the muscle layers of the

uterus, causing its enlargement, or they may be beneath the endometrium, causing engorgement and prolonged menstruation (*menorrhagia*). *Rarely, a fibromyoma may be seen in the inguinal region. Its occurrence here is due to the fact that the gubernaculum of Hunter (analogue of the gubernaculum testis which causes the descent of the ovary) is attached in the inguinal canal. It fuses with the Müllerian* duct of each side in its upper third *and at a point just below its union* with the uterus. It contains muscle fibers *like the uterus and may there*fore develop a fibromyoma. In addition to the benign solid growths, there are many cysts, such as Bartholin's cysts, mucous cysts of the vagina, Nabothian cysts of the cervix, and follicular, dermoid, and luteal cysts of the ovary. The treatment for these conditions is surgical excision through the vagina if accessible (as in the case of a cervical polyp, urethral caruncle, vaginal cyst, or cervical cyst); if not, then abdominal operation must be done. *Multiple fibromyomas* may require the removal *of the uterus (supravaginal hysterectomy). Single tumors may be enucleated (myomectomy). The fibrous tissue may preponderate, and, if so,* it is not affected by the involutional changes at the menopause or the enlargement in pregnancy, whereas the muscle component will stretch in the latter and atrophy in the former instance. Retention cysts of the ovary require either no treatment or simple puncture, whereas dermoids and cystadenomas require the removal of the affected ovary (oophorectomy).

Far more serious are the malignant growths because *of their tendency to spread to adjacent tissues and to metastasize to distant ones. Carcinoma of the cervix* usually occurs *in women* past 40 *years.* It is a *painless* growth in its early stage and manifests itself by intermenstrual bleeding (metrorrhagia) and a foul, dark brown discharge. Since these complaints are not uncommon during the menopause, the patient is apt to overlook their importance. The physician will make a vaginal examination with the use of the speculum and make smears for cell study by the Papanicolaou method or other methods and, *if in doubt, he will take tissue for pathological study.*

Prevention of Carcinoma of the Cervix: Recent studies indicate that "intraepithelial carcinoma" or "carcinoma in situ" is a far more common lesion than formerly suspected. The relationship of carcinoma of the cervix to such diseases as chronic cervicitis and chronic cystic cervicitis, cervical stenosis, cervical empyema, cervical polyps, and cervical granuloma while not proved is strongly suspected. Therefore, *such conditions must be "cleaned up" by cauterization or surgery. A debatable issue is the practice of performing a total* hysterectomy because of the possibility of carcinoma in the remaining cervical stump of the supravaginal hysterectomy. Some statistics show this incidence to be as high as 5 per cent. The performance of a total or panhysterectomy because the remaining cervix might become cancerous is hardly justifiable since *supravaginal* hysterectomy is a much *safer procedure in the average surgeon's hands*

as to morbidity and even mortality. However, if there is cervical disease, the more radical operation is indicated.

Treatment of Carcinoma of Cervix: Because of its early involvement of the ureters, bladder, the broad ligaments, the iliac glands, and the posterior cul-de-sac, excision even by the Wertheim panhysterectomy (removal of the entire uterus, including the cervix, the tubes, the ovaries, and the anatomic lymph glands) often fails to effectuate a cure. Therefore, radium inserted into the cervix and x-ray to the pelvis are the treatment of choice in most cases. This statement is true because of the stage of involvement. The classification usually employed is that of the League of Nations, Radiological subcommittee: stage I, the lesions are confined to the cervix; stage II, there is moderate local invasion; stage III, there is extensive local invasion or unilateral fixation; stage IV, there is great local invasion or metastasis elsewhere. Admittedly it is difficult to establish the exact stage preoperatively because often what appears to be stage I or II in a young healthy person may have lateral involvement on exploration. The largest group are in stage III and the next largest are in stage IV, and for these, radium and x-ray will probably provide the largest number of cures. The effect of radiation may be studied by examining the exfoliated cells in the vaginal smear, and based upon their change, the effect of treatment and the prognosis may be more or less accurately judged. When radium and x-ray are properly employed, the effects on the ureters and bladder are minimal in stage I and II growths. It is true that stage I and II growths are best treated by radical surgery followed by x-ray treatment. Palliative surgery may include urethral transplantation, and heroic efforts to effect a cure may involve, in addition, cystectomy, panhysterectomy, and abdominoperineal resection of the rectum which may also include the vagina. Such measures rarely halt the progress of the disease.

Recently there has been a return to radical surgery, that is, the Wertheim type of operation, especially in stage I and II lesions. Briefly the operation proceeds as follows: (1) ligation and division of the infundibulopelvic and round ligament far from the uterus; (2) incision of the broad ligaments laterally and extending the incision anteriorly through the uterovesical peritoneum and posteriorly to the uterosacral ligaments; (3) dissection of the ureters down to the uterine arteries; (4) separation of bladder from the uterus and vagina; (5) farther dissection of ureters to the bladder; (6) Freeing the uterine arteries which cross the ureters at about the level of the internal os (closest point of the ureters to the uterus is at level of lowermost cervix and here it is about 1 to 1.5 cm.); (7) ligation and division of uterine arteries; (8) ligation and division of uterosacral ligaments; (9) excision of lateral pelvic cellular tissues (Mackenrodt's ligaments and musculofascial sheaths are tied and divided; the bladder may be injured in this dissection unless extreme care is exercised); (10) dissection of vagina down as far as possible; (11) vagina incised and upper part removed; (12) closure of vagina and peritonealization.

Carcinoma of the uterus is less malignant and metastasizes late. It is usually an adenocarcinoma; however, "embryonal" or undifferentiated carcinoma is also found. The interesting adenoacanthoma which is

a metaplasia-like tumor illustrating a squamous-cell change as described in lesions of the cervix (erosions) is also seen. It also occurs after 40 years as a rule. Its chief symptoms are hemorrhage (menorrhagia and metrorrhagia) and a foul, dark discharge. Diagnosis is made by bimanual examination (which reveals uterine enlargement) and search for exfoliated cancer cells in vaginal smears and is confirmed by a *diagnostic curettage* with careful examination of the endometrial scrapings. The treatment is removal of the uterus, the tubes, and the ovaries; that is, panhysterectomy and bilateral salpingo-oophorectomy. Some observers recommend preliminary radiation; others prefer postoperative x-ray therapy and a few employ both pre- and postoperative therapy. Surgery alone, if adequate, gives the best results in early cases, whereas surgery followed by x-ray therapy is the treatment of choice in late cases.

Stilbestrol and excessive estrogenic hormone therapy may induce endometrial hyperplasia and metaplasia. The symptoms (menorrhagia and metrorrhagia) resemble those of carcinoma.

Hydatidiform mole, or cystic degeneration of the chorionic villi, takes place in the placenta (which is of fetal origin), especially in the syncytial cells of the chorion. Several varieties of chorioma have been described. The usual symptom is bleeding after about the fifth month of pregnancy. Diagnosis is made by curettage. The uterus is emptied of its contents, and if the Aschheim-Zondek test remains positive after one to two months, chorioepithelioma is suspected. This demands hysterectomy and x-ray treatment, for it is very malignant, metastasizing by the blood stream and the lymphatics.

Other malignant neoplasms of the uterus include sarcoma (usually spindle or round cells), mixed tumors (teratomas), rhabdomyosarcoma, and chondrosarcoma. *Vulvar carcinoma* represents about 4 per cent of all cancers of the female genital tract. They may be epidermoid carcinoma, melanoma, basal-cell carcinoma, adenocarcinoma (Bartholin gland), vulvar Paget's disease (originating in apocrine glands). Usually they are of the squamous-cell type. Vulvar pruritis, kraurosis, and leucoplakia may be forerunners. The treatment is vulvectomy together with bilateral surgical excision of the inguinal nodes followed by x-ray therapy.

MALE REPRODUCTIVE SYSTEM

Embryology

By referring to the diagram we may see that in the male the Mullerian ducts degenerate, except for a small upper and lower portion (the appendix testis and vagina masculina). The mesonephric duct is functional, its derivatives being the ductus epididymis, the ductus deferens, the ampulla, and the seminal vesicle. The collecting tubules of the mesonephros (wolffian body) form the efferent ductules of the epididymis and the vestigial paradidymis. The phallus enlarges and becomes the penis, into which extends a portion of the urogenital sinus as the urethra. The corpora cavernosa develops from the mesenchyma at seven weeks. The genital tubercle disappears, and the scrotum is developed as a new structure from the labioscrotal swellings, into the vaginal

sacs in which the testes descend. At five months the prepuce is fully developed and covers the glans; at first the adjacent surfaces are fused, but later they again separate except along the undersurface of the glans where the fusion persists as the frenulum.

Anatomy

The male reproductive glands or testes are described in Chapter 22. The duct of each gland, at first very tortuous, forms a structure known as the *epididymis* which lies against the posterior and lateral parts of the testis. The superior part (caput) is attached by many small ducts, and the inferior portion (cauda) by areolar tissue. From the epididymis the excretory duct (ductus deferens) passes upward toward the inferior part of the anterior abdominal wall, which it pierces obliquely (inguinal canal) to enter the abdominal cavity through the internal inguinal ring. Here each ductus deferens is covered by peritoneum and, crossing the pelvic brim, enters the pelvis. The duct then courses along the side wall of the pelvis toward the base of the bladder, where it comes into contact with the *seminal vesicles.* These sacculated structures lie

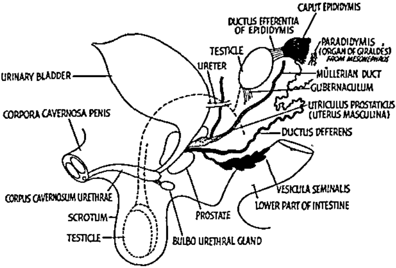

Fig. 410.—Male type of sexual organs. The Müllerian ducts become vestigial, except for the occasional persistence of the lower end as the utriculus prostaticus, or uterus masculina. The Wolffian duct gives rise to the ductus deferens and the seminal vesicles. (Redrawn from Prentiss: Textbook of Embryology.)

between the bladder and rectum and are about two inches long. The duct of the seminal vesicle joins the ductus deferens and forms a short canal called the *ejaculatory duct* which opens into the prostatic part of the urethra. The prostate is a partly glandular, partly muscular structure surrounding the first part of the urethra. The bulbourethral glands (Cowper's glands) lie in relation to the second or membranous portion of the urethra. Their ductules unite to form a single excretory duct which empties into the cavernous portion of the urethra. The ejaculatory ducts empty into the first part of the urethra, opening into a groove on each side of the cresta urethralis. The penis is enclosed by a fascia connected above to Scarpa's fascia and below to the dartos muscle of the scrotum and Colles' fascia. The blood supply to the penis from branches of the internal pudendal artery. The erectile tissue of the corpora cavernosa is supplied chiefly by the deep arteries of the penis, while that of the corpus cavernosum urethral is from the artery to the bulb. The dorsal artery of the penis supplies the erectile tissue and the glans. The veins with which the cavernous spaces communicate carry the blood into the pudendal plexus directly into the dorsal vein and so to the pudendal plexus. The lymph vessels end in the medial nodes of the inguinal group. The nerve supply is from

the hypogastric and pelvic plexuses (to the erectile tissue) and the branches of the pudendal nerve (dorsal nerve of the penis and branches from the perineal nerves). These supply the cutaneous structures.

The prostate is entodermal in origin and develops from the urethral epithelium as multiple outgrowths, which arise above and below the entrance of the male ducts. It varies greatly in size. The average is about 1½ by ¾ by 1¼ inches. The ducts open onto the lateral and posterior walls of the urethra. Glands and ducts of the prostate are embedded in a framework made of fibrous tissue and muscle, and the whole gland is enclosed in a fibrous capsule penetrated by the ejaculatory ducts which open on the verumontanum at about the middle of the prostatic urethra on the posterior side. The ejaculatory ducts run downward medially and forward to open into the prostatic portion of the urethra. The wedge-shaped portion of the prostate which lies between these ducts and the posterior aspect of the urethra is known as the median lobe. When hypertrophied, it causes an elevation and, therefore, partial obstruction to the bladder outlet. The two laterals are not clearly divided but join in front by what has been called an isthmus. The sheath of the prostate is formed by the visceral pelvic fascia and encloses the gland posteriorly and laterally. In the perineal prostatectomy, three potential fascial spaces could be developed between the rectum and prostate: (1) between the muscular wall of the rectum and rectal fascia (posterior layer of Denonvilliers' fascia), (2) between the rectal fascia and anterior layer of Denonvilliers' fascia, and (3) between the anterior layer of Denonvilliers' fascia and the fibromuscular covering of the prostate and seminal vesicles. The prostate receives its blood supply from branches of the hemorrhoidal and inferior vesical arteries. The venous plexus pudendalis surrounds the prostate and reaches the veins of the penis. This plexus communicates with the vesical plexus and draws into the hypogastric veins. The nerves are derived from the hypogastric plexus.

Physiology

The function of the prostate is to aid in reproduction. It has no internal secretion as far as is known. It is an accessory in function along with the seminal vesicle and the bulbourethral glands of Cowper. It often causes obstruction to the bladder outlet because of median bar formations, inflammations, cysts, prostatic calculi, and benign neoplasms, but rarely by cancer.

Congenital Anomalies

The urethra may be double, the second channel emptying into the normal one and lying posterior to it. Congenital strictures may occur, and in children, folds of mucous membrane (valves) in the prostatic urethra may cause an obstruction. Stenosis, atresia, diverticula of the urethra, hypertrophy of the verumontanum, and fistula between the rectum and urethra (Chapter 20) have been reported. The penis may be absent, concealed by the skin of the scrotum, hypoplastic, duplicated (diphallus, *Epispadias* is a dorsal and *hypospadias* a ventral cleft in the male urethra. The latter may occur anywhere along the urethra or in the scrotum. In the perineal type, with bifid scrotum, the genitals may resemble the vulva, although a urethra has never been reported in a clitoris. The treatment of these anomalies is plastic repair. Congenital cysts of the prostate arise from remnants of the Müllerian and wolffian ducts or occlusions of prostatic ducts. Congenital diverticula also occur. Cysts and diverticula should be removed or fulgurated.

Phimosis or congenital narrowing of the prepuce leads to irritation and obstruction. The treatment of this condition is circumcision.

Infections

Infections may occur anywhere along the genitourinary tract. In the penis, nonspecific infections include acute balanitis, cellulitis with or without gangrene, boils, herpes progenitalis, lichen planus, balanitis xerotica obliterans (kraurosis of the penis), and plastic induration (Peyronie's disease). The granulomatous infections which may occur are tuberculosis, syphilis, chancroid, lymphopathia venereum, granuloma inguinale, and histoplasmosis. The urethra is commonly the seat of gonorrheal infection (urethritis), which may extend into the prostate (prostatitis), the seminal vesicles (seminovesiculitis), the epididymis (epididymitis), and the testis (orchitis). This disease is of venereal origin and requires strict quarantine. The treatment is by hypertonic salt packs, the use of penicillin and sulfonamides, and bed rest (q.v.). Instrumentation must not be done. Strictures of the urethra may result, demanding dilatation, or a prostatic abscess may form, requiring drainage in rare instances. So-called nonspecific prostatitis is caused by direct invasion or organisms from the posterior urethra as a rule. The bacteria most frequently encountered are gonococci, staphylococci, streptococci, pneumococci, colon bacilli, and diphtheroids.

Granulomatous infections include tuberculosis, syphilis, actinomycosis, coccidioidomycosis (caused by) *Coccidioides immitis*), and granulomatous prostatitis.

Tuberculosis may affect the epididymides, testicles, seminal vesicles, and, rarely, the prostate. The treatment is, as a rule, conservative. If primary (in the epididymis or seminal vesicles), their removal may halt the spread of the disease.

New Growths

The *prostate* gland is frequently affected by new growth. The various components of the prostate gland may give rise to the following neoplasms: from the epithelium, benign hypertrophy and carcinoma; from connective tissue, fibroma, myxoma, fibrosarcoma, and myxosarcoma; from muscle tissue, leiomyoma, leiomyosarcoma, and rhabdomyosarcoma; from blood vessels, hemangioma and hemangiosarcoma; from lymphoid tissue, lymphoblastoma; from nerves, neurofibroma and neurofibrosarcoma; and from mesodermal elements, chondroma and chondrosarcoma; metastatic tumors also occur. A common type is *diffuse adenosis,* also known as *prostatism* or *adenoma of the prostate,* nodular hyperplasia, fibroglandular hyperplasia, benign hyperplasia. Simple hypertrophy of the prostate also occurs after the fifth decade and is thought to be associated with glandular dysfunction (testis and pituitary) in very much the same way that the fibroadenoma in the breast of the female may be associated with ovarian dysfunction. At times the pathological process is one of fibrosis,

with no increase in size of the prostate. At other times there is a diffuse enlargement due to nodular hyperplasia or stromal hyperplasia and associated with masses of lymphoid tissue. As the hyperplasia continues, the peripheral portion of the prostate is compressed, *forming a false capsule* made of prostate gland. As a result of pressure or associated spasm of the internal sphincter, obstruction of the *prostatic urethra* occurs and interferes with urination, so that there is a retention of urine, with formation of a small pouch in which the urine accumulates. The symptoms at first are usually nocturnal frequency and dysuria. Sometimes acute retention occurs. If left untreated, infections supervene which may involve the bladder, the ureters, and the kidneys. Diagnosis is made by rectal examination and cystoscopic examination, if possible. The treatment is *transurethral*,

Fig. 411.—Adenomatous hypertrophy of the prostate (benign prostatic hypertrophy). Note the cystic areas, which are due to a dilatation of the acini. There is great infolding of the epithelium into the lumina of the acini. Occasionally such lesions show a hypertrophy of muscle tissue as well as of connective tissue. This patient had urinary obstruction due to the enlarged prostate. The prostate was successfully removed through a suprapubic incision.

partial prostatectomy, which is done through the urethroscope with a cautery loop, or *suprapubic prostatectomy*, which is done through the bladder. The former operation removes the obstructing wedge. The latter attempts to remove the affected portions of the lobes (*lobectomy*), leaving a rim of compressed prostate behind. Other methods are the retropubic and perineal.

Transurethral resection has the lowest mortality and morbidity. However, incomplete removal, distortions and strictures of the urethra and vesical neck, incontinency, and early recurrence of symptoms have limited its use according to some urologists, whereas others find few, if any, contraindications to its use. All are agreed that the procedure is useful for

the removal of bars, median lobes, vesical neck contractures, smaller prostates which protrude into the bladder, and in neurogenic bladder. It is an especially desirable procedure in poor-risk patients, and those with associated pathological changes in the bladder such as papillomas and calculi; also in younger patients the operation is useful because of preservation of sexual function.

Suprapubic prostatic resection is the easiest method to use. It is usually employed in large prostates or those associated with large or inaccessible bladder tumors, large or multiple stones, and diverticula of the bladder. It is not used in fibrotic or calcareous or cancerous obstructions.

Perineal prostatectomy is more difficult but will take care of almost any pathological condition in the gland. It is in connection with this operation as developed by Dr. Hugh Young that early postoperative ambulation was practiced, an especially useful maneuver in older people.

Retropubic prostatectomy is useful in benign hypertrophy of the lateral or median lobes or both and calculous disease of the prostate, especially when associated with benign hypertrophy. The operation is done through a low midline incision. The prevesical space is exposed. The prevesical fat and peritoneal fold are then pushed upward. The endopelvic fascia is incised transversely, an inverted V incision is made in the false capsule, and the enteral lobes are brought up, the pedicles clamped, and the lobes removed. The median lobe is then enucleated from below and behind the floor of the vesical outlet. The bladder neck is incised if it is small, and a Foley balloon catheter is passed up through the urethra through the prostatic cavity into the bladder. The false capsule and endopelvic fascia are then closed.

Carcinoma of the prostate is a common disease and is said to cause 5 per cent of all deaths in men past 50 years of age. Normal development and maintenance of the prostate requires testicular male hormones influenced by gonadotropic hormones secreted by the anterior pituitary. Castration causes simple atrophy of the normal prostate and hyperplasia and increased secretory activity of the anterior pitutiary and perhaps the adrenals. This is not true of the hypertrophied prostate. The normal adult prostate tissue is extremely rich in phosphatose with optimum activity at pH 5.0. Both acid and alkaline phosphatase are capable of dephosphorylating monophosphoric esters to form inorganic phosphate. Alkaline phosphatase is present in large amount in osteoblasts, and therefore when there is prodigious osteoblastic activity, this enzyme is increased—rapid growth in children, Paget's disease of bone, osteogenic osteoblastic sarcoma, and osteoblastic metastases from prostatic cancer. In Chapter 22 we learned that alkaline phosphatase is also increased in disease of the liver. *Acid phosphatase is increased only in cancer of the prostate with metastases* to bone or lymph nodes. Here the secretions of metastatic cells find their way into the blood plasma, increasing the acid phosphatase above normal. The normal value (King and Armstrong

method) is less than 4.5 units for acid phosphatase and less than 12.5 units per 100 c.c. of serum for alkaline phosphatase.

Prostatic cancer is either of the undifferentiated or adenocarcinoma type. It rarely ulcerates through the rectovesical fascia into the rectum but often extends into the bladder in the trigone. The spread is also apt to be along the surface of the seminal vesicles and the perineural lymphatics. Bone marrow and lymph nodes are frequently involved but the lungs or brain seldom. Cancer of the prostate has been successfully transplanted heterologously into guinea pigs, and here it is under the influence of endocrine factors as in its primary habitat, but it loses its acid phosphatase activity.

Symptoms and signs are variable and usually insidious. In a man 50 years of age or over who complains of some frequency and difficulty in urination with low backache and scrotic pain and loss of weight, cancer of the prostate should be suspected. The symptoms are usually of a few months' duration. On rectal examination there is a hard lumpy prostate, or a single lump may be present. In late cases there is a diffuse hardness into surrounding tissues.

Carcinoma cells may be found in prostatic secretions, and this should be done routinely in suspected cases. X-ray of the pelvis and spine may reveal osteolytic or osteoblastic lesions. The long bones are not often involved, and very rarely below the elbow or knee. Cystoscopic examination may show infiltration of the trigone or notches around the vesical neck. A study of serum acid phosphatase is diagnostic in the lesions which have already metastasized. Biopsy is sometimes necessary and may be done through the perineum so that perineal prostatectomy may be carried out if the diagnosis is positive. A special stain for acid phosphatase (Gomori) will help differentiate between carcinoma of the prostate and carcinoma of the bladder.

The treatment of cancer of the prostate is surgical removal of the gland by perineal route if the lesion is early. This is not often possible. Antiandrogenic treatment is based on the fact that cancer of the prostate is stimulated by injection of male sex hormone (androgens) and is inhibited by reduction of androgens either through castration or neutralization through the administration of female sex hormones (estrogens). Serum acid phosphatase decreases when diethylstilbestrol, 5 mg. daily, is injected, whereas it increases when testosterone propionate, 25 mg. daily, is given. Great improvement follows administration of estrogens not only in the prostate, but in the metastatic areas as well. Bilateral orchiectomy is the treatment of choice because it is more complete and more permanent than estrogenic therapy. The latter should be used when castration is refused or when the diagnosis is doubtful or if surgery is too risky because of the debility of the patient. Failures occur in both methods due to the androgen-independent quality of the cancer or the production of androgens in the adrenals (see Chapter 22). X-ray treatment is not often successful except insofar as it produces sterilization.

Teratoma of the testicle is described in Chapter 22. New growths of the external genitals also occur. They are Leucoplakia, Paget's disease, Bowen's disease, papilloma (penile horn, condyloma acuminatum). Carcinoma of the penis occurs, as a rule, under the prepuce. Metastasis occurs early to the superficial inguinal glands. The treatment consists of resection of the organ, together with excision of the inguinal glands on either side.

THE URINARY SYSTEM

Embryology

The kidney in its embryological development recapitulates philogeny. The *pronephros* (fore-kidney) is the functional kidney of some of the lowest vertebrates *(Hemichorda)*. It is called the fore-kidney or head kidney because it lies in the animal's proboscis. Here it forms a puckered membrane richly supplied with blood vessels (glomerulus) and appears to act as a kidney. The pronephros contains only two to five straight tubules and is considered a precocious development of the most anterior tubules of the nephrotomes. (See Fig. 412.)

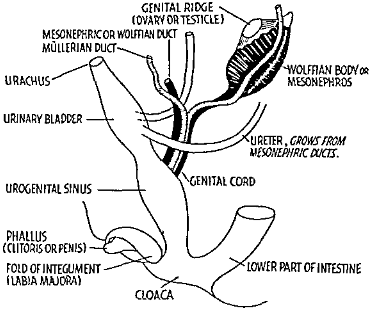

Fig. 412.—Primitive urogenital organs. Embryo of about 6 weeks (up to 12 mm.). This represents the undifferentiated stage. (Redrawn from Allen Thompson, and from Prentiss: Textbook of Embryology.)

The *mesonephros* (mid-kidney or wolffian body) usually forms the functional kidney in adult fishes and amphibians. The tubules are more numerous and more convoluted, and they enter into close connection with the genital organ. In mammals the true or permanent kidneys arise later and the wolffian bodies degenerate, being retained only as a portion of the epididymis in the male and as certain vestigial structures in the female (the parovarium, epoophoron, and paroophoron, and sometimes the cyst of Morgagni).

From the diffuse *substantia cellulosa* along the ventral side of the spinal column, as seen in the chick embryo on the third day of incubation, appear the *wolffian ducts* emptying into the cloaca. Since the wolffian duct is primarily the duct of the anterior kidney or pronephros, it is called the *pronephric duct* by some but is more often

method) is less than 4.5 units for acid phosphatase and less than 12.5 units per *100* c.c. of serum for alkaline phosphatase.

Prostatic cancer is either of the undifferentiated or adenocarcinoma type. It rarely ulcerates through the rectovesical fascia into the rectum but often extends into the bladder in the trigone. The spread is also apt to be along the surface of the seminal vesicles and the perineural lymphatics. Bone marrow and lymph nodes are frequently involved but the lungs or brain seldom. Cancer of the prostate has been successfully transplanted heterologously into guinea pigs, and here it is under the influence of endocrine factors as in its primary habitat, but it loses its acid phosphatase activity.

Symptoms and signs are variable and usually insidious. In a man 50 years of age or over who complains of some frequency and difficulty in urination with low backache and scrotic pain and loss of weight, cancer of the prostate should be suspected. The symptoms are usually of a few months' duration. On rectal examination there is a hard lumpy prostate, or a single lump may be present. In late cases there is a diffuse hardness into surrounding tissues.

Carcinoma cells may be found in prostatic secretions, and this should be done routinely in suspected cases. X-ray of the pelvis and spine may reveal osteolytic or osteoblastic lesions. The long bones are not often involved, and very rarely below the elbow or knee. Cystoscopic examination may show infiltration of the trigone or notches around the vesical neck. A study of serum acid phosphatase is diagnostic in the lesions which have already metastasized. Biopsy is sometimes necessary and may be done through the perineum so that perineal prostatectomy may be carried out if the diagnosis is positive. A special stain for acid phosphatase (Gomori) will help differentiate between carcinoma of the prostate and carcinoma of the bladder.

The treatment of cancer of the prostate is surgical removal of the gland by perineal route if the lesion is early. This is not often possible. Antiandrogenic treatment is based on the fact that cancer of the prostate is stimulated by injection of male sex hormone (androgens) and is inhibited by reduction of androgens either through castration or neutralization through the administration of female sex hormones (estrogens). Serum acid phosphatase decreases when diethylstilbestrol, 5 mg. daily, is injected, whereas it increases when testosterone propionate, 25 mg. daily, is given. Great improvement follows administration of estrogens not only in the prostate, but in the metastatic areas as well. Bilateral orchiectomy is the treatment of choice because it is more complete and more permanent than estrogenic therapy. The latter should be used when castration is refused or when the diagnosis is doubtful or if surgery is too risky because of the debility of the patient. Failures occur in both methods due to the androgen-independent quality of the cancer or the production of androgens in the adrenals (see Chapter 22). X-ray treatment is not often successful except insofar as it produces sterilization.

dependent on the effective pressures which result from such an arrangement. Here, as elsewhere in the body, the osmotic pressure, the hydrostatic pressure, and the permeability of the capillary determine the movement of fluid (see Chapter 11). In the tubules the capillaries are covered by tubular epithelium. If this is destroyed, uncovering the capillaries (as in mercury poisoning), absorption may be greatly increased, resulting in anuria, other factors remaining constant. All of the blood which enters the kidney passes through the glomerular tufts except a small amount which nourishes the capsule and interstitial tissue. Thus the tubules are supplied with blood which has gone through the glomeruli. Very few anastomoses exist between glomerular or tubular vessels, and the afferent components resemble arterioles, whereas the efferent are much smaller in diameter.

The *ureters* are also retroperitoneal. The left ureter descends close to the aorta in front of the common iliac artery; the right descends along the vena cava and in front of the external iliac; both ureters pass behind the uterine arteries and enter the bladder obliquely and somewhat laterally. The abdominal part of the ureter receives its blood supply from the renal and internal spermatic arteries. The pelvic portion is supplied by the superior vesicle and middle hemorrhoidal vessels. The nerves reach the ureter through the renal, spermatic, and hypogastric plexuses.

The *bladder* is covered by peritoneum except for a small space anteriorly, which is accessible only when the bladder is distended. The space of Retzius lies between the bladder and the pubis and contains many veins and loose areolar tissue. This is the uncovered area of the bladder, and cystectomy is performed here. The bladder occupies a much higher position in children than in the adult. Even when empty, it is an abdominal organ. The peritoneum forming the rectovesical pouch covers the whole of the posterior surface of the bladder and reaches as low as the upper limit of the prostate. The internal urethral orifice is high at birth (level of symphysis pubic upper margin) and then sinks to a lower level. The openings of the ureters lie on a plane with the pelvic brim. The obliterated portions of the umbilical arteries lie closer to the bladder than in the adult as they pass upward toward the umbilicus.

The bladder is held in position by the ligamentum umbilicale medium (fibrous cord of the urachus) which binds the apex to the anterior abdominal wall, by the false ligaments which are peritoneal folds (lateral, superior, and posterior) by the connective tissue attachment to the symphysis anteriorly, the lateral loose areolar attachments to the fascial lining, by processes of the pelvic fascia continuous with those forming the sheath of the prostate (puboprostatic or anterior ligaments, reaching the bladder from the pubis in front; lateral ligaments reaching the bladder from the side wall of the pelvis), by fibrous and unstriped muscular tisue which surrounds the seminal vesicles, and by the terminal portions of the ductus deferentes and the ureters.

In the female the basal part of the bladder is supported and held in place by its connections with the anterior wall of the vagina. The region of the urethral orifice is the most firmly fixed part of the bladder in both sexes.

The bladder receives its blood supply bilaterally from the superior vesical arteries (from the umbilicals just before they become obliterated) and the inferior vesical arteries (from the hypogastrics). The veins are found just above the prostate and in the region of the ureter-bladder junction. They form plexuses and empty into the tributaries of the hypogastric veins and communicate below with the pudendal venous plexus.

The lymph vessels drawing the anterior wall follow the obliterated hypogastrics on either side toward the neck of the bladder, near the origin of the ureter. There they turn laterally after receiving trunks from the posterior wall and then join the primary nodes. The posterior bladder wall collectors usually leave the bladder wall separately to course to the nodes of the first echelon; namely, the external iliac nodes and occasionally the hypogastric and common iliac nodes. The nerve supply on each side is

referred to as the *mesonephric duct*. An outgrowth from this duct enters into the formation of the permanent kidney. The duct itself degenerates in the female, leaving only the vestigial Gartner's duct, in which cysts sometimes form; in the male, it is retained as the ductus epididymis, the ductus deferens, and the seminal vesicle.

All the renal organs—the pronephros, the wolffian body (mesonephros), and the kidney (metanephros)—are developed from the nephrotomes. They are all composed of mesodermal tubules, each of which is in close relation with a knot of capillary blood vessels derived from branches of the aorta. Such a knot of vessels is called a *glomerulus*.

The *metanephros* (hind-kidney) is the functional kidney in reptiles, birds, and mammals, arising from a caudal position in man. It develops after the wolffian body has been formed. It arises from two parts: one, an outgrowth of the wolffian duct, forms the ureter, and the pelvis, calyces, and collecting tubules of the kidney; the other, a mass of dense mesenchyma (metanephric cell mass), surrounds this outgrowth and gives rise to the uriniferous tubules, the blind ends of which become invaginated and envelop the glomeruli and are known as Bowman's capsule. The unit is called the Malpighian body or renal corpuscle.

The short functional tubules of the adult kidney lie in the region where these developmentally distinct portions of the kidney unite. These two parts may fail to unite in the same plane. Failure of the two parts to join properly results in congenital cystic dilatations.

Anatomy

The *kidneys* lie behind the peritoneum, the left a little higher than the right, and are crossed by the eleventh and twelfth ribs. The right kidney is in close relation with the duodenum; the left, with the tail of the pancreas, the stomach, and the splenic flexure. Superior to the kidneys are the adrenal glands. The transversalis fascia (fascia renalis) splits to enclose the kidneys. The anterior layer covers the renal vessels, the aorta, and the inferior vena cava and is continuous with the other side. The posterior is attached to the vertebral column. Between the layers is a pad of fat, which also surrounds the kidney. Above, the two layers unite, but below, there is an opening, so that exudates may extend downward on the psoas muscle. The kidney is a compound tubular gland which is roughly divided into two components: (a) secretory, composed of the nephron, and (b) excretory, composed of ducts which convey the urine to the ureter which is the large excretory duct arising in the kidney's hilus and ending in the urinary bladder. The latter is a storage unit which expels the urine to the outside through the urethra. The kidney capsule is made of dense collagenous bundles and some elastic fibers. The glandular part of the kidney surrounds the sinus which contains the renal pelvis and is filled with loose connective tissue and fat vessels and nerves. The pelvis is the funnel-shaped beginning of the ureter. The wide part of the funnel faces the renal tissue and forms several projections known as major calyces, each of which in turn has several outpocketings known as minor calyces. The outer part of the kidney is known as the cortex and it surrounds the medullary substance composed of eight to eighteen renal pyramids (malpighian). These pyramids are cones with their bases pointing peripherally and their apices or *papillae* projecting into the lumen of each minor calyx. The papilla is perforated by ten to twenty-five small openings—the area cribrosa. The renal columns (Bertin) are formed by the dark brown cortex separating the pyramids. The pyramids can be considered as lobes which in the fetal period are separated from each other by connective tissue and which fuse later. Sometimes they remain separate throughout life as they do also in the ox. The pyramids may be subdivided into lobules because of the branching of the excretory ducts.

The kidneys' arterial supply is close to the aorta and therefore its hydrostatic pressure is high. The renal artery breaks up suddenly into short branches within the kidney. This supply is all one vessel so far as each glomerulus is concerned, with its afferent, efferent, and tubular components finally becoming venous. Filtration is largely

cutaneously, carba-minoyl-choline (Doryl). These drugs are contraindicated in vesical neck obstructions, asthma, hyperthyroidism, bowel surgery, in elderly people, and in those with coronary disease. *Reactions* such as dizziness, nausea, flushing, and even vomiting are not uncommon. Prostigmine (1 c.c. of a 1:4000 solution hypodermatically) has been used with success. (b) Parasympathetic depressants—atropine is of little use but, at times, may for unaccountable reasons give good results; the same is true of Syntropan 50 to 100 mg., by mouth. If more than four catheterizations are necessary, a catheter is anchored for a twenty-four-hour period and then removed. This is at variance with most teaching, but an anchored catheter means immobilization in bed and this perpetuates a general as well as a bladder atonic state. During catheterization and for a short time thereafter Sulamyd, 0.5 Gm., is given by mouth every four hours. If nothing is permitted by mouth, penicillin and streptomycin may be given intramuscularly as prophylactics against bladder infection. Ambulation with a catheter in place may be necessary, particularly in male patients who have had bladder surgery. This will not be necessary, as a rule, for other postoperative retention because early mobilization ordinarily precludes urinary retention.

The Paralyzed Bladder.—The term "atonic" bladder is used loosely to describe a bladder which cannot be emptied voluntarily. Tone implies a condition of tension in the detrusor muscle which, when increased, sends impulses to the central nervous system, initiating the "voiding reflex." Atonicity occurs when there has been overdistention for a varying period of time or when there has been an interruption of the segmental reflex concerned with micturition. *Often it is the overdistention* that leads to atony, even in the presence of such conditions as tabes dorsalis (loss of sensation) or spinal injury (loss of entire segmental reflex arc) (see Chapter 18). The treatment of the paralyzed bladder is designed to keep it clean and elastic so that when automaticity sets in, it will be in condition to respond and not become a small contracted infected organ. To accomplish this, the vesical neck should be open (removal of prostatic obstruction or stones), and a closed system of irrigation with a slight pressure gradient should be instituted (Chapter 18). Specific aids include (1) the use of mild antiseptic solutions, (2) "G" and "M" citric acid solutions to dissolve crusts, (3) the use of small Foley catheters (F16 or 18), (4) attention to acid-base, protein and electrolyte balance, (5) frequent trials at urination with cystometric readings to determine pressure and capacity of the bladder, and tests for residual will show the ability of automatic control, (6) Sulamyd as a prophylactic aided by penicillin and streptomycin when infection is present in the epididymis or kidney, (7) early ambulation insofar as possible, (8) attention to bed sores (see Chapter 6), (9) anterior rhizotomy in some cases changes a paralysis from the spastic type with its mass reflex to a flaccid type.

derived from the vesical plexus, the fibers of which come from the upper lumbar nerves through the hypogastric plexus and from the third and fourth sacral nerves, whose fibers join the vesical plexus directly.

Physiology and Functional Derangements of the Urinary Bladder

Postoperative urinary retention is common in spite of the fact that the bladder is full and there is no organic obstruction to account for the inability to void. The urinary bladder normally fills passively and empties under voluntary control. We have seen that the sympathetic nerve supply to the bladder is through the presacral and hypogastric nerves. Stimulation of these nerves relaxes the wall and contracts the internal sphincter. The parasympathetic nerve supply is by way of the nervi erigentes. Stimulation of this nerve causes relaxation of the external sphincter and contraction of the detrusor. Voluntary control of the external sphincter and other perineal accessory muscles is through the pudendal nerve. The desire to void comes from intravesical pressure, usually caused by 250 to 300 c.c. of urine in the adult.

Postoperative urinary retention is due to many factors: (1) psychic (position on voiding, embarrassment, previous experience); (2) pain (contraction of accessory muscles causes this); (3) reflex inhibition due to pain (especially after rectal operations, herniorrhaphy, vaginal operations, interference through pudendal nerves); (4) sedation so that desire is not felt until overdistention occurs; (5) partial paralysis of detrusor (which constitutes the entire bladder mechanism) due to overdistention for long periods; (6) irregularity of urine accumulation, at first very little urine, then a rather sudden large amount, especially after intravenous medication; (7) actual injury to nervi erigentes in abdominoperineal resection; (8) displacement of bladder after certain gynecological operations.

Treatment: Since the advent of early mobilization, the problem of postoperative retention has greatly diminished. Patients are allowed to sit up or stand up as soon as consciousness returns. Should the patient void small amounts frequently, overflow incontinence should be suspected and catheterization done immediately after voiding. Overdistention should be avoided because it leads to atony and actual injury to the bladder wall with small petechial hemorrhages resulting. Residual urine in an atonic bladder leads to cystitis because the urine acts as a good culture medium and the atonic bladder is susceptible to infection. Simple measures and an indifferent attitude by the surgeon should be tried first. Some aids are as follows: Sitting on commode or standing (male). (2) Privacy during urination. (3) Warm packs or water bottle to perineum. (4) Warm retention enema of physiological saline with 60 mg. of procaine or simply warm water as an enema. (5) Drugs—(a) parasympathetic stimulants such as acetyl-beta-methylcholine (Mecholyl chloride) 25 to 50 mg. by mouth, beta-methylcholine urethane, 5 mg. sub-

5. Ureterovaginal fistulae may be congenital or acquired (operative—especially vaginal hysterectomy or irradiation injury). Treatment consists of transplantation of the ureter into the bladder.

Physiology and Functional Derangement of the Kidneys

Physiology.—

The kidney's functional or secretory unit is the nephron, which consists of the renal corpuscle with its Bowman's capsule, the proximal convoluted tubule, the descending and ascending limbs of Henle's loop, and the distal convoluted tubule. A short connecting tube joins the collecting tubule or excretory duct with the nephron. These excretory tubules convey the urine to the ureter. The connections of the collecting tubules with the nephrons are located in the cortex and are called the "peripheral branchings" of the collecting ducts. From here they pass inward and become larger (papillary ducts of Bellini) and open on the area cribrosa, the apex of the papilla. The mode of action of the kidneys has been the object of much research, but even now there are differences of opinion. Certain experiments may be cited. The kidney has been removed and transplanted into the neck of experimental animals by suturing the carotid artery and jugular vein to its vascular pedicle, and, although deprived entirely of its nerve supply, continues to function without nervous control. Secondly, Goldblatt has shown the effect of partial constriction of the renal artery on the blood pressure, demonstrating that a rise is attained by this method, whereas complete ligation of the artery or nephrectomy (unilateral or bilateral) is not accompanied by a similar rise. This has led to the assumption that when the blood supply of the kidney is diminished, a pressor substance is liberated which causes an increase in blood pressure.

Theories of renal function date back to Bowman and Heidenhain. Bowman discovered the relation between the glomeruli and the tubules; Heidenhain thought that the formation of urine was a secretory process. Ludwig believed that the glomerulus acted as a filter and that the walls of the renal tubules acted as absorbing membranes. Cushny believes that absorption by the cells of the tubules is selective. We have already seen in Chapter 11 that the kidney plays an important role in maintaining the level of the body fluids. We have also seen that according to Starling, filtration and absorption are the results, respectively, of hydrostatic and osmotic pressure. Since the hydrostatic pressure in the afferent arteriole of the glomerulus is about 75 mm. Hg and the osmotic pressure is about 30 mm., there is a possible effective filtration pressure of about 45 mm. The pressure in Bowman's capsule is 5 mm., which is, of course, too little to affect filtration. The pressure in the capillary loop is about 60 per cent of the systolic pressure, or about 70 to 80 mm. Hg. Should the systolic blood pressure fall sufficiently to bring the capillary pressure below the osmotic pressure, we should expect urinary suppression to occur, and this actually happens when the pressure in the afferent arteriole falls to a level of 35 to 50 mm. Hg. The injection of isotonic salt solution causes profuse diuresis because it dilutes the plasma and therefore decreases the osmotic pressure. The injection of gum acacia or gelatine does not cause so great a diuresis because these solutions have a higher colloid osmotic pressure. When the blood pressure is extremely low, injection of large amounts of normal saline restores urine formation by diluting the plasma colloids, increasing the blood volume, and so increasing the hydrostatic pressure. Should urine formation cease because the intracapsular pressure in the renal corpuscle exceeded the filtration pressure, it could be restored by diluting the blood with isotonic salt solution, which would lower the colloid osmotic pressure and so increase the effective filtration pressure. The dependence of urine formation on filtration pressure differentiates the kidney from the truly secretory gland, such as the salivary, in which secretion continues for a time in spite of obstruction of the duct.

On the basis of Starling's theory of filtration, it is easy to explain many clinical facts, such as the loss of protein due to damaged capillaries in the nephrotic kidney

Incontinence in Women.—

1. Stress incontinence is a condition occurring in women usually as a result of a urethrocele but sometimes without any visible lesion. It manifests itself by a slight dribble of urine when intra-abdominal pressure is increased (sneezing, coughing, lifting) or, in severe cases, on the slightest motion. The treatment consists of surgical repair of the urethrocele and usually the accompanying cystocele and procidentia. These operations have been discussed previously in this chapter and include advancement operations, advancement with transfer of cardinal ligaments and amputation of the cervix (Manchester or Fothergill operation), transposition operation (Watkins), vaginal hysterectomy, and plastic repair. Special operations for the urethrocele include plication of the urethral sphincter (Kelly), overlapping of supporting pubocervical fascia, and other plastic procedures utilizing residual tissues. In addition, fascial slings have been employed, using the fascia lata of the thigh and the anterior rectus sheath (Goebell-Frangenheim-Stoeckel).

2. Vesicovaginal fistulae have been discussed previously in this chapter. They may be due to childbirth injuries, surgical injuries, malignancy of the vaginal and bladder walls, and irradiation therapy. The treatment is surgical and will vary with the position and size of the fistula. A few general principles concerning the management of this defect should be stressed. (1) Use healthy tissue for suture. This is done by waiting more than six months after discovery of the lesion and then excising all scar or unhealthy tissue. Failure to get union means more scar tissue and as in the repair of cleft palate, each failure makes more uncertain the ultimate success because scar tissue is poor healing material and if completely excised after many trials the defect becomes enormous. If incompletely cut out, the tissue remaining does not heal easily (see Chapter 3). (2) Adequate exposure. This may be facilitated by a lateral episiotomy (Schuchardt). (3) Adequate mobilization of flaps even at the expense of shortening the vagina. This is necessary to avoid tension on the suture line and to afford broad surface opposition. (4) Separation of bladder from vagina. In accomplishing (3) this will usually be done but it should be meticulously complete. (5) Suture of bladder and vagina in opposite direction. (6) Relaxing incision if necessary. (7) Rest to the part by catheter or suprapubic drainage (if fistula is close to urethra). (8) Prone position on Bradford frame.

3. Incontinence may result from urethral and sphincteric defects due to congenital anomalies, violent trauma, obstetrical and surgical accidents, malignancy, and lymphopathia venereum. Treatment consists of attempts at forming a new urethra. First, adequate drainage is obtained through cystotomy. Then vaginal flaps are dissected up, the remaining sphincter region of the bladder is reconstructed with silk sutures, and the vagina mucosa used to cover the newly created sphincter.

4. Neurological disease incontinence (spina bifida, multiple sclerosis, tabes dorsalis, spinal cord injury) has been discussed.

5. Ureterovaginal fistulae may be congenital or acquired (operative—especially vaginal hysterectomy or irradiation injury). Treatment consists of transplantation of the ureter into the bladder.

Physiology and Functional Derangement of the Kidneys

Physiology.—

The kidney's functional or secretory unit is the nephron, which consists of the renal corpuscle with its Bowman's capsule, the proximal convoluted tubule, the descending and ascending limbs of Henle's loop, and the distal convoluted tubule. A short connecting tube joins the collecting tubule or excretory duct with the nephron. These excretory tubules convey the urine to the ureter. The connections of the collecting tubules with the nephrons are located in the cortex and are called the "peripheral branchings" of the collecting ducts. From here they pass inward and become larger (papillary ducts of Bellini) and open on the area cribrosa, the apex of the papilla. The mode of action of the kidneys has been the object of much research, but even now there are differences of opinion. Certain experiments may be cited. The kidney has been removed and transplanted into the neck of experimental animals by suturing the carotid artery and jugular vein to its vascular pedicle, and, although deprived entirely of its nerve supply, continues to function without nervous control. Secondly, Goldblatt has shown the effect of partial constriction of the renal artery on the blood pressure, demonstrating that a rise is attained by this method, whereas complete ligation of the artery or nephrectomy (unilateral or bilateral) is not accompanied by a similar rise. This has led to the assumption that when the blood supply of the kidney is diminished, a pressor substance is liberated which causes an increase in blood pressure.

Theories of renal function date back to Bowman and Heidenhain. Bowman discovered the relation between the glomeruli and the tubules; Heidenhain thought that the formation of urine was a secretory process. Ludwig believed that the glomerulus acted as a filter and that the walls of the renal tubules acted as absorbing membranes. Cushny believes that absorption by the cells of the tubules is selective. We have already seen in Chapter 11 that the kidney plays an important role in maintaining the level of the body fluids. We have also seen that according to Starling, filtration and absorption are the results, respectively, of hydrostatic and osmotic pressure. Since the hydrostatic pressure in the afferent arteriole of the glomerulus is about 75 mm. Hg and the osmotic pressure is about 30 mm., there is a possible effective filtration pressure of about 45 mm. The pressure in Bowman's capsule is 5 mm., which is, of course, too little to affect filtration. The pressure in the capillary loop is about 60 per cent of the systolic pressure, or about 70 to 80 mm. Hg. Should the systolic blood pressure fall sufficiently to bring the capillary pressure below the osmotic pressure, we should expect urinary suppression to occur, and this actually happens when the pressure in the afferent arteriole falls to a level of 35 to 50 mm. Hg. The injection of isotonic salt solution causes profuse diuresis because it dilutes the plasma and therefore decreases the osmotic pressure. The injection of gum acacia or gelatine does not cause so great a diuresis because these solutions have a higher colloid osmotic pressure. When the blood pressure is extremely low, injection of large amounts of normal saline restores urine formation by diluting the plasma colloids, increasing the blood volume, and so increasing the hydrostatic pressure. Should urine formation cease because the intracapsular pressure in the renal corpuscle exceeded the filtration pressure, it could be restored by diluting the blood with isotonic salt solution, which would lower the colloid osmotic pressure and so increase the effective filtration pressure. The dependence of urine formation on filtration pressure differentiates the kidney from the truly secretory gland, such as the salivary, in which secretion continues for a time in spite of obstruction of the duct.

On the basis of Starling's theory of filtration, it is easy to explain many clinical facts, such as the loss of protein due to damaged capillaries in the nephrotic kidney

or the retention of nitrogen by the capillaries of the sclerotic kidney. Damaged capillaries allow the escape of plasma, deplete the blood protein, and reduce the blood osmotic pressure, with resultant edema. Sclerotic capillaries retain nitrogen while allowing the escape of fluids, producing azotemia and renal insufficiency. It should be remembered, however, that reabsorption in the kidney tubules cannot be explained on purely chemical grounds. Certain substances (such as glucose) are reabsorbed against a gradient; that is, work is done by the kidney cells. The process, in short, is one of selective absorption. The reabsorption of water by the tubules is probably regulated by the antidiuretic hormone of the pituitary (see Chapter 11).

The functions of the kidney, then, include not only filtration and excretion, but also absorption, synthesis (hippuric acid and ammonia), and even secretion by the tubules of certain dyes and creatinine. At least nine-tenths of the volume of "urine" that goes through the glomerulus is absorbed by osmosis. The concentration of this urine is explained by the absorptive action of the tubules.

An important anatomic arrangement which has recently been re-emphasized is the juxtaglomerular apparatus. This is a cuff of neuromyoepithelioid cells more prominent in the wall of the afferent arteriole. That portion of the distal convoluted tubule which lies in contact with this cuff of cells is shown by histological study to differ from neighboring epithelial cells in that the cells covering this area are tall columnar cells which show a peculiar striation in the basilar portion of the cytoplasm. This plaque of epithelium is known as the *macula densa*.

The function of this mechanism is not definitely known. Variations in the concentrations of urine affect it and thereby regulate the volume of blood entering the glomerulus. The mechanism resembles the shunt in the glomus of the skin.

The kidneys are the buffer organs for fluid excretion and waste excretion, and they share with the lungs acid-base regulation (Chapter 12). The afferent arteriole enters the glomerulus, carries blood to the glomerular capillaries for the elaboration of a glomerular filtrate, becomes efferent after leaving the glomerulus, and continues in intimate contact with the convoluted tubules through a second capillary network, and, then, after the functions of excretion and reabsorption are performed, it becomes a venule.

Apparently the kidney does not work in units—it is all or none (*Talbott*); approximately 1.2 liters of whole blood go through the nephrons each minute. This is called effective renal blood flow and is about one-third of the total cardiac output. No other tissue or organ except the lungs can claim a proportionate amount of blood. Renal blood flow is highly variable and is very easily and quickly adjusted to decreased circulating blood volume and to cardiac inadequacy, especially in chronic anemia and orthostasis. In shock, intrarenal vasoconstriction may be so prolonged that irreversible kidney damage may occur (Chapter 14). Therefore, the kidneys (and liver) play an important role in increase or decrease of blood volume, often at their own deleterious expense.

The kidney shows very little fluctuation in its oxygen arteriovenous difference in spite of the wide variations in blood flow. Thus the variation in oxygen consumption is a function of blood flow.

The rate of formation of glomerular filtrate is about 125 c.c. per minute, or about one-fifth of the effective renal plasma flow is concerned with glomerular filtrate. After the formation of glomerular filtrate, the plasma, with proteins which have been concentrated nearly 20 per cent, flows into the efferent arteriole and then into the capillaries about the tubules. Here there is reabsorption of a large portion of glomerular filtrate, formation of ammonia, and elimination of waste products by failure to reabsorb them. Most of the filtrate is attracted back through the tubular epithelium because hydrostatic pressure is reduced and osmotic pressure of plasma is increased. Ninety per cent of water and salts are reabsorbed this way. Urea, chlorides, and inorganic phosphates are the principal waste products not reabsorbed in proportionate fluid. All except 1 to

2 per cent of the remaining 10 per cent of the fluid of the glomerular filtrate is reabsorbed by the tubular epithelium because of the presence of the antidiuretic hormone of the posterior lobe of the pituitary gland. Only 1 to 2 per cent of the glomerular fluid goes into the bladder. This accounts for the 2 liters of urine a day. One per cent of 125 c.c. equals 1.2 c.c. per minute or 70 c.c. an hour or 1,800 c.c. in twenty-four hours (Talbott).

When water is drunk, the preformed antidiuretic hormone gradually disappears from the circulating blood. But for about thirty minutes it is present in sufficient quantity to restrain the kidney. After its concentration diminishes, the rate of urine formation increases. When, as a result of diuresis, water excess is removed, the secretory activity of the pituitary increases again and the formation of urine diminishes. The stimulation is thought to be through the central nervous system (see Chapter 11).

Approximately 90 per cent of the sodium and chloride in the glomerular filtrate is reabsorbed due to osmosis of the remainder that is reabsorbed hormonal control takes hold. Adrenal cortex, estrone, progesterone, and testosterone may play a role. Cortin is perhaps most important (see Chapter 22). If cortin is absent, normal amounts of salt are not reabsorbed.

Rehberg groups the glomerular filtrate into three classes: (1) substances which are actively reabsorbed (high threshold). They are substances which are conserved to the body and are usually in lower concentration in the urine and in higher concentration in the reabsorbed fluid than in the plasma (glucose, Na, K, Ca, Mg and Cl). (2) Substances which pass back through the tubular epithelium by a simple process of diffusion when their concentration in the tubular fluid rises above their concentration in the plasma (low threshold substances)—(urea, uric acid, and phosphates). They are not actively reabsorbed. Forty to 50 per cent of the filtered urea is returned to the blood in this way. (3) Nonthreshold substances which are not actively reabsorbed or diffused back into the blood. They are absent from the reabsorbed fluid.

Diuresis occurs as a result of the complex mechanisms already described, and, in addition, it may be stimulated by certain substances which are said to act as diuretics. The exact method by which they accomplish this is not known in every case, but in general their action falls into the following groups: (1) osmotic diuretics such as *dextrose, sucrose, urea* are present in high concentrations in glomerular and tubular urine, and because of their intrinsic osmotic pressure, they prevent normal reabsorption of water and salt. *Sodium sulfate* prevents reabsorption because tubular epithelium is impermeable to it; the same is true of acid forming salts (ammonium chloride, ammonium nitrate, calcium chloride) and neutral salts (sodium chloride, potassium chloride, and potassium nitrate). (2) Xanthine diuretics (caffeine, theobromine, theophylline)—*caffeine*, which increases the chloride concentration and lowers the concentration of urea in the urine (although the absolute amount of urea excreted is increased), was formerly thought to act by increasing kidney blood flow. Xanthine diuresis probably results from decreased tubular absorption of fluid and a small increase in glomerular filtration. (3) Reduced re absorption—mercurial diuretics such as Salyrgan, mercurous chloride, merbaphen, Mercurin, Mercupurin all act by preventing or reducing tubular reabsorption of water. (4) Paralysis of tubular function—*phloridzin* produces polyuria and glycosuria in this manner. (5) Miscellaneous and combination diuretics. Digitalis is not a diuretic but in cardiac failure with edema the improved circulation results in diuresis. Water is the best diuretic known and acts by decreasing osmotic pressure, increasing hydrostatic pressure, and depressing the antidiuretic hormone. However in water balance its action is influenced by electrolytes, acid-base balance, and other factors (see Chapter 11). Acidifying salts such as ammonium chloride and calcium chloride act not only by their osmotic, but also by their acid-base balance effects (Chapter 12). Glucose must be in high concentration to act as a diuretic; this explains in part the polyuria of diabetes. The diuretic action of plasma and whole blood in hypoproteinemia and hypotension states is discussed in Chapters 11, 13, and 14.

or the retention of nitrogen by the capillaries of the sclerotic kidney. Damaged capillaries allow the escape of plasma, deplete the blood protein, and reduce the blood osmotic pressure, with resultant edema. Sclerotic capillaries retain nitrogen while allowing the escape of fluids, producing azotemia and renal insufficiency. It should be remembered, however, that reabsorption in the kidney tubules cannot be explained on purely chemical grounds. Certain substances (such as glucose) are reabsorbed against a gradient; that is, work is done by the kidney cells. The process, in short, is one of selective absorption. The reabsorption of water by the tubules is probably regulated by the antidiuretic hormone of the pituitary (see Chapter 11).

The functions of the kidney, then, include not only *filtration* and excretion, but also *absorption*, *synthesis* (hippuric acid and ammonia), and even *secretion* by the tubules of certain dyes and creatinine. At least nine-tenths of the volume of "urine" that goes through the glomerulus is absorbed by osmosis. The concentration of this urine is explained by the absorptive action of the tubules.

An important anatomic arrangement which has recently been re-emphasized is the juxtaglomerular apparatus. This is a cuff of neuromyoepithelioid cells more prominent in the wall of the afferent arteriole. That portion of the distal convoluted tubule which lies in contact with this cuff of cells is shown by histological study to differ from neighboring epithelial cells in that the cells covering this area are tall columnar cells which show a peculiar striation in the basilar portion of the cytoplasm. This plaque of epithelium is known as the *macula densa*.

The function of this mechanism is not definitely known. Variations in the concentrations of urine affect it and thereby regulate the volume of blood entering the glomerulus. The mechanism resembles the shunt in the glomus of the skin.

The kidneys are the buffer organs for fluid excretion and waste excretion, and they share with the lungs acid-base regulation (Chapter 12). The afferent arteriole enters the glomerulus, carries blood to the glomerular capillaries for the elaboration of a glomerular filtrate, becomes efferent after leaving the glomerulus, and continues in intimate contact with the convoluted tubules through a second *capillary network*, and, then, after the functions of excretion and reabsorption are performed, it becomes a venule.

Apparently the kidney does not work *in units—it is all or none (Talbott)*; approximately 1.2 liters of whole blood go through the nephrons each minute. This is called effective renal blood flow and is about one-third of the total cardiac output. No *other tissue or organ except the lungs can claim a proportionate amount* of blood. Renal blood flow is highly variable and is very easily and quickly adjusted to decreased circulating blood volume and to cardiac inadequacy, especially in chronic anemia and *orthostasis*. *In shock, intrarenal vasoconstriction* may be so prolonged that irreversible kidney damage may occur (Chapter 14). Therefore, the kidneys (and liver) play an important role in increase or decrease of blood volume, often at their own deleterious expense.

The kidney shows very little fluctuation in its oxygen arteriovenous difference in spite of the wide variations in blood flow. Thus the variation in oxygen consumption is a function of blood flow.

The rate of formation of glomerular filtrate is about 125 c.c. per minute, or about one fifth of the effective renal plasma flow is concerned with glomerular filtrate. After the formation of glomerular filtrate, the plasma, with proteins which have been concentrated nearly 20 per cent, flows into the efferent arteriole and then into *the capillaries* about the tubules. Here there is reabsorption of a large portion of glomerular filtrate, formation of ammonia, and elimination of waste products by failure to reabsorb them. Most of the filtrate is attracted back through the tubular *epithelium because* hydrostatic pressure is reduced and osmotic pressure of plasma is increased. Ninety per cent of water and salts are reabsorbed this way. Urea, chlorides, and inorganic phosphates are the principal waste *products not* reabsorbed in proportionate fluid. All except 1 to

adequate fluid intake, excessive fluid loss as in intestinal obstruction, or severe diarrhea. (5) Severe alkalosis due to its causes (vomiting), loss of base by urine, thereby depleting water stores and tetany. (6) Hypernatremia and retention of water (salt block). (7) Cardiac failure which causes hypotension, engorgement of renal vessels, and slowing of renal blood flow and stagnant anoxemia. (8) So-called hepatorenal syndrome probably due to peritonitis, dehydration, and hepatic insufficiency.

II. Renal anuria "lower nephron nephrosis," "*hemoglobinuric nephrosis*," may be due to: (1) The extreme congestion of acute nephritis. (2) Posttraumatic or "crush syndrome" with myoglobin and hemoglobin casts, necrosis of the epithelium of the distal convoluted tubules said to be due to vasoconstriction in renal cortex. (3) Bilateral cortical infarction, postoperative. (4) Incompatible (hemolytic) transfusions. (5) Transurethral prostatectomy with water used as an irrigating fluid which may cause intravascular hemolysis. (6) Sulfonamide crystals blocking tubules. (7) Degenerative nephritis (mercury, lead, phosphorus, carbon tetrachloride). (8) Severe hemolytic infections, "black water fever," severe septicemia due to hemolytic streptococcus (other factors as enumerated in I. also enter into this type). (9) Polycystic kidneys. (10) Severe pyelonephritis. (11) Bilateral renal tuberculosis (severe).

III. Postrenal anuria is due to blockage of the ureters by: (1) Stones. (2) New growth. (3) Sulfonamide crystals. (4) Sometimes oliguria or anuria may follow instrumentation probably through reflex causes. (5) Surgical severance of both ureters. (6) Large pelvic or abdominal tumors blocking the ureter. (7) Vesical carcinoma involving both ureters. (8) Congenital anomalies involving both ureters.

The pathology of the different types will vary with their cause. In group I, degeneration of the tubules is said to occur in about twenty-four hours, followed by necrosis of tubule cells. Regeneration occurs in ten to twelve days and is normal in about four weeks. The symptoms and signs will vary with the different causes. However, the type seen most commonly belongs in group I. Since this type will be encountered following surgery or injury, it will be unsuspected for the first few hours because the primary or causative state will mask the symptoms. However, this is the time during which injury occurs. Urinary output will be depressed, but here again this is the rule following prolonged anesthesia or during or following shock states from any cause. Soon it will be observed that oliguria persists or changes to anuria. Azotemia follows. The little urine that is put out has a low specific gravity (1.005 to 1.010), chlorides are low, albumin is present, and there are red cells, white cells, granular casts (with or without degenerated hemoglobin or myoglobin), and heme casts (after incompatible blood transfusions). Blood studies show high urea, nonprotein nitrogen, and *creatinine* valves, but there may be a disproportion between the urea elevation and

The Mechanism of Kidney Hypertrophy.—When one of two kidneys is removed, the surviving organ increases in size, in proportion to the increase in the functional demand made upon it. The hypertrophy of kidney tissue is due to hypertrophy of the glomeruli with hypertrophy and hyperplasia of the cells of the tubules and not to regeneration of new elements (nephrons). Factors determining the degree of hypertrophy are as follows: (1) The greater the proportion of total renal substance resected, the greater is the hypertrophy of what remains. (2) The degree of growth is greater on a high than low protein diet. (3) The retention of urinary products in the blood (achieved experimentally) has been shown to hasten and increase the hypertrophy which occurs following unilateral nephrectomy. While no particular substance has been demonstrated, it has been noted that blood urea and the phosphates and sulfates were markedly increased. (4) Testosterone propionate increases kidney weight.

Functional compensation of the remaining kidney for the loss of the other is almost immediate and precedes by several weeks the structural compensation. After the loss of an active kidney, the following physiological changes occur: (1) Tubular excretory mass, glomerular filtration rate, and effective renal blood flow are cut in half. (2) Very soon the glomerular filtration rate and the effective renal blood flow increase considerably. (a) The early increase in glomerular filtration rate is apparently the maximum expansion of this function under these conditions. (b) But the effective blood flow continues to increase for several months—Arteriolar dilatation results in lowered intraglomerular pressure. (c) There is a relative hyperemia of tubular tissue in that the latter's increase is slower at first than is the increase in renal blood flow. (d) In one case reported, two years were required for the compensatory hypertrophy to catch up with the renal flow. After the removal of a nonfunctioning kidney, the function of the remaining kidney is about three-fourths of the average for the two normal kidneys.

Decreased Kidney Function.—This is observed normally in muscular exercise as a result of diversion of blood to the active muscles in hot weather due to excessive sweating and when fluid intake is restricted.

Oliguria and Anuria.—These are due to many diverse conditions, but the principal causes may be grouped under the following headings:

I. Prerenal anuria has also been known as "renal anoxia syndrome" and may be due to: (1) Shock from any cause where the *hypotension* is sustained long enough and filtration ceases. (2) Oliguria due to traumatic, operative, or obstetrical causes. Here anoxia and hypotension play a role. (3) Hemoconcentration as seen in burns or diffuse infections like peritonitis. There is loss of plasma, reducing the osmotic pressure, so that fluid cannot be drawn into the blood stream for excretion. Other factors are stagnant anoxemia and toxemia. At least part of the "crush syndrome" is due to loss of plasma. (4) Dehydration due to in-

toxic cases is important. Alkalinization in renal injury from sulfonamides and transfusion reaction seems helpful. BAL, 2,3-dimercaptopropanol, neutralizes mercuric chloride poisoning, and, in addition, the stomach may be lavaged with sodium formaldehyde sulfoxylate.

2. *Maintenance of as near a normal state of hydration and nutrition as possible* is necessary; however, the treatment should not be carried too far. With kidney excretion absent, the body must depend upon the lungs (about 300 c.c. daily), the skin (1,500 c.c.), and the bowel (150 c.c.) to carry the load. In addition, potassium which increases due to cellular damage is not eliminated by the damaged kidneys, permitting a dangerous accumulation of this base. Since the kidneys normally put out almost as much as all other avenues (1,500 c.c.), the fluid intake should not exceed this figure in the average adult unless added amounts are lost by vomiting, diarrhea, or other causes. Glucose reduces endogenous protein breakdown and so does plasma. Protein hydrolysates should not be used since they add to the burden of the nonfunctioning kidneys and increase azotemia. One hundred grams of glucose given daily should prevent ketosis and reduce protein breakdown greatly. Thus nitrogen waste products, potassium, sulfate, and phosphate released by protein catabolism accumulate less rapidly. The metabolism of 37.5 Gm. protein daily will lead to the formation of about 6,000 mg. of nonprotein nitrogen. This will be distribued to the body fluids which amount to about 3.5 liters in a 100 pound adult or over 17 mg. per 100 c.c. rise per day. Sodium chloride should not exceed normal requirements of 5 to 6 Gm. unless it is being lost in large quantities, lest a hypernatremia and edema result. Certainly forcing fluid to "wash out" the kidneys leads only to generalized edema including the brain and lungs (see Chapter 11). In many cases within 10 to 14 days diuresis begins. Careful watch on blood chlorides, serum protein, hematocrit will help guide in the treatment.

3. In severe cases, *provision for elimination by dialyzing or other procedures* may be necessary. This is done with the hope that the tubules will return to normal after two to three weeks. Man may survive four to five weeks without renal function if not hyperhydrated.

a. *Artificial kidney.* In lower nephron nephrosis and toxic nephrosis some method of removing diffusible substances from the blood is desirable. Most artificial kidneys use cellophane as the dialyzing membrane through which blood is circulated outside the body through a medium which will remove diffusible crystalloids but which will not take away essential substances from the blood stream. The dialysates vary in their composition but most of them contain NaCl, Ca Cl_2, Mg Cl_2, Na H_2 PO_4, dextrose, K Cl, Na HCO_3. Some remarkable cures have been reported. Indeed the method has been referred to as "parabrosis" by some.

b. *Peritoneal* dialysis seeks to convert the peritoneum into a dialyzing membrane so that diffusible substances may be removed from the plasma and ultimately from the extracellular fluid. This method is useful in severe cases of anuria, but careful planning and meticulous attention to

the creatinine. There is hyponatremia and hypochloremia, hyperpotassemia (hyperkaliumemia or hyperkalemia), usually hypoproteinemia with reversal of albumin-globulin ratio, and also anemia with low hematocrit (except in burns). In hemolytic transfusion cases, hemoglobinemia and hemoglobinuria is present for at least forty-eight hours or longer. Methemalbumin in the serum as demonstrated by spectrophotometric analysis means intravascular hemolysis. There will be slight increase in the serum bilirubin in the transfusion incompatibility as well as in the hepatorenal syndrome, the latter due to liver damage. The CO_2 combining power is decreased. The nitrogen retention and acidosis are probably not the lethal factors, but potassium intoxication may be.

During this stage the clinical picture, in our experience, is at first one of cerebral stimulation with continual loud talking which is fairly coherent and euphonic; restlessness and muscular twitchings are present. Intervals of complete rationality are present. These may progress to stupor or coma, and then there may be a return to the stage of stimulation. There is generalized and early pulmonary edema.

As diuresis returns, there is usually a diarrhea, or this may precede the diuresis. The urine contains large quantities of salt. Soon there will be a large amount of urine with increase in specific gravity. The azotemia persists for about six days and does not return to normal for two to three weeks after diuresis begins. Indeed, diuresis is not invariably followed by recovery, but it is usually, specially if the concentrating power of the kidney is restored. Slowly the patient's mental state returns to normal, although he will have no recollection of his illness.

Treatment may be considered under three headings: (1) elimination of the cause or causes to minimize damage; (2) maintenance of water, electrolyte, blood volume, and protein balance in as nearly a normal state as possible; (3) provision for elimination by dialyzing or other procedures. Put in another way, the destroyed kidney cells cannot be revitalized but damaged cells may recover. Treatment then consists of measures designed to stop the injury to tubule cells so that the extent and degree of damage will not be irreversible. Moreover, measures must not be instituted which will burden the kidney and thereby indirectly produce kidney damage. Having stopped or at least discouraged the cause of the trouble, time must be allowed for tubular cells to recover, and during this time life must be maintained by attention to water, oxygen, food vitamins, and electrolytes, and elimination of waste products must be provided for.

1. *Elimination of the causative factors* is not always easy. A list of the causes will in most cases suggest the remedies: whole blood for shock due to oliguria, water and electrolytes in dehydration, plasma in hypoproteinemia, the Miller-Abbott tube in postoperative adynamic ileus, etc. The immediate exclusion or neutralization of the causative agent in nephro-

syndromes are due to a neurogenic effect, this may be helpful. Many cases of anuria have been successfully treated by spinal block or continuous caudal block but not those due to kidney changes associated with chronic hypertension.

The Kidney Pressor System.—*Hypertension* has many causes. Some are not definitely known. In Chapter 18 the role of the sympathetic nervous system in essential hypertension has been discussed. Its relationship to kidney disease is better understood. Since the two are often related, it is sometimes difficult to determine which is cause and effect. The benefits of sympathectomy in cases of hypertension are probably not due to improvement in renal circulation but rather to venous stasis, with decrease in venous return and thus a decrease in cardiac output. The relation of the renal vasopressor system to hypertension is thought to be humoral (renin) rather than neurogenic. Normal kidneys and other tissues are thought to have a substance capable of destroying or inactivating renin (angiotonin). Prior to the surgical treatment of coarctation of the aorta, the hypertension, although largely confined to the upper extremities, was thought to be due to the decreased blood flow to the kidneys. This is now known to be erroneous in many cases. However, in some despite the release of the obstruction and improved blood flow to the lower extremities, the hypertension is not relieved and continues to progress. The role of the liver in hypertension is discussed in Chapter 22.

There is, however, much experimental evidence that interference with the circulation of one or both kidneys may result in the liberation of a pressor substance into the blood stream with resulting hypertension. This substance has not been demonstrated in the peripheral circulation of human beings or experimental animals with hypertension. Nevertheless, hypertension associated with unilateral kidney disease in man is sometimes cured by nephrectomy. The commonest pathological condition is pyelonephritis, but no specific lesion is more apt to be causative than another, and no prediction can be made on the effect of nephrectomy on the hypertension. However, compensatory hypertrophy of the healthy kidney is a good indication of a favorable result. The younger the patient and the shorter the duration of the hypertension, the better the results.

Organic Diseases and Injuries of the Kidneys, Ureters, and Bladder

Congenital Malformations of the Kidneys.—These are usually multiple and may occur due to failure of the proper fusion between the tubular structures and the renal parenchyma at the level of the collecting tubules, giving rise to *polycystic kidneys*, or *solitary cysts* may form, the former resulting from faulty fusion between the collecting and convoluted tubules or from persistent primary tubules of the metanephros. Most cysts are therefore glomerular or secreting tubular. Some are excretory tubular due to fibrous occlusion of the collecting tubules. There may be *supernumerary arteries* or vessels, due to the persistence of some of the

details are necessary. Some of its hazards are electrolyte unbalance, excessive loss of glucose, peritonitis, fibrin deposition around the afferent and efferent tubes, leaving only a small channel along the path of the dialyzing fluid instead of the whole peritoneal cavity, edema, and acidosis. To combat the ill effects of this method, the irrigating fluid is composed of a modified Tyrode's solution (Na Cl 7.4 Gm. per liter; K Cl, 0.2; Ca Cl_2, 0.2; Na HCO_3, 1.0; gelatin, 10.0; Mg Cl_2 . 6 H_2O, 0.22). Glucose is added to prevent the loss of blood sugar, heparin is used to delimit fibrin deposition, and penicillin and streptomycin are used to prevent peritonitis. Edema frequently occurs in this method, because there is absorption of some of the irrigating fluid (anywhere from 2 to 8 per cent and excess of sodium. However, the acidosis of uremia is not usually corrected unless it is treated by intravenous solutions of glucose (to impede ketosis and reduce protein catabolism) and alkali. Large volumes of fluid must be used (30 to 60 c.c. per minute), and this may be continuous or intermittent (the latter is probably preferable). To reduce the nonprotein nitrogen by one-half in forty-eight hours, the blood urea clearance (by peritoneal clearance) through peritoneal irrigation must be at least 20 c.c. per minute.

c. *Intestinal lavage* is one of the oldest methods employed to rid the body of nitrogenous and other waste products. As first employed, it consisted of diaphoresis and purgation; later, by colonic irrigation; and more recently, the stomach, duodenum, jejunum, and ileum have been used for dialyzing purposes. The methods employed are the use of double lumen tubes passed through the nose or mouth or the creation of enterostomies or cecostomy. These methods are safe and easy to use but are not very effective.

d. *Renal decapsulation* is used with the idea of decreasing intrarenal pressure which presumably interferes with effective filtration in toxic nephrosis because the net or effective filtration pressure is reduced. Although this procedure reduces intrarenal pressure, this fact alone is probably not the sole cause of improvement in the case reported, because spontaneous diuresis usually occurs in favorable cases on the tenth to twelfth day, when fluid retention is at a maximum. Interruption of the sympathetic nerve supply to the kidney by this procedure is thought to be the reason for its apparent effectiveness in some cases. Decapsulation of one kidney gives as good results as bilateral decapsulation.

e. *Plasmapheresis and reciprocal transfusions* have been used in Rh and other blood transfusion incompatabilities and also in toxemias of pregnancy with anuria. The method is hazardous because of the depletion of blood proteins temporarily and also because of the large quantity of blood required and its potential unfavorable reaction.

f. *Spinal anesthesia or splanchnic block.* Reflex stimulation of the splanchnic nerves can divert blood from the cortical glomeruli. After section of these nerves, the effect is reversed. If crush and other allied

jection of substances into the ureter under pressure may give rise to pyelovenous backflow. This has been observed in making pyelograms. The phenomenon has been explained by assuming an actual connection between the kidney pelvis and the veins due to a tear in the latter, or by extravasation into the kidney substance and reabsorption by the veins. Should such a kidney become infected, *pyonephrosis* ensues. There may be supernumerary kidneys, usually one but sometimes two on each side. Agenesis (complete absence), aplasia (defective formation), hypoplasia, and hypertrophy also occur. The kidney may fail to ascend (pelvic kidney, ectopia, or dystopia), or may rotate, allowing the pelvis of the kidney to face anteriorly or posteriorly instead of medially. Sometimes

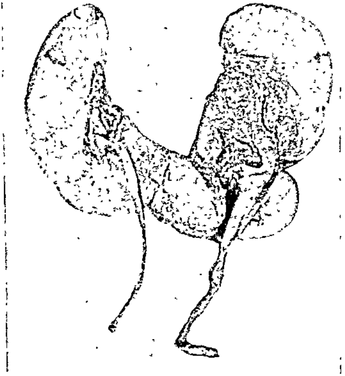

Fig. 414.—Horseshoe kidney. This illustrates the result of fusion of the fetal kidneys at the lower poles. Such anomalies prevent ascension and rotation, so that the pelves face anteriorly and the kidneys lie low in the bony pelvis The notch at lower right is due to an anomalous vessel.

the lower poles of the two kidneys fuse across the midline, forming a *horseshoe kidney,* or both kidneys may be on the same side without fusion (crossed ectopia). Other changes in form include sigmoid kidney, disc kidney, lump kidney, and anteroposterior fusion. If the kidney is unusually *movable,* it may produce a kink in the ureter, giving rise to *dietl's crisis,* or *intermittent hydronephrosis.* Diagnosis of these lesions is by physical examination and by intravenous and retrograde pyelogram through the cystoscope. Surgery aids these conditions. Polycystic kidneys are not very amenable to treatment (although solitary cysts may be

many vessels from the primitive aorta which supply the kidney in its development and which normally disappear, leaving only the renal artery and vein. Supernumerary arteries impede the passage of urine down the ureter, giving rise to hydronephrosis or to a dilatation of the renal pelvis and calyces. Normally urine is propelled into the bladder by the peristaltic movement of the ureter. Mild impediments may be overcome by ureteral hypertrophy and strong "peristaltic" waves. Intravenous pyelograms are helpful in making the diagnosis. If the dye outlines the ureter, there is interference with ureteral propulsion. Normally the ureter is not demonstrated.

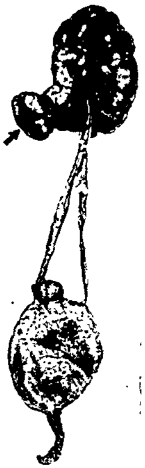

Fig. 413.—A type of congenital anomaly. The right kidney is rudimentary, misplaced, and fused with the lower pole of the left kidney. Arrow points to rudimentary mass. Note fetal lobulations. Post-mortem specimen.

According to Cohnheim's law, a complete obstruction of the duct of an organ gives rise to atrophy. The organ becomes distended and the increased pressure causes interference with the venous return. The mechanism is the same as in Volkmann's contracture of the hand and arm. Arterial blood enters, while intravenous pressure mounts, giving rise to stasis, local asphyxia, and death of the tissue, with fibrosis. In-

Injuries.—Injuries may occur to the urethra, bladder, or kidneys. The diagnosis is made from a history of trauma, with identification of the site of the injury, from blood in the urine, or from discovery of a palpable mass in the kidney. The x-rays reveals dense shadows where blood has extravasated. Treatment may be conservative in minor injuries. For lacerations in the kidney or bladder, surgical repair is necessary. Often nephrectomy must be done. In all bladder injuries adequate suprapubic drainage is helpful.

Infections of the Kidney and Bladder.—Like infections elsewhere, infections of the kidney and bladder do not usually occur when there is free drainage. This is as true of a sebaceous gland as of the kidney, and as true of the gall bladder as of the urinary bladder. The local immunity of the urinary tract is extremely high, unless there is devitalization of cells due to trauma or obstruction which, as we have seen leads to devitalization. Stasis alone would probably cause a collection of fluid, but when it reaches a point where it interferes with blood supply, and hence with cell metabolism, infection ensues.

To prevent stasis, the urinary tract, through involuntary muscle in the renal pelvis and the ureter, exhibits a wave of contraction resembling peristalsis. The bladder empties itself often enough to prevent stasis also. The cause of stasis may be (1) pressure from without by bands, aberrant vessels, new growths, collections of pus, etc.; (2) disease in the walls of the channels, such as strictures, inflammations, kinks, new growths; (3) improper nerve control, which causes interference with function; (4) partial or complete obstruction within the lumen of the channel by congenital folds, neoplasms, or calculi; (5) ureteropelvic obstructions due to external causes (kinking, distortion by adhesions, fibrous or vascular bands, and anomalous vessels) and internal causes (stricture at ureteropelvic junction, valve formation due to high insertion of ureter); (6) vesical neck obstructions in men (usually prostatic hypertrophy) and in women (due to fibrosis) and associated with chronic cystitis; (7) stenosis following ureterosigmoidostomy or external ureterostomy. The diagnosis is established by a careful history, the symptoms and signs, x-ray studies, intravenous, and retrograde pyelography. Treatment consists of (a) an attempt to remove the cause if possible, (b) if not, adequate drainage may be secured by (i) plastic repair (pyeloplasty, ureteroplasty), (ii) short circuiting (ureteropyeloplasty, ureteroenterostomy), (iii) external drainage (pyelostomy, ureterostomy, cystostomy); (iv) removal of the kidney as a last resort.

Infections rarely, if ever, start in the kidney or bladder but are usually carried to the kidney by the blood stream, from neighboring tissues (for example, the bowel), and by the lymphatics unless there is obstruction to urinary excretion. So-called nonspecific infections are due to mixed organisms—*Staphylococcus aureus*, streptococci, and colon bacilli.

removed). Therefore, patients with polycystic kidneys die from either renal failure or hypertension. Retention cysts may be relieved by the division of aberrant vessels or by moving the kidney and anchoring it in such a way as to prevent obstruction. Sometimes the renal pelvis is anastomosed to the ureter around an obstruction. Horseshoe kidneys may be divided if sufficient pedicle exists, or if one kidney is much larger than the other.

The *ureters* may be double, or they may be narrowed near the ureteropelvic juncture. Treatment in the former case may be unnecessary, or one ureter may be removed. Ureteral dilatation may be required for the latter. Sometimes they end in the urethra or vagina and are associated with supernumerary kidneys. Thus the ureters may be abnormal as to their number, position, or place of implantation. Other anomalies include congenital atresia and stenosis, congenital valves, diverticula, kinks of the ureter and ureterocele (a cystic dilatation of the intravesical part of the ureter). Any of these anomalies may lead to obstruction, dilatation, infection, and calculus formation in the ureter and ultimately hydronephrosis and pyonephrosis.

The treatment for these anomalies is primarily directed to relieve the obstruction so that the kidney may be preserved. This is accomplished by dilatations, short-circuitings, resections of abnormal parts, reimplantation, and various changes in position to relieve kinks and pressure from anomalous vessels. The *bladder* may have diverticula which require surgical excision. The urachus (the part of the allantois extending from the umbilicus to the cloaca, the anterior part of which later becomes the bladder) may persist *in part*, causing cystic formations, or *in toto* as a fistula from the bladder through the umbilicus. Such lesions may be excised extraperitoneally as a rule (see Chapter 20). Rarely, the anterior *abdominal wall between the umbilicus and the symphysis* pubis fails to unite, giving rise to *exstrophy of the bladder*. When this happens in the male, the external genitals are usually split anteriorly—*epispadias*. Since the anterior bladder wall is absent, urine dribbles over the area, causing excoriation and infection. Treatment is by transplantation of the ureters into the sigmoid, followed by excision of the bladder wall and repair of the abdominal wall. We have usually transplanted both ureters at the same time, using Sulfasuxidine to prepare the bowel before surgery. Small Penrose drains are introduced through the loin and extended *retroperitoneally* to the site of transplantation. The operation is due as soon as there is bowel control (18 months to 2 years). The second stage is deferred until the age of 4 or 5 years. After mobilizing the bladder mucosa and repairing the abdominal wall defect, a portion of the mucosa is saved to form an anterior wall for the urethra. The superior surface of the penis is covered with skin which is brought backward from a flap of the foreskin. Thus the full length of the urethra is maintained so that the reproductive tract may be established.

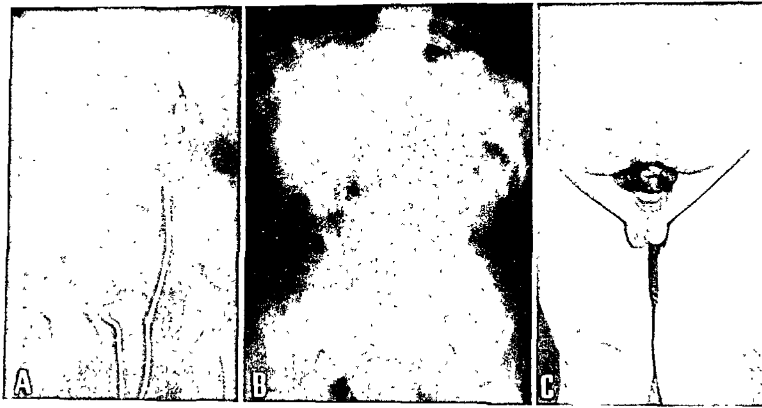

Fig. 416.—Exstrophy of the bladder and epispadias. *A*, Preoperative retrograde pyelogram. *B*, Six months after operation an intravenous pyelogram was made. It will be noted that the right ureter is normal. The left ureter shows a slight amount of dilation although not enough to be of consequence. *C*, Clinical photograph of child with extrophy of the bladder following the first stage operation which consisted of bilateral transplantations of the ureters into the sigmoid colon. The operation was done through a lower midline incision, although a transverse incision may be employed. The ureters were divided and transplanted into the colon on both sides. The lateral flaps of peritoneum were dissected to the pelvic wall, and extraperitoneal stab wound drainage was established in both loins. The free margins of the peritoneum were then closed over the inserted ureters.

No attempt was made to tunnel the ureter. Instead it was split and anastomosis was attempted between the mucosa of the ureter and the bowel, then there was an infold of serosa over the transplanted ureter, and, lastly, the free fold of peritoneum was sewed down over the transplant. The child is in perfect health, and a second stage operation will be done, excising the remaining bladder mucosa and correcting the epispadias. (*Referred by Dr. Francis T. Brown.*)

In this group are the following: (1) Carbuncle of the kidney, which is a collection of pyogenic abscesses in the kidney parenchyma secondary to primary foci elsewhere and carried by the blood stream (pyemia). Such foci include boils, osteomyelitis, and otitis media. (2) Perinephritis and perinephric abscess which are infections of the perirenal fatty tissue. The infection occurs *secondary* to hematogenous foci from various parts of the body or by extension from the kidney or other adjacent structures (vertebrae, lungs, pleura, appendix, colon, and pelvic organs). (3) *Pyelonephritis* which is an infection of the kidney pelvis and parenchyma. Pyelitis was a term used to denote infection of the kidney pelvis alone, a condition which probably does not occur. The disease may be acute, chronic, or recurrent. It is due to hematogenous or ascending infection from the lower urinary tract due to urinary obstruction. Sometimes

Fig. 415.—Exstrophy of the bladder, with epispadias, in an infant. There is also a prolapse of the rectum.

both factors are present. In children (usually girls) congenital anomalies may be causative; in pregnancy the disease is commonly thought to be due to ureteral spasm, or pressure and hematogenous causes. In adult males calculi are the most common cause. (4) Pyonephrosis—a term used to describe the hydronephrotic kidney with infection. (5) Kidney infarction due to endocarditis which may result in secondary infection with abscess formation. (6) Trauma with kidney tears which may be followed by infection.

Symptoms and signs: A careful history often leads to the diagnosis. Attacks since childhood, kidney colic, and associated disease in adjacent organs are some of the common stories. In addition, there are the following: (1) pain in the kidney region which radiates along the course of the ureter; (2) urgency and frequency if an associated cystitis is

Fig. 418.—Pyonephrosis of the kidney. Patient was a woman aged 46 years. Arrow points to the dilated pelvis, which was filled with pus.

present; (3) general symptoms of infection, chills, fever, malaise, and anorexia; (4) laboratory studies (urinalysis, blood cultures, and blood counts); (5) plain x-ray of kidney, ureter, and bladder; (6) intravenous urography; (7) retrograde pyelography.

Treatment: If the cause can be eliminated, there is a good chance of cure. Kidneys seem to have a remarkable regenerative ability. The elimination of an acute focus or adjacent abscess plus the establishment of good drainage where this is impaired are the major forms of attack.

Fig. 417.—Traumatic rupture of the kidney. The patient, a man aged 60 years, was in an automobile accident. Nephrectomy was done. Arrow points to the tear.

In addition, penicillin, streptomycin, aureomycin, and the *sulfonamides* are necessary. Local abscess may demand drainage, and persistent obstructions may necessitate temporary surgical drainage (pyelostomy).

If the kidney is hopelessly destroyed, nephrectomy may be indicated. *Bilateral cortical necrosis* is a rare lesion seen in pregnant women but also in nonpregnant women and in men. It is associated with septicemias and with infections which arise in the debilitated and also in children. The more common accompanying diseases are scarlet fever, diphtheria, pneumonia, tonsillitis, tuberculosis, and severe dysentery.

may arrest the disease. Before any surgery is done, the disease should be treated by medical means. This includes the general treatment of tuberculosis and the use of streptomycin. *Remissions and even cures* are not uncommon under this management.

Cystitis.—Cystitis is not an uncommon postoperative complication. The inability of patients to void, whether for psychic, reflex, or mechanical reasons, constitutes an obstruction, even though it may be only the function of the sphincteric mechanism which is at fault. Some maintain that this type of cystitis is due to overdistention and advise early and frequent catheterization. Others believe it is the trauma inflicted by the (sterile) catheter that starts it. Or perhaps it is the sudden removal of large amounts of urine from an overdistended bladder. This subject has been discussed previously in this chapter and is mentioned here as a cause of cystitis. *Acute cystitis* is due to other causes such as (1) ascending by instrumentation or catheterization, (2) descending from the kidneys, (3) contiguity from adjacent organs, (4) external trauma (fractured pelvis with perforation, penetrating, or perforating wounds).

Gangrenous cystitis may result from pressure by a pregnant uterus. A generalized form is seen in men with prolonged internal or external bladder pressure and vascular occlusion. *Proliferative cystitis* is a form of chronic infection with excessive granulation tissue. There are several varieties: (a) cystitis follicularis (lymphoid follicles), (b) cystitis granulosa and polyposa (protrusion of granulations), (c) cystitis glandularis (glandlike protrusions), (d) cystitis cystica (cystlike gland spores), (e) cystitis emphysematosa (gas-producing bacteria produce spaces in the tunica propria). *Chronic interstitial cystitis* (Hunner's ulcer) occurs in the submucous and intermuscular connective tissue of the bladder. The cause is not definitely known, but the disease is chronic and difficult to cure. *Incrusted cystitis* is due to the deposit of magnesium and ammonium phosphates derived from the bacterial action on urea. *Tuberculosis cystitis* is almost always secondary to renal tuberculosis. *Malakoplakia* is a chronic cystitis occurring in middle-aged women. It resembles Boeck's sarcoid. *Blastomycosis, actinomycosis,* and *monilia* infections are rare. *Schistosomiasis* is seen commonly in some tropical countries. *Chemical cystitis* is known to occur from *aniline* dyes. The symptoms and signs of cystitis are urgency, frequency, dysuria, pyuria, nocturia and the general reaction to infection. Diagnosis is established by a careful history, general physical examination, study of the urine and blood, and cystoscopy. Treatment is designed to eliminate the cause where possible. In addition, chemotherapy and antibiotics are used. Local treatment consists of adequate drainage where necessary, fulguration, or local cauterization of chronic lesions.

Calculus.—Urinary calculi may develop around foreign bodies, mucous plugs, or cellular debris, or de novo. Calcium phosphate is present in some stones and is said to be associated with hyperparathyroidism. Ex-

Granulomatous Diseases of the Kidney.—*Syphilis* is rare and exists as a diffuse parenchymatous or interstitial infection or gumma. Actinomycosis is also rare and is secondary to lesions of adjacent structures.

Tuberculosis of the Kidney.—This is considered in Chapter 8. It is probably a blood-borne infection, secondary to tuberculosis elsewhere. Some maintain that tuberculosis often originates in the epididymis or seminal vesicles and ascends by retrograde lymphatic involvement to the

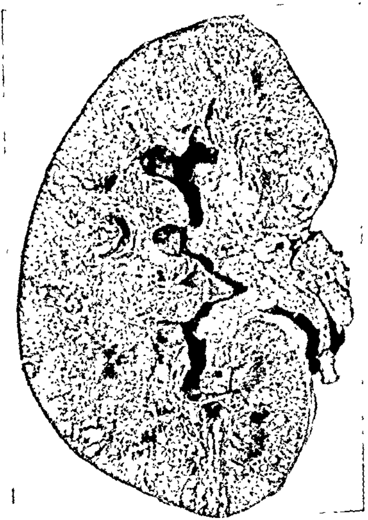

Fig. 420.—Miliary abscesses (pyemia) of the kidney. These developed in the course of a staphylococcic bacteriemia.

kidney. The early symptoms are those of cystitis: urgency, frequency, stranguria, and hematuria. The diagnosis depends upon a careful history, physical examination (which usually reveals evidences of the disease elsewhere), laboratory tests (such as the von Pirquet and Mantoux), a finding of tubercle bacilli in the urine, and, most important, cystoscopic examination and pyelography. Guinea pig inoculation with the urine may aid in the early diagnosis. The kidneys, the ureters, and the bladder are frequently involved, usually only kidney first; therefore, nephrectomy

and usually pus. Many of these attacks may occur until the stone returns to the kidney pelvis, or descends into the bladder, or is passed through the urethra.

Diagnosis is conclusively made by x-ray and pyelography. Renal colic on the right side may simulate appendicitis. If the inflamed appendix is retrocecal, it may cause pyuria by causing a ureteritis. X-ray films of the abdomen, the site of pain and tenderness, and the history aid in differential diagnosis. The treatment during colic consists of bed rest and relief of pain by the use of sodium nitrite, morphine, or calcium chloride intravenously. Passage of the stone may be facilitated by ureteral catheterization and the injection of glycerine. Should this fail, surgery is indicated. According to the location of the stone, an incision is made in the kidney (nephrotomy), in the pelvis of the kidney (pyelotomy), or in the ureter (ureterotomy), and the calculus is removed. It is unnecessary to close these openings in the kidney, pelvis, or ureter, but drainage must be used.

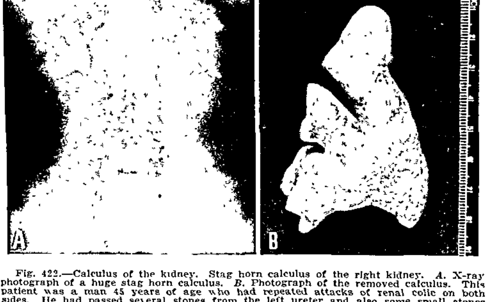

Fig. 422.—Calculus of the kidney. Stag horn calculus of the right kidney. *A.* X-ray photograph of a huge stag horn calculus. *B.* Photograph of the removed calculus. This patient was a man 45 years of age who had repeated attacks of renal colic on both sides. He had passed several stones from the left ureter and also some small stones from the right The large calculus on the right was removed through a loin incision. A nephrectomy was necessary because of the destruction of the kidney parenchyma.

Surgery of the kidney requires adequate exposure. Since most of these cases are infected, a retroperitoneal approach is desirable. Resection of the eleventh and twelfth ribs and a subcapsular approach facilitate maneuvers and reduce the possibility of pleural or peritoneal injury. Renal tissue must be handled gently; and any tear must be carefully avoided by an incision if the stone is wedged or is staghorn in shape. A pedicle clamp controls bleeding during this maneuver. Tears and incisions must be carefully closed so that postoperative bleeding will not

perimentally, stones may be produced in animals by excessive amounts of vitamin D. However, most stones are composed of uric acid, urates, oxalates. Some are made of cystine, xanthine, and magnesium ammonium phosphate, concentrated urine; urinary stasis (immobilization in bed as in burns and fractures, obstructions to urinary outflow), infection, and diet (alkaline ash, avitaminosis of A and B, high calcium) may also play a role in the formation of calculi.

"Renal rickets" is a disturbance of calcium metabolism in which *there is rarefaction of bones. The serum calcium is low and the serum* phosphate high due to the fact that the kidney cannot excrete the latter. A rise in the serum phosphate causes a reciprocal reduction in the calcium, which is excreted to some extent in the urine. As a result of this calcuria, stones may occur (see Chapter 22).

Fig. 421 —Opaque kidney stones revealed by flat plate of the abdomen without aid of dye or pyelogram.

Urinary calculi vary in size from minute granules to stones so large that they fill the bladder. They may cause obstruction anywhere *along* the urinary tract except the bladder, or they may remain in the kidney pelvis or bladder, associated with infection. Calculous anuria, hydronephrosis, ulcerations, or pyonephrosis may develop.

Clinically, a stone may be "silent"; that is, it may cause no symptoms unless it moves into the ureter. Here it causes extreme pain (renal colic) by distending this tube. This pain radiates rather typically along the course of the ureter into the genitals. *The urine is filled* with blood

more plausible. Pain in the flank may be due to inflammatory lesions as previously described, and when bilateral is more easily distinguished as due to inflammation than when present on one side. A mass in the flank may be due to an enlarged spleen (especially in children), neoplasm of the colon, sympathicoblastoma of the adrenal, chronic cystic fibrosis of the kidney, hydronephrosis (congenital in children or acquired in adults), polycystic kidneys, retroperitoneal sarcoma (in children).

Hematuria may come from many sources. It may originate anywhere along the genitourinary tract or may come from systemic causes. In general, the causes fall into the following groups, whether the seat of the trouble is in the kidneys, ureters, bladder, or urethra: (1) congenital malformations such as polycystic kidneys, (2) systemic causes, (3) infections, (4) new growths, (5) foreign bodies (calculi), (6) obstructions due to movable kidney, aberrant vessels, etc., (7) varicosities. Treatment consists of early surgical removal of the involved kidney.

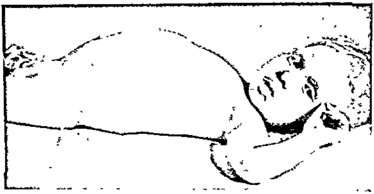

Fig. 423.—Wilms' tumor of the left kidney in a child. Treatment by x-ray reduced its size There was recurrence within nine months, resulting in death.

This should be done through the abdomen so that the renal vessels may be ligated and divided before there has been any manipulation of the growth. In this way tumor cells in the involved vein will not be separated and allowed to migrate to the lungs. In smaller growths this preliminary step may be accomplished through a loin incision. The same maneuver may be done through a long McBurney incision with resection of the twelfth rib and mobilization of the peritoneum medially as is done in lumbar sympathectomy. The important fact to remember is that with an adequate exposure (best through the abdominal cavity), tumor masses in the renal vein or vena cava may be recognized and resected, manipulation before ligation is minimal, and retroperitoneal lymph nodes may be removed. The ureter is not usually involved in parenchymal neoplasms. In tumors of the renal pelvis, however, nephrectomy with removal of all of the ureter and the adjoining corner of the bladder is indicated. This may be done through the abdomen, the loin, or by a combined approach.

occur. Resection of damaged renal tissue is preferable to suture of this substance which will slough. *If an obstruction of the ureteropelvic juncture remains, it is treated by plastic repair.* X-ray at the time of operation will disclose overlooked particles of calculi. The wounds are drained and in the case of nephrostomy or pyelostomy tubes, solutions "M" and "G" may be used for irrigation.

New Growths of the Kidney

New growths of the kidney may be benign or malignant. Benign tumors may arise from epithelial elements (adenoma, papilloma) *blood vessels* (*hemangioma*), *fat* (*lipoma*), connective tissue, muscle (*leiomyoma*), nerve tissue (neurofibroma). Malignant neoplasms may arise from any of the above kidney components; namely, carcinoma, hypernephroma (adrenal rest), *embryoma* (*primitive embryonic tissue*—Wilms' tumor), *hemangiosarcoma*, *liposarcoma*, *fibrosarcoma*, *leiomyosarcoma*, abdomyosarcoma, myoblastoma, lymphoblastoma (reticulum cells, leucemia), neurofibrosarcoma, sympathoblastoma, and secondary malignant growths from distant foci.

Cancers may be further classified as to their position as follows:

1. *Renal parenchymal tumors: (a) clear-cell carcinoma; (b) granular-cell carcinoma*—sometimes (a) and (b) occur together and show *various* architectural arrangements of renal cells (alveolar, adenomatous, tubular, papillary, or cystic formations); (c) true hypernephroma (adrenal rests); (d) neoplasms in solitary cysts; (e) multiple papillary adenoma or carcinoma in sclerotic tubular cysts or sclerotic kidneys; (f) mixed forms of carcinosarcoma in infants (Wilms) and adults.

2. Tumors of renal pelvis: (a) papillary carcinoma; (b) squamous-cell carcinoma; (c) undifferentiated carcinoma.

3. *Renal capsule malignancies:* (a) fibrosarcoma; (b) liposarcoma. *The neoplasms more commonly encountered are* hemangiomas, carcinomas, *and embryomas.*

Symptoms and signs in the order of frequency are *hematuria*, lumbar pain, and discovery of a mass. There are also anorexia, *loss of weight*, chills and fever, leucocytosis, and secondary anemia. The *diagnosis is* established by a study of the urine, especially by means of smears of fixed urinary sediment; that is, the urine is centrifuged and the sediment is fixed and stained (see Chapter 2). In this way desquamated cells may reveal early "carcinoma in situ." Intravenous pyelograms will reveal function, and *retrograde pyelograms will disclose* pathognomonic morphology. X-ray studies of the lungs and long bones may show metastases because malignant neoplasms of the kidneys spread by the lymphatics and the blood stream as well as by contiguity. Since the three cardinal *symptoms* are pain in the flank, hematuria, and a mass, each is subjected to careful *investigation*. A combination of the three makes the diagnosis

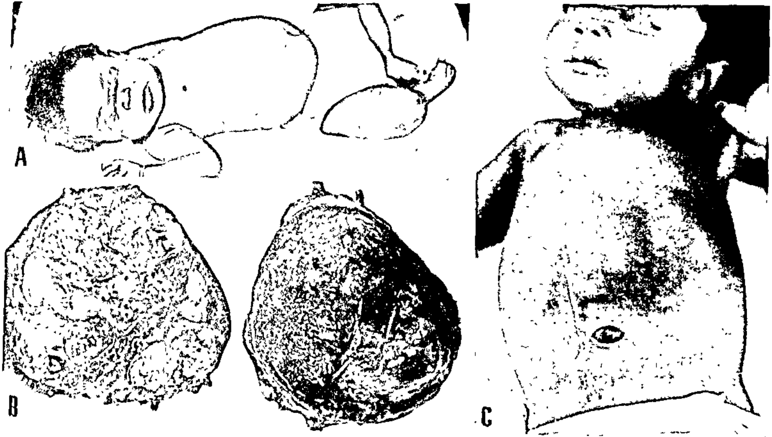

Fig. 425.—Wilms' tumor. Child 9 months of age with a Wilms' tumor of the right kidney. The mother stated that she had noticed an increase in the child's abdomen for six weeks prior to his admission to the hospital. There was no passage of blood in the urine. Studies indicated that the lesion was outside of the intestine, and retrograde pyelograms showed the lesion to be in the kidney. *A*, Clinical photograph made before operation showing enormous swelling of abdomen. *B*, Gross specimen cut in half. *C*, Postoperative condition two weeks following surgery. This child is now 2 years of age and is without detectable recurrence. There was no preoperative x-ray therapy. However, extensive postoperative x-ray therapy was given.

The operation was performed through a transabdominal approach where the renal vein was freed and the renal artery clamped and then the renal vein divided close to the vena cava. Division of the vein was done first before any mobilization of the kidney in order to avoid expressing tumor cells from the kidney. The division of the renal vein was so close to the vena cava that the latter was sutured because the pedicle was not long enough to afford a tie. Preoperative x-ray therapy has been advocated by some. However, much

The most common neoplasms which occur in the kidney *parenchyma* in childhood are the embryomas of Wilms or embryonal carcinosarcoma. They are of primitive nephrogenic tissue origin and metastasize by the lymphatics and blood stream. They may attain an enormous size and *may be bilateral. Diagnosis is made from hematuria, from finding* a mass in the kidney region, and from pyelography. The treatment is nephrectomy. Formerly, preliminary x-ray therapy was given to reduce the size. This is probably a waste of time. Transabdominal section with preliminary ligation of the renal pedicle gives the best results. We have in addition given postoperative x-ray therapy.

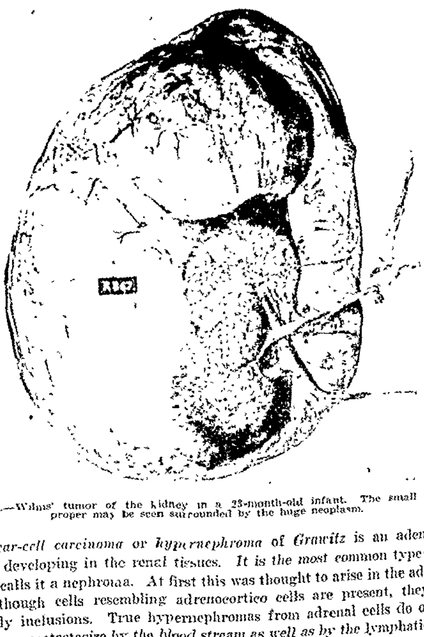

Fig. 421.—Wilms' tumor of the kidney in a 23-month-old infant. The small kidney proper may be seen surrounded by the huge neoplasm.

Clear-cell carcinoma or *hypernephroma* of *Grawitz* is an adenocarcinoma developing in the renal tissues. *It is the most common* type seen. Young calls it a nephroma. At first this was thought to arise in the adrenal but, although cells resembling adrenocortico cells are present, they are probably inclusions. True hypernephromas from adrenal cells do occur. Nephromas metastasize *by the blood stream as well as by the* lymphatics, so

Fig. 437.—Primary carcinoma of the kidney. Note the extension of the growth into the renal pelvis.

From adjacent organs the more common extensions are from carcinoma of the rectum and cervix and endometriosis from the tubes, ovaries, or uterus. The most common of all primary tumors of the bladder are the epithelial types, *papilloma and carcinoma*. *Although the cause of*

that very often the earliest evidence is a metastatic lesion in the lungs or the bones. Local extension also occurs into surrounding tissue but earlier in the veins as thrombotic masses. *The chief symptoms are hematuria and the palpation of a mass.* Diagnosis is by cystoscopic examination and pyelography. The treatment is nephrectomy. This may be done by the intra- or extraperitoneal approach. Even extremely large growths may be removed through the loin by a combined extrapleural, extraperitoneal approach. This is accomplished by resecting the eleventh and twelfth ribs, and, if necessary, a portion of the tenth rib. The pleura is gently pushed forward and then the lateral lumbocostal arch (external arcuate ligament of the diaphragm) is divided.

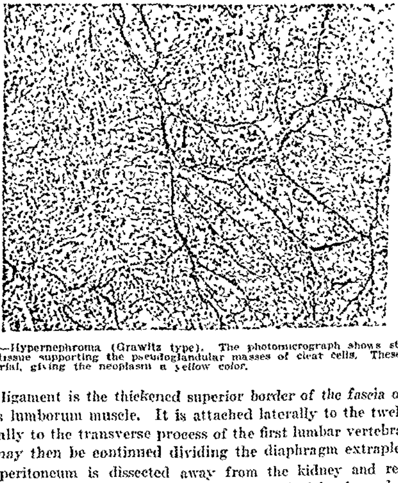

Fig. 426.—Hypernephroma (Grawitz type). The photomicrograph shows strands of connective tissue supporting the pseudoglandular masses of clear cells. These contain lipoid material, giving the neoplasm a yellow color.

This ligament is the thickened superior border of the fascia over the quadratus lumborum muscle. It is attached laterally to the twelfth rib and medially to the transverse process of the first lumbar vertebra. The incision may then be continued dividing the diaphragm extrapleurally.

The peritoneum is dissected away from the kidney and retracted anteriorly. Thus a combined thoraco-abdominal incision is made which is extrapleural and extraperitoneal and which affords ample exposure.

Tumors of the renal pelvis such as papillomas, adenomas, and carcinomas, may, in addition, to hematuria, cause *pain resembling colic*, due to the passage of a blood clot. These growths are revealed by the pyelogram and are treated by simple excision (benign polyp), nephrectomy, or ureterectomy or both.

Neoplasms of the bladder may be benign or malignant (Table XXX).

Fig. 427.—Primary carcinoma of the kidney. Note the extension of the growth into the renal pelvis.

From adjacent organs the more common extensions are from carcinoma of the rectum and cervix and endometriosis from the tubes, ovaries, or uterus. The most common of all primary tumors of the bladder are the epithelial types, papilloma and carcinoma. Although the cause of

carcinoma of the bladder is not known, there is a great incidence of the disease in men working with aniline dyes (Chapter 15). Men are affected six times more frequently than women. Early symptoms and signs are hematuria, urgency, frequency, and dysuria. Later, as the growths infiltrate, they involve the ureters and may break through the wall of the bladder to adjoining organs and tissues, spreading along nerve sheaths and finally involving lymphatics and blood vessels, causing metastases in the liver, lungs, lymph nodes, vertebrae, and other bones. Therefore,

Fig. 428.—Metastasis to the femur. A spontaneous fracture occurred. This is from the tumor shown in Fig. 427.

late symptoms are extremely variable, depending upon the degree of extension of the growth. Diagnosis is established early by examining the urine for cancer cells, cystoscopic examination, and biopsy. Intravenous pyelography is carried out to determine the possibility of ureteral occlusion or dilatation. Treatment depends upon the size and extensiveness of the growths. (1) Papillary tumors of small size are treated by endoscopic fulguration. (2) Papillary tumors of large size but with a narrow pedicle are treated by transurethral resection. (3) Papillary

tumors of large size with a broad base may be resected through a suprapubic cystotomy. (4) Massive involvement of the bladder requires ureteral transplantation and cystectomy. The transplanted ureters may be cutaneous or into the bowel. If the former is done because of great ureteral dilatation or obesity, one ureter may be tied and one transplanted, thereby avoiding two cutaneous openings. (5) Involvement from adjacent organs requires resection of the involved part along with the primary growth or total cystectomy may be done with abdomino-

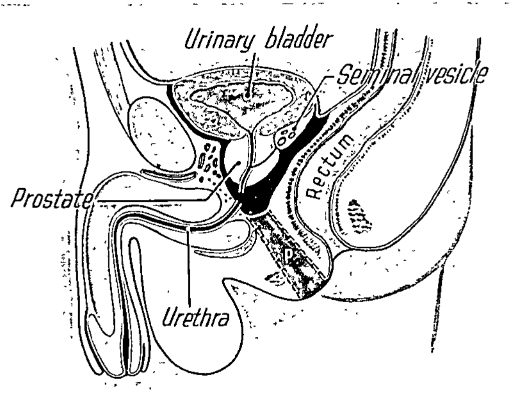

Fig. 429.—Diagram illustrating total cystectomy. This operation is indicated for carcinomas of the bladder or vesical neck or prostate and is done either by the abdominal route, when the lesion is far from the bladder neck, or by the combined perineal-abdominal route, when the carcinoma involves the bladder neck. We have employed the abdominal operation in practically all cases. The combined operation is done in two stages. The first stage consists of transplantation of the right ureter into the sigmoid colon or transplantation of both ureters at the same time. We have practiced the latter technique because by forming a flap of peritoneum and instituting stab wound drainage in both loins we do not fear leakage as we formerly did. Furthermore, the anastomosis between the ureter and the bowel is done by an oblique division of the ureter and mucosa-to-mucosa suture, then inversion of the sigmoid colon over the ureter, thereby protecting the peritoneal cavity from any leakage. Lastly, the lateral margin of the peritoneum is tacked down over the inverted ureter.

At the second stage the total cystectomy, prostatectomy, bilateral seminal vesiculec- tomy, and posterior urethrectomy are performed. The perineal part of the operation is done through an incision in the perineum, first dividing the urethra and then freeing the prostate and seminal vesicle as illustrated in the diagram (*P*). Then the abdominal part of the operation is done in which the bladder is extirpated in its entirety. If the lesion is far from the bladder neck, abdominal excision is preferable and bilateral trans- plantation and excision of the bladder may be done in one stage in patients who are in good condition. More recently the abdominal route alone has been used even in vesical neck carcinomas. The retropubic approach from above enables the surgeon to control the bleeding more completely and expeditiously, particularly that which ensues from the superior vesical and prostatico-vesical plexus. In carcinomas of the rectum which have invaded the bladder, the second stage consists of abdomino-perineal resection of the rectosigmoid along with the bladder as shown above.

perineal resection and bilateral transplantation *of the ureters.* (6) *Late cases* not suitable for operation may have ureteral transplantation and x-ray therapy *for palliation.* (7) Cases not suitable for surgery because of concomitant disease may be treated *by radon implants.*

Cystectomy may be performed in one, two, or three stages and may be done through the abdomen or by combined abdominoperineal resection. *Many prefer all in one stage.* This can be done if the ureters are transplanted into the skin. *A more desirable technique is the transplantation of both ureters into the sigmoid transperitoneally.* At this time exploration is done for metastases. If the lesion is far from the bladder neck, abdominal excision suffices. If the growth involves the bladder neck, abdominoperineal *resection* is required in which the bladder, seminal vesicles, prostate, and posterior urethra are removed en *masse. In males* the perineal portion of the operation is done first. The *urethra is tied and divided as far out as necessary; then the prostate and* bladder neck and seminal vesicles are mobilized, drains are introduced, and the suprapublic operation is done. Recently we have found that the entire operation may be done in one stage through the abdomen in good-risk patients. Even in carcinomas of the vesical neck, complete extirpation may be *accomplished by* the abdominal route with less *blood loss* and shock than with the *combined methods.*

A refinement of technique in the creation of an artificial bladder has been the use of isolated segments of bowel. These may be satisfactory when the *sigmoid colon* is used. However when the cecum is employed, even though it is used as an isolated pouch (with ureters implanted into the cecum and the distal end of the ileum brought to the outside), absorption of waste products may occur, producing azotemia and *uremia.*

Although *retention* or reabsorption of *nitrogenous waste* is associated with *uremia, there is no proof* that urea, uric acid, or creatinine is responsible for the symptoms. None of these is toxic in large doses, and experimental implantation of the ureters in the small intestine with reabsorption of urine and an increase of urea nitrogen to 800 or 900 mg. per cent may fail to produce symptoms of uremia. Yet the intravenous *injection of amino acid solution* aggravates *the symptoms.* Perhaps the symptoms *are due in part* to a reduction of ionized calcium in the body fluids (see Chapter 22) which may be the result of phosphate retention, and in addition the hyperchloremia which ordinarily occurs. We have recently made studies on patients with transplanted ureters, and we have found that the clinical picture of uremia *may* be present even though *blood* chlorides and ionized calcium *values are* within normal limits. There is, however, an elevation of urea nitrogen, uric acid, and creatinine in such cases. Because of the above, these patients are put on a restricted salt diet and 15 grains of sodium bicarbonate three times a day.
